Congenital defects in the cardiac valves and orifices deserve a passing notice. They may be the result of endocarditis during fetal life or of arrest of development. Their most frequent seat is the right heart, and the most frequent form is *stenosis of the pulmonary orifice*, the effects and signs of which have already been considered. Another is a permanently *patulous foramen ovale*; or there may be a *defect of the septum of the ventricles*, or a communication between the aorta and pulmonary artery,—a *persistent ductus arteriosus*,—or *between the aorta and the vena cava or aorta and right auricle*. All of these intercommunications produce murmurs difficult to separate, and it is, after all, by attention to the general condition that the defect is recognized. The patient is a child of arrested development, more or less permanently cyanosed, with continued embarrassed breathing—all of these are conditions which point to the congenital defect. If there be

added to these a persistent loud murmur at the base of the heart without other signs or symptoms of valvular disease, this may be due to congenital defect.

In addition to these, there are a large number of defects of development which are rather pathological curiosities than of clinical interest. Among these may be mentioned *acardia*, or absence of heart, met in the monstrosity thus named; *double heart*, sometimes present in high degrees of fetal defect; *dextrocardia*, in which the heart is on the right side, alone or with other viscera. In *ectopia cordis*, or dislocation, which is associated with fission of the chest-wall and of the abdomen, the heart may be in the cervical, pectoral, or abdominal regions. Then there are anomalies of the cardiac septa, of which the patulous foramen ovale is the most frequent, various in degree. Next is a small defect in the upper part of the septum, between the ventricles, in what is known as the "undefended" space, or just anterior to it. A *bicuspid* state of the semilunar valves, from fusion of cusps, is often met—most frequently of the aorta. The combined valve is more liable to sclerotic change. Finally, there is fenestration of the semilunar cusps.

Relative Frequency of Valvular Defects.—The order of frequency of the various valvular defects is not entirely agreed upon. As to one, however, there seems to be universal concurrence, and that is that mitral regurgitation is the most frequent. After this, however, statistics differ. Thus, of the older authors, W. H. Walshe presents the following order of frequency for the single or simple murmurs:

1. Mitral incompetency. 2. Aortic stenosis. 3. Aortic incompetency. 4. Mitral stenosis. 5. Tricuspid incompetency. 6. Pulmonary stenosis. 7. Tricuspid stenosis. 8. Pulmonary incompetency. Presumably, this list is based upon necropsy records.

This order, in the light of modern studies, must be corrected, except as to mitral incompetency. Frederick J. Smith, analyzing the registers and postmortem records of the London hospitals for eleven years,—1877-87,—and taking the fatal cases only, arrived at the following order:

- | | |
|-------------------------|-----------------------------------|
| 1. Mitral incompetency. | } Of practically equal frequency. |
| 2. Mitral stenosis. | |
| 3. Aortic incompetency. | |
| 4. Aortic stenosis. | |
| 5. Tricuspid stenosis. | |

To these we may add:

6. Tricuspid incompetency.
7. Pulmonary stenosis.
8. Pulmonary incompetency.

It is evident that the older observers mistook the aortic systolic murmur to mean aortic stenosis, when roughening only of some kind was present.

Out of 705 cases, Smith found 26, or 3.38 per cent., of mitral stenosis, and 25, or 3.25 per cent., of aortic regurgitation; so it cannot be said there is any practical difference in the relative frequency of these two lesions. Von Leube says that, after mitral incompetency, aortic incompetency is the most frequent, and this is my experience. Smith's statistics, being recent and based, as they are, upon the examination of registers and autopsy records, are probably nearly correct, but these two lesions approximate in frequency. Such are to be distinguished from those based on

observation at the bedside, regardless of autopsy. Such observation certainly fails to detect all cases of mitral stenosis.

Of "double" *murmurs* heard at one orifice, those of mitral stenosis and insufficiency are more numerous than aortic stenosis and insufficiency, women being the most frequent subjects. It should be mentioned, however, that George S. Middleton, in a clinical study of 150 cases of chronic valvular disease at the out-patient department of the Royal Glasgow Infirmary, found a much larger number—22 per cent.—of the double aortic lesions, as against Dr. Smith's 4 per cent.; also, that Walshe makes the double aortic lesion the second in frequency of all valvular diseases. I am inclined to agree with the latter statement.

Associated or Combined Valvular Lesions.—These terms are applied when two valves are diseased at the same time—a very frequent occurrence.* The valves which are most frequently jointly affected are, of course, the aortic and mitral, then the mitral and tricuspid, then the aortic, mitral, and tricuspid. Aortic disease of either kind is more frequently associated with mitral incompetency than mitral stenosis, because the former is, sooner or later, a result of the aortic disease, while mitral stenosis arises by a separate process. The very careful analysis by Frederick J. Smith referred to furnishes the following order, which is not far from correct:

1. Aortic incompetency and stenosis; mitral incompetency.
 2. Aortic stenosis and mitral incompetency.
 3. Aortic incompetency and mitral incompetency.
- There is less than one per cent. difference in the frequency of 2 and 3.
4. Aortic incompetency and stenosis, with mitral stenosis and incompetency.
 5. Mitral incompetency and tricuspid incompetency.
 6. Aortic incompetency and stenosis, with mitral incompetency, tricuspid incompetency.

Too much reliance must not be placed on the order of combined murmurs, as after 1 the arrangement is not altogether what would be expected from a consideration of the natural sequence. In children, it is said, the most frequent combination is aortic incompetency and mitral incompetency. One would expect this to be the case with adults also.

The diagnosis of these combinations is based upon the quality and situation of the murmurs and their conduction.

Prognosis of Chronic Valvular Disease.—Possible positive statements as to the prognosis in chronic valvular disease are few, so uncertain is it and so many circumstances influence it. Undoubtedly, valvular disease often exists where the subject is totally free from symptoms, and therefore quite unconscious of it. Yet such subject is not free from danger. On the other hand, fifteen, twenty, thirty, and even forty years pass over such cases without inconvenience, compensation being easily maintained. Such cases are usually of mitral incompetency or stenosis, or both. Much depends upon the life led by the patient—whether one of ease and quiet, associated with proper food and clothing and without dissipation. Even when such disease occasions symptoms, the same measures may hold them in abeyance for a long time, and occasional judicious medication may raise

* Dr. Sansom has suggested that the term "combined" be retained for two murmurs at one orifice, commonly known as "double" murmurs—an unfortunate suggestion, as it will be sure to give rise to confusion, while the term double is easily understood.

the patient from a serious condition to one of comfort. It is astonishing with what little disturbance women with these affections sometimes bear children. Of the lesions at the mitral orifice, incompetency is usually most easily compensated, then combined stenosis and incompetency, and finally stenosis only; but even the last exists at times without subjective symptoms in persons who have worked hard. After all, the prospect of life must be judged from the symptoms in each case. The compensation which is obtained by extreme hypertrophy and apex displacement is tottering. An additional danger in mitral disease, especially mitral stenosis, is that of embolism. Recurring attacks of rheumatism not only increase the latter danger, but augment the valvular defect. The supervention of dropsy and dyspnea indicate failing compensation, and though they may be overcome, it is with increasing difficulty at each recurrence.

Aortic incompetency is a much graver condition. It is this valvular disease in which sudden death overtakes the patient. Yet it, too, may be compensated for years. Much here depends upon the state of the arteries, the danger being increased when associated with sclerosis or atheroma, for these conditions are likely to affect the root of the aorta and the valves, and especially the coronary arteries. Any obstruction in these, as already stated, may be the cause of sudden death. Angina pectoris indicates a diseased condition of the coronary arteries, which may at any time be followed by complete obstruction and sudden death. Overdistention, such as takes place during exertion, may be too much for a fatty heart already dilated, and becomes also a cause of sudden death.

The most unfavorable of all forms of cardiac valvular disease is tricuspid regurgitation, which occasions obstinate dropsy and dyspnea.

Chronic valvular disease is regarded as much more serious in young children, say those under ten years of age; this, in spite of the fact that many conditions favorable to compensation are present, such as integrity of heart muscle and vascular supply. Notwithstanding this, the valve lesion is apt to increase. On the other hand, there is a popular notion, which physicians are disposed to encourage, that a child may outgrow a heart disease under favorable circumstances, such as abundance of good food and protection against exposure and overwork. This may be true, but it is more likely that compensation is established with the growth and development of the organ. That the apparent event does sometimes occur, I can attest. Congenital defects in the heart are apt to destroy the lives of children the first few years of their existence.

Finally, almost any serious illness, especially when involving the lung, increases the danger to the life of the subject of cardiac disease, while mitral disease, and especially mitral stenosis, invites pulmonary congestion and inflammations.

Treatment of Chronic Valvular Diseases of the Heart.—1. *Prophylaxis.* There can be no doubt that the number of cases of chronic valvular disease may be decreased by a careful treatment of the diseases which excite them or favor their occurrence, especially acute rheumatism. The student is referred to a valuable monograph by R. Caton, M. D., on "The Prevention of Valvular Disease of the Heart."* This author emphasizes, especially (1) the importance of rest and a minimum of exertion of all kinds for the rheumatic patient; (2) stimulation of the trophic centers by small

* London, C. J. Clay & Sons, 1900.

blisters in the neighborhood of the affected joints and in front and in the axilla, preferably in front between the clavicle of the nipple on both sides, with a view to stimulating vasomotor nerves; (3) treatment by absorbents, including the iodid of sodium and mercury. The rest and quiet should be prolonged long after the symptoms of pain and fever have subsided, and a second attack of rheumatism should especially be guarded against, as an apparently cured endocarditis is sure to be followed by another attack.

2. *Remedial Measures.*—Since there are certain points in the treatment of disease of the cardiac valves which are the same for the different orifices, I shall consider first such measures as are thus common, referring more especially to mitral and aortic disease.

In the first place, it is well known that there exist chronic valvular defects at either of these orifices which give rise to no symptoms whatever and are often accidentally discovered. From the standpoint generally conceded, that such defects themselves are irremediable, it is clear that, in the absence of symptoms, medicinal treatment is quite unnecessary. On the other hand, it is a happy circumstance when the subjects of such lesions are made aware of their presence, because they are enabled so to regulate their mode of life as to prevent harmful consequences, either symptomatically or organically. Such persons should avoid overexercise and excitement. Running or even walking rapidly, hurriedly ascending stairs, extremes of passion of all kinds, and especially of anger, should be avoided, as should also exposure and irregular living. In a higher grade of involvement of either orifice, the same treatment is demanded in a more imperative manner, since its omission results in a loss of compensation, manifested by dyspnea, palpitation, and precordial distress.

In a still more advanced degree of interference with normal functions the treatment becomes different with the seat of the lesion. Let us first consider lesions of the mitral valve, and first the most common of all forms—*mitral regurgitation*. We have seen that the blood flows back into the left auricle during systole of the ventricle, at a time when all communication between these cavities should be cut off and the movement of the blood should be forward only. Averted for a time by hypertrophy of the left auricle, engorgement of the lungs ultimately results, with defective aëration of blood, and consequent shortness of breath. This effect is at first counteracted by the increased effort of the *right* ventricle, whence its hypertrophy, with sharp accentuation of the pulmonary second sound.

So long as compensation is thus maintained there is probably no sign of embarrassed breathing, irregularity, precordial oppression, or digestive derangement; but as soon as compensation begins to fail, in consequence of a suspension of the conditions which co-operate to help it, or of a slight yielding of the heart muscle, assistance is demanded. The heart tonics, of which digitalis is the type, are the agents pre-eminent for this purpose. That they operate by directly increasing the force of the right ventricle and left auricle, and thus contribute to the compensation, can scarcely be doubted; but that they help also to make the closure of the mitral orifice more complete by forcibly increasing the contraction of the left ventricle seems also reasonably sure, since the experiments of Ludwig and Hesse have made it so plain that this can occur. They have shown that the mechanism for closing the mitral orifice does not reside in the valve alone, but that the surrounding muscles of the ventricle have an active share, not only in floating up the valve curtains, but in reducing also the size of the

opening which these valve curtains have to close. This is, of course, less applicable in chronic valvular conditions where there is stiffness from calcareous change, than where regurgitation results from simple feebleness of muscle in anemia and after the infectious fevers.

The effect required of this class of drugs varies with the degree of obstruction to be overcome, and the doses vary accordingly. Very often the heart requires but little steadying to enable it to accomplish the desired end, and moderate doses—such as five minims (0.3 c. c.) of the tincture of digitalis once in six or eight hours—suffice. On the other hand, it is a mistake to give too small a dose, and too great timidity often results in failure. Doses of from ten to fifteen minims (0.6 to 1 c. c.) of the tincture of digitalis every four hours, and corresponding doses of the other preparations, are often necessary and sometimes produce magical effects. The irregular and halting pulse becomes regular, the dropped beat is again taken up, the dusky lips become pink, the scanty urine is increased, the shortness of breath disappears, and calmness and quiet succeed distress and restlessness. As soon, however, as the desired effect is produced, the dose should be lowered. Digitalis is a remedy always better intermitted to obtain its best effects, and a remedy, too, which, having once excited nausea, is thereafter badly borne.

The same principles apply to the management of the still more serious engorgements of the venous system which succeed upon tricuspid insufficiency, and produce dropsies and serous effusions. This engorgement is also relieved by the use of purgatives, and as the portal area, including the liver itself and the stomach, is especially involved, mercurial purgatives are especially indicated. From five to ten grains (0.32 to 0.65 gm.) of blue mass at bedtime, followed by a saline in the morning, relieve the congestion, and with it the nausea and indisposition to take food which attend it. Such remedies may be resorted to occasionally. Sometimes the continued use of small doses for a long time—say 1-2 to one grain (0.03 to 0.065 gm.) of blue mass three times a day—is more efficient. It is generally recognized that digitalis produces also contraction of the arterioles, and that through this, in connection with the forcible systole, the arterial pressure is increased. This effect is desirable and useful in the early stages of mitral regurgitation, before tricuspid regurgitation and dropsy have set in. Later in the disease, however, when dropsy has set in, this effect militates against the diuretic action which is so much needed. The manner in which this may be overcome will be described later.

As to the relative value of the different preparations of digitalis: While testimony is generally favorable to the infusion as the most efficient remedy, yet, on account of convenience and accessibility, the tincture is most frequently used. I am inclined to believe that the greater apparent efficiency of the infusion is partly due to the fact that it is generally given in larger doses. Thus, a tablespoonful, or 1-2 ounce (15 c. c.), is not an infrequent dose of the infusion, while ten minims (0.6 c. c.), or twenty drops, of the tincture and one grain (0.066 gm.) of the powder are not often exceeded. When it is remembered that 1-2 ounce (15 c. c.) of the infusion, as made by the United States Pharmacopeia, represents nearly three grains (0.19 gm.) of the powder, or twenty minims (1.2 c. c.) of the tincture, one may understand why it is more efficient. It is true, however, that the infusion is sometimes better borne by the stomach than equivalent doses of the tincture. It may be that the cinnamon water with which it is made has this effect. All

preparations of digitalis thus far mentioned are more or less uncertain, and I purpose to use hereafter more of the so-called "normal liquid," which, if correctly represented, must be a constant preparation. Each minim represents one grain of the drug, and hence the proper dose is easily determined.

Of remedies which may be substituted for digitalis, strophanthus should be first mentioned, not that it is always the best. It was at one time thought that strophanthus might have all the effects of digitalis on the left ventricle without the contracting effect on the arterioles. This expectation was not, however, realized by clinicians, but it is a fair substitute for digitalis in about the same dose. It is better borne by the stomach, as a rule, than digitalis.

Caffein is an admirable heart tonic in mitral regurgitation. I do not give less than three grains (0.2 gm.) at a dose, but seldom give more, every four to six hours. When caffein has been given in full doses for some time, it may produce mental symptoms quite characteristic, consisting in hallucinations not unlike those of delirium tremens, the patient imagining there are persons, animals, and other objects about him, and he is sometimes difficult to control. These symptoms, however, cease immediately when the drug is discontinued. Another effect of caffein which sometimes interferes with its usefulness is insomnia.

Sparteïn sulphate is another heart tonic which I have come to value very highly, especially when a diuretic effect is desired. The dose should never be less than 1-4 grain (0.016 gm.), increased to 1-2 grain (0.032 gm.), four, five, and six times a day. I am sure many have been disappointed in sparteïn because they have given too small a dose. Broom itself, in the shape of an infusion or "tea," is a popular and efficient remedy, less well borne by the stomach than its active principle, sparteïn. Sparteïn and broom are more commonly used as diuretics, and will be again referred to in the treatment of the dropsy of Bright's disease.

In the much rarer disease of simple *mitral stenosis*, compensation is even easier and longer maintained by nature's own resources than in mitral regurgitation. Here, for evident reasons, there is no tendency to dilatation or hypertrophy of the left ventricle. On the other hand, hypertrophy of the left auricle becomes a conspicuous condition, succeeded by hypertrophy of the right ventricle, for the same reason as in mitral regurgitation. Especially easy is it to maintain compensation if the narrowing is not too great and if there is a well-preserved left auricle and a strong right ventricle. If, however, the mitral narrowing is extreme, it is plain that the pulmonary engorgement will become greater if we increase the force of the right ventricle. Much more cautious must we be, therefore, in the use of digitalis. Much more important under these circumstances is relief to the pulmonary congestion, which in turn will relieve the right heart tension. Blood-letting is the most direct method of accomplishing this, and in severe cases associated with great dyspnea and cyanosis it may be practiced. For the same purpose, aconite is sometimes of advantage in these cases, in small doses, say one minim or 1 1-2 minims (0.06 to 0.09 c. c.) every two hours or every hour, watching its effect. It is possible that it is through a somewhat similar action that *convallaria majalis*—a remedy in which most observers have been disappointed—has been found useful by Dr. Sansom* in mitral stenosis, and also by French physicians. By these observers it has been found diuretic,

* "The Treatment of Some of the Forms of Valvular Disease of the Heart," Lettsomian Lectures, second edition, with corrections, London, 1886.

increasing the twenty-four hours' urine to 85 and even to 115 ounces (2550 to 3450 c. c.), reducing the pulse rate, regulating irregularity, and improving the breathing, even when accompanied by tricuspid regurgitation. The doses given are from ten to twenty minims (0.6 to 1.2 c. c.) of the tincture three times a day, and it may with advantage be associated with caffeine. The French physicians give the extract in doses of from one gram to 1 1-2 grams a day—*i. e.*, fifteen to twenty grains (1 to 1.3 gm.). Veratria may be used under the same circumstances. More effectual than either of these remedies to relieve pulmonary congestion is purging, sometimes blood-letting, and repeated small bleedings are often of great advantage in this form of chronic valvular disease.

The principles governing the treatment of combined mitral regurgitation and stenosis are rather those of mitral regurgitation than of mitral stenosis.

And what shall be the treatment of *pure aortic disease*? It will be remembered that both aortic obstruction and regurgitation give rise to hypertrophy of the left ventricle, and that this is compensatory in purpose. For a time this is quite sufficient to ward off any unpleasant symptoms, and for a still longer time when associated with a quiet life, the absence of excitement, of exposure, and privation. High degrees of hypertrophy are accompanied with a powerful systolic impulse, a symptom which is of itself often a source of great discomfort. Shall we, then, give heart tonics which increase the force of this thumping blow? Certainly not. Shall we give aconite or veratrum viride, which slow the heart and diminish the force of its stroke? Yes, at times these remedies are very useful. Whenever, as the result of overexertion or undue excitement or gastric derangement, the heart is turbulently overactive, and even irregular in its rhythm, then I have often seen aconite in small doses—say one minim (0.06 c. c.), or two drops, repeated every half hour or hour under close observation—act happily, especially when combined with bromid of potassium, say fifteen grains (1 gm.). The tincture of veratrum viride may be given in slightly larger doses. As soon, however, as this period is past, the aconite should be omitted. Even in mitral regurgitation I have seen aconite act most happily under these circumstances.

We want also in this condition remedies which will help to maintain the integrity of the heart muscle. Such are strychnin, iron in small doses, arsenic, and nutritious, easily assimilable food. Especially useful are well-ventilated living- and sleeping-rooms, wholesome outdoor life, with moderate, deliberate muscular exercise. Like all other muscles, the heart is strengthened by judicious exercise. In the light of this fact even the mountain-climbing advocated by Oertel is not so irrational and dangerous as it seems at first thought. Very cautious and gradually increased exercise is doubtless intended. On the other hand, so much judgment is required in the application of this treatment that it is perhaps better honored in the breach than in the observance.

Such measures as those described tend to ward off the next stage, for sooner or later the integrity of the muscle of the ventricle yields, dilatation is added to hypertrophy, the auriculo-ventricular orifice enlarges, and we have mitral regurgitation. Then the treatment becomes that for mitral disease.

The treatment for aortic regurgitation and of aortic stenosis with regurgitation is similar to that of aortic stenosis.

Treatment of Dyspnea.—As the dyspnea is primarily the result of deficient blood aëration in the congested lungs, the same remedies which force the blood through these organs, and thus relieve the congestion, tend also to

relieve the dyspnea, and often do so. When the dyspnea persists, it is frequently caused by effusions into the pleural cavity, which are most promptly and successfully removed by tapping, although a blister may also answer the purpose. Repeated tapping may be necessary. Dyspnea not thus relieved demands an opiate, and of opiates under these circumstances, morphin is the best. One-fourth of a grain (0.0165 gm.) at bedtime, by the mouth or hypodermically, gives unspeakable comfort. Hoffmann's anodyne, given in fluid dram doses (3. 5 c. c.), will sometimes relieve the milder degrees, and should perhaps be tried first, as it is always desirable to put off the use of morphin as long as possible. Paraldehyd may be substituted for Hoffmann's anodyne in the same doses. Chloralamid is even a better remedy in thirty-grain (2 gm.) doses. Sulphonal may be tried in full doses of fifteen to thirty grains (1 to 2 gm.). Trional in the same doses is a similar drug. So is thermol. None of these is an anodyne. They are simple hypnotics, and cannot be expected to take the place of morphin, though they may be tried at first. All the coal-tar products are more soluble in hot liquids, of which milk is a typical form. Inhalations of oxygen should not be forgotten as sometimes giving signal relief in dyspnea.

Treatment of Dropsy.—In like manner the measures that relieve the congestion and dyspnea tend also to relieve the dropsy, but special means are also necessary. Here it is that full doses of digitalis are especially indicated, and at closer intervals—every three hours.

But these measures are often insufficient. They may be materially aided by restricting the ingestion of liquids. With the tissues water-logged and secretion insufficient, it is plain that copious liquid ingestion only increases the difficulty. I am speaking now of cases in which there is general dropsy which resists the ordinary treatment. The principle of the Matthew Hay method is correct, but in practice it is limited, because, with an already congested stomach, solids cannot be digested without an admixture of liquid, and further embarrassment results from the effort to dissolve them and from the presence of undigested residue. Therefore it is better to omit solid food altogether and reduce the liquid to a minimum that will sustain life—not more than three ounces every two hours, and that only during the waking hours. To this may be added the use of purgatives. While diuretics sometimes fail us, we can always secure an effect from purgatives. A daily morning dose of Epsom salts or Rochelle salts or compound jalap powder is given. Then, when action of the bowels begins, full doses of digitalis, caffenin, or spartein, associated with nitro-glycerin, are almost sure to be followed by copious diuresis; and when diuresis starts in in these cases, it is astonishing what quantities of urine are passed. The association of nitroglycerin with digitalis at this stage may be helpful. The object of nitroglycerin is to dilate the renal artery and allow more blood to pass through the kidney: 1-100 to 1-50 grain (0.00065 to 0.0013 gm.) may be given as often as the digitalis and simultaneously. One need not be afraid of this drug. I have given this dose every two hours for twenty-four hours or more at a time. Elimination by the bowels and kidneys being simultaneously stimulated, the sucking up of the interstitial fluid is greatly favored and often rapidly brought about. If these measures be associated with paracentesis of the chest, which may be required, the diuresis set up is often enormous, while the swelling rapidly declines. As diuresis is established or hunger sets in the quantity of milk allowed may be increased, and when the dropsy has entirely disappeared, a cautious return to solid food may be permitted.

A time-honored remedy in the treatment of cardiac dropsy which should not be overlooked is the combination of calomel, squills, and digitalis, in doses of 1-2 grain (0.03 gm.) of the first and one grain (0.065 gm.) of the second and third every three or four hours; this is most happy in its results. Still another remedy sometimes very efficient in this form of dropsy is theobromin. It is obtained from cacao, and is chemically closely allied to caffeine, the latter being trimethyl-xanthin, while theobromin is dimethyl-xanthin. Like caffeine, theobromin is a renal diuretic as well as a heart tonic. The dose I have found most satisfactory is forty-five grains (3 gms.) in the twenty-four hours, conveniently divided into doses of 7 1-2 grains (.5 gm.) every three hours, which, allowing for necessary interruptions, results in the administration of at least forty-five grains in this period. On the other hand, diuretin, which is supposed to contain 50 per cent. of soluble theobromin in combination with salicylate of sodium, I have found of little or no use in any form of dropsy.

Treatment of Irregularity of Heart Action and Palpitation.—For these symptoms, in addition to the cardiac tonics mentioned, belladonna is also a useful remedy. It may be combined with digitalis. A good belladonna plaster placed over the palpitating heart is one of the most efficient agents in subduing it. Nitroglycerin is often very useful to the same end; 1-100 grain (0.00065 gm.), rapidly increased to 1-50 grain (0.0013 gm.), every four hours or oftener, is the proper dose. It may also be combined with digitalis, as previously directed. Cardiac pain is also sometimes relieved by the same remedy.

For further treatment of dropsy see section on Bright's disease. See also treatment of cardiac dilatation by the Schott treatment and Nauheim baths.

DISEASES OF THE MYOCARDIUM.

The heart is subject to alterations in its muscular substance independent of valvular defect. Simple hypertrophy, dilatation, fatty infiltration, and fatty metamorphosis or true fatty degeneration, and atrophy are the most important. Myositis, abscess, and aneurysm of the walls of the heart are such rare conditions that they need only be mentioned in passing, especially as there is no way to recognize them before death.

HYPERTROPHY AND DILATATION—ATROPHY.

Definition.—Some vagueness exists in the application of these terms. The word *enlargement* may be applied with its literal meaning to any increase of size, whether hypertrophy or dilatation. *Hypertrophy* should be limited to indicate such enlargement as is associated with increased thickness of the walls, with or without increase in the size of the cardiac cavities. When such increased thickness is associated with a cavity of normal size, it is known as *simple hypertrophy*. More frequently the cavity is also enlarged, producing *eccentric hypertrophy*, also known as hypertrophy with dilatation, but I prefer to retain the term dilatation for pathological states. Hypertrophy is physiological. The term *concentric hypertrophy* was applied to a condition in which thickening is associated with reduction in the size of the cavity, but

it is now conceded that such condition is a postmortem product and does not exist antemortem. Even simple hypertrophy is more infrequent in the post-mortem room than is supposed. When the left or right ventricle alone is affected, the hypertrophy may be simple or eccentric; when there is general hypertrophy, it is always eccentric. All true hypertrophies are numerical—that is, there is an actual increase in the number of muscular fasciculi, due partly to a fission of previously existing fibers and partly to a new formation of fibers.

The word *dilatation* is applied to conditions in which the cavities are enlarged without corresponding thickening of the walls. Usually there is attenuation of the walls. The latter is the typical condition. Dilatation implies fatty degeneration, for it is through intermediate degeneration that the muscular fasciculi waste and ultimately disappear, producing thinning.

Hypertrophy more frequently affects the left ventricle, dilatation the left auricle and right ventricle, but the whole heart may be involved by one or the other condition.

HYPERTROPHY OF THE HEART.

Etiology.—Hypertrophy implies an overgrowth of muscular tissue, and is naturally the result of extra work, increased effort to overcome increased resistance, whatever its cause. The term *idiopathic* hypertrophy is applied to such hypertrophy associated with no abnormality in the valves and no cause external to the heart exciting it to overaction. Hypertrophy without valvular disease involves the left ventricle more frequently, but may involve both cavities, and even the right ventricle alone.

The resistance needed to excite increased action may be from within or from without, or due to nervous influence. Resistance from within is occasioned by obstruction to the outflow of blood from the heart, or to increased intravascular pressure.

Such obstruction is offered in the case of the *left ventricle* by aortic stenosis, congenital narrowing, aortic insufficiency, and mitral insufficiency. Increased intravascular pressure is caused by endarteritis and resulting sclerotic changes in the vessel-walls and by aneurysm; by contraction stimulated by the irritation of toxic substances in the blood, such as accumulate in Bright's disease, or as the result of overeating or excessive drinking, especially of large quantities of beer; finally, by excessive physical exertion. All these are, therefore, causes of hypertrophy of the left ventricle.

External obstruction to the contraction of the left ventricle is found in pericardial adhesions and myocarditis. Such hypertrophy is always eccentric. Hypertrophy of the left ventricle from nervous influence is seen in exophthalmic goiter and allied conditions, and in long-continued palpitation. Constant mental excitement is a possible cause.

In the case of the *right ventricle*, internal resistance is produced by pulmonary congestion due to mitral regurgitation or to mitral stenosis, to narrowing of the same vessel or branches, such as occurs in pulmonary emphysema. Valvular lesions of the right side of the heart produce hypertrophy of the right ventricle, just as those of the left cause it to hypertrophy. The greater infrequency of these lesions and their frequent development *in utero* are to be remembered. Pericardial adhesions also constitute a cause of external resistance to contraction of the right ventricle.

Auricular hypertrophy is always eccentric—that is, while the walls are

thickened, the cavities are also dilated. Hypertrophy of the left auricle is usually caused by stenosis of the mitral orifice, and to a less degree is a result also of regurgitation of the blood in incompetency of the mitral valve. Hypertrophy of the right auricle might also be expected as a consequence of regurgitation of blood from the right ventricle to the right auricle, but the resistance to the further backward flow into the veins is so much less than on the left side of the heart that hypertrophy is correspondingly less frequent. In like manner, even if stenosis of the tricuspid orifice is present, the same conditions prevent any marked degree of hypertrophy of the right auricle.

In all cases of hypertrophy due to disease of the valves it is likely that a certain amount of distention of the heart cavity by blood precedes the muscular growth.

Morbid Anatomy.—The hypertrophied heart is altered in its weight, dimensions, and shape. The adult heart weighs in health, in the male fifty to sixty years old, about 335 grams (11.8 ounces); in the female, 295 grams (10.44 ounces). The average thickness of the wall of the left ventricle in health is from 5-8 to 2-3 inch (1.6 to 1.7 cm.); of the right ventricle, 1-6 to 1-4 inch (0.4 to 0.6 cm.); of the left auricle, 1-8 inch (3 mm.); the right auricle, 1-12 inch (2 mm.).

Hearts exceeding these weights and measurements are, therefore, hypertrophied. Measurements should be made before rigor mortis sets in or after it has passed away. The latter may be favored by soaking the heart in water. Commonly, the hypertrophied heart does not exceed 25 ounces (750 gm.), though hearts weighing 48 and 53 ounces (1440 to 1590 gm.) have been noticed.

The shape of the heart varies: in left ventricular hypertrophy it is elongated to the left and lies more horizontally, while the conical shape is less marked; when both ventricles are hypertrophied, the heart is round. In mitral stenosis with hypertrophy of the left auricle and right ventricle it is also quadrate, the right ventricle occupying the chief bulk of the organ, while the left ventricle recedes behind it.

Symptoms.—Hypertrophy, being a process of compensation, is not at first attended by any symptoms. It is the result of a generous conservative effort of nature, by means of which symptoms are averted. But unlike the hypertrophy of the muscles of the blacksmith's arm, it tends ultimately to degeneration, and thus becomes the initial link in a chain of evil which is well stated by J. G. Adami: * "In the first place, it leads to an increased nutrition of the walls of the *arteries*; increased nutrition leads to increased connective-tissue growth of the walls; increased fibrous tissue of the walls leads to contraction and increased rigidity of those walls; the increased rigidity leads to increased resistance to the passage of the blood current. The increased resistance requires increased propulsive power on the part of the ventricular muscle—that is to say, increased work; the increased work of the heart leads to overgrowth and hypertrophy (myocarditis), and with this, heightened blood pressure and further increased nutrition of the walls, and now, at last, the stage is reached, this vicious circle continuing, in which either the vessel walls give way or the heart." From this standpoint increased blood pressure alone is sufficient to explain the anatomical changes—*i. e.*, the arterial sclerosis, atheroma, and fibroid thickening so constantly seen in valves and heart-walls without calling in chronic inflammation or

* "Notes upon Cardiac Hypertrophy," "Montreal Medical Journal," May, 1895.

specific agency. Certain it is that the two conditions react on each other, and it is more than likely that the former (increased blood pressure) may produce the latter (chronic inflammation) *de novo*, and many otherwise unexplained facts are rendered clear.

When reactive effect sets in, we begin to have symptoms which are at first intermittent, brought about only by some temporary cause which excites the heart, such as exercise, mental emotion, fatigue, mental or physical, tobacco, or alcohol. There is a feeling of vague discomfort about the heart, seldom amounting to pain, sometimes increased when the patient lies on the left side. To this may be added palpitation, a consciousness of the beating of the arteries in the head, dizziness, headache, ringing in the ears, flushes or flashes of light, and a tendency to hemorrhage of the nose.

Physical Signs.—While symptoms other than physical signs may be wanting, the latter are present from the beginning, increasing with the duration of the hypertrophy.

In hypertrophy of the left ventricle inspection and palpation furnish much the same information as in hypertrophy of the left ventricle from valvular disease—an apex-beat lower and to the left, strong and diffuse. The radial pulse is strong and tense, the carotids pulsate visibly, and the auscultated vessel sounds are loud and distinct. Percussion shows enlargement to the left and downward. To auscultation there is no murmur, but a distinctive intensification of the aortic second sound is noticed, sometimes ringing, quite characteristic, and itself of great diagnostic value. It may be reduplicated. The first sound, while louder, is also duller, more prolonged and diffuse, sometimes suggesting a systolic murmur not present. It may also be reduplicated.

In hypertrophy of the right ventricle the signs of enlargement are toward the right edge of the sternum and beyond, also without murmur, but with sharp accentuation of the second sound in the pulmonary area to the left of the sternum. The apex-beat is also displaced outward, but not downward; pulsation may be distinct in the lower sternal or epigastric region or between the ensiform cartilage and the seventh rib. In persons with thin chest-walls an impulse may be seen in the third and fourth right interspaces. The pulse at the wrist is small, unless there be associated hypertrophy of the left ventricle.

Diagnosis.—In view of the fact that hypertrophy is a part of the morbid anatomy of chronic valvular defect, we need concern ourselves only with the so-called idiopathic hypertrophy. The resemblance to *hypertrophy* may arise from pericardial effusion, circumscribed pleuritic effusion, aneurysm, or mediastinal tumor in the neighborhood of a normal heart, the latter especially if it push the heart forward. A normal heart may appear enlarged to percussion when it is uncovered by a lung retracted from any cause, as cirrhosis of that organ. Simple *palpitation* of the heart may be mistaken for hypertrophy.

In all cases the situation of the apex-beat is a valuable criterion, because, although its position may be changed in pleuritic effusion and pericardial effusion, it is in the opposite direction from that in hypertrophy, while the impulse is feeble instead of being strong. Aneurysm and mediastinal tumor will certainly furnish some of the signs peculiar to them, and thus permit a distinction. Simple palpitation is without the percussion signs of enlargement of the heart. Under none of the circumstances named will its situation be altered.

Hypertrophy may be obscured if the heart is overlapped by an emphy-

sematous lung. This is partly the case in hypertrophy of the right ventricle, which is often associated with emphysema of the lungs. In such cases the pulse does not help, but rather tends to mislead, because it is small in hypertrophy of the right ventricle.

Prognosis.—When associated with valvular disease, the prognosis is that of the disease itself, against which hypertrophy is, for a time, a protection, counterbalancing the growing defect of the valve until the nutrition of the heart begins to be impaired and dilatation replaces hypertrophy with loss of compensation. The latter may be sudden, though it may be delayed for a time by treatment. While such malnutrition may be of local origin,—that is, resident in the heart muscle itself,—it may be due to general causes also, as general illness, hardship and exposure, overexertion, fatiguing occupation, insufficient food, and the like. When it is the result of endarteritis and aneurysm, the termination comes with the rupture of the vessel or of the aneurysm.

In the so-called idiopathic forms due to toxic substances in the blood danger does not threaten until sclerotic changes are established in the blood-vessel walls.

Treatment.—This embraces that of the causal condition and of measures to reduce overaction.

DILATATION OF THE HEART.

SYNONYM.—*Fatty Degeneration of the Heart.*

Definition.—This has already been defined on page 600, so far as the state of the chambers is concerned. Dilated heart is of two kinds: first, acute dilatation; and, second, chronic dilatation, or dilatation accompanied by fatty degeneration. Of the latter, two varieties exist: (1) Those succeeding valvular disease; (2) those succeeding hypertrophy due to muscular effort, especially when associated with alcoholic intemperance and other forms of dissipation. Acute dilatation may be unassociated with structural change, except as to mechanical arrangement of the muscular elements. Cloudy swelling may be present. The latter is associated with fatty change.

Etiology.—Chronic dilatation is the last stage in a valvular disease the result of failing nutrition. The conditions under which this manifests itself have been described. Acute dilatation is the result of prolonged muscular effort, such as occurs in rowing, running, and mountain-climbing. Moderate degrees of distention occur with any decided muscular effort. The more marked degrees capable of mischievous consequences are the result of prolonged severe muscular exertion. The effect of moderate, well-regulated exercise on the heart, known as training, by which endurance is developed, is to produce eccentric hypertrophy, or hypertrophy with dilatation, which is not dilatation in the sense under consideration—enlargement of the cavity with thinning of the walls. The right heart is the seat of such dilatation. In overexertion the harmful effect of excessive acute strain is averted for a time by the safety-valve action of the tricuspid valve, permitting a regurgitation of blood into the right auricle. Dilatation has exceeded its physiological limit when the cavity is no longer able to empty itself of blood. While moderate degrees of acute dilatation may be recovered from, either rapidly or slowly, dilatation may be carried to degrees at which recovery is impossible and death results. Such results have followed rowing and mountain-climbing.

The so-called *irritable heart*, to which attention was first called by J. M. Da Costa in a graphic description based on a study of the cases of soldiers in the American War of the Rebellion, is an example of an abnormally dilated heart, a heart in which compensation has failed. Another example of the idiopathic hypertrophy already referred to is seen in those persons who, through hard work, acquire muscular strength and at the same time, through alcoholic indulgence, become obese. Such are the drivers of beer-wagons and workers in breweries where an unlimited amount of beer is allowed—as much as twenty liters (as many quarts) a day. After a while, in these hearts compensation is lost and the symptoms of dilated heart follow. Sudden dilatation may happen to hearts whose muscular substance is degenerated, though seemingly hypertrophied, as in chronic Bright's disease, where overexertion often brings on dilatation. In a few instances in malignant forms of the infectious diseases, such as scarlet fever and diphtheria, the nutrition of the heart may be so rapidly impaired by the toxic agency which causes the disease that dilatation occurs with very little or no undue intravascular pressure. All these belong to the second category, that of chronic or slow dilatation.

Symptoms.—The symptoms of “heart strain” are sudden *pain* in the region of the heart or epigastrium, *shortness of breath*, and *rapid, feeble action of the heart*. If it be not immediately fatal, the symptoms may pass off, but are renewed on the slightest exertion. In the acute cases described as due to the toxic causes of infectious disease, sudden death may be the only symptom. In some cases it may be preceded or not by very brief precordial distress. Less serious degrees may be associated with *faintness* or *palpitation* on exertion, *extreme feebleness* of the heart's action, and *dyspnea*. It is rather characteristic for these symptoms to pass away when the patient is at rest, to be renewed on the slightest exertion.

Symptoms growing out of dilatation of the heart, going also to make up the sum of those constituting chronic valvular disease with failure of compensation, are *general venous congestion*, *dropsy*, *feeble, frequent, and irregular radial pulse*—rarely, on the other hand, a *slow pulse*. The former may be due to impaired pneumogastric inhibition the result of anemia of the brain, the latter to scanty nutrition and a loss of irritability of heart muscle. To anemia especially affecting the medulla oblongata may be ascribed Cheyne-Stokes breathing, also a symptom of the terminal stage of the disease. To it may be ascribed, too, symptoms simulating apoplexy, which characterize the slower dying in some of these cases. Palpitation, angina pectoris, and dyspnea—cardiac asthma, with syncopal attacks, coldness, and slow pulse (thirty to forty)—are all symptoms more or less associated with dilatation of the heart. It is further characteristic of these symptoms of dilatation that they are often not transient or amenable to treatment by the usual heart tonics, of which digitalis is the type.

In some instances, especially in the dilated heart of pernicious anemia, there may be a full, strong, and regular pulse.

High-colored, scanty urine of high specific gravity, sometimes containing hyaline casts and blood discs, also result from cardiac dilatation.

Physical Signs.—When the termination is not immediate, physical signs may be recognized. To *inspection* the impulse, if visible, may be diffused over a wide area, but is feeble and fluttering, a point of greatest intensity or an apex-beat being often wanting. At times it is found higher up and to the left of its normal position. If the right heart is chiefly involved, the beat,

as far as caused by the left apex, is completely wanting, while an impulse may be felt below or to the right of the ensiform cartilage, as well as a wavy impulse in the fourth, fifth, and sixth interspaces to the left of the sternum. A pulsation may be seen in the second left interspace, which, while sometimes presystolic, is commonly systolic. In the latter event it may be a further expansion of an already dilated auricle by blood regurgitating during systole of the left ventricle; or if presystolic, it may be the pulse of auricular systole. Such at least are possible explanations. The fact that at autopsies, even in extreme dilatation, the left auricle is found so far back from the thoracic wall as to be scarcely able to beat against the second interspace, does not preclude the possibility of this during life. In dilatation of the *right* auricle, on the other hand, there is sometimes seen an impulse in the third interspace on the right side which is clearly systolic and due to regurgitation from the right ventricle during its systole. The pulsating symptoms described in this paragraph are commonly seen only in persons with thin chest-walls.

To *percussion* there should be increased dullness to the right and downward toward the epigastrium or to the left beyond the normal line, though these boundaries may be obscured by an emphysematous lung. The results of *auscultation* are greatly influenced by complications. If cardiac murmurs are present, they may obscure all else. On the other hand, previous murmurs may disappear. The typical sounds are found in the dilatation following idiopathic hypertrophy. The impulse is feebly heard as well as felt; the first sound is feeble but pure—that is, shorter and more like the second, lacking, as it does, the muscular element. It may be scarcely audible, even in the absence of murmurs. It is sometimes reduplicated because of asynchrony in the action in the two halves of the heart. Sometimes there is a loud systolic murmur at the apex, due to relative insufficiency of the mitral valve, the true nature of which becomes apparent only in the event of its disappearance. The second pulmonic sound may remain sharp if there is dilatation only of the left ventricle and there is compensatory hypertrophy of the right; feeble if the right ventricle is involved. Finally, there is intermittent and irregular action; at times the characteristic *gallop rhythm*,* which is almost pathognomonic of dilatation, is present. The pulse is very rapid and feeble.

Diagnosis.—An acknowledged difficult matter at times is the distinction of *pericarditis with effusion* from the dilated heart. Whether inspection furnishes any information, depends mainly upon the stoutness or leanness of the patient. In the stout person nothing is recognizable in either condition. In the thin-chested the impulse is visible and wave-like in dilatation; it is not visible, or barely so, in pericardial effusion. The same is true of palpation, except that, if the patient leans forward, the impulse may be felt in pericarditis.

Percussion affords the most valuable information. If it brings out the well-known triangular shape of dullness, with the apex toward the inner end of the left clavicle, and the base in the fifth or sixth interspace, especially in the absence of a cardiac impulse, there must be *pericardial effusion*. To *auscultation*, while the heart-sounds have lost their characteristic sharpness, they still contrast with the distant and muffled sounds in pericardial effusion. Especially if there is left any of the original hypertrophy, the second sound will retain some of its sharpness, while, if there happens to have been valvular disease, the murmurs remain to help us.

* For explanation of gallop rhythm see Barth and Roger, "Traité Pratique d'Auscultation." Thirteenth Edition, Paris, 1898, p. 352.

Bamberger's sign, described on p. 561, must be sought for in evidence of pericardial effusion. There may be encroachment on the lung in dilatation, but it is very much less in dilatation than in pericarditis with effusion. This encroachment in the case of dilatation does not give rise to Skodaic resonance in the axilla. While there is shortness of breath in both, it is less pronounced in dilatation and more influenced by exertion, being less while the patient is quiet.

Prognosis.—This is ultimately fatal; in fact, the stage of dilatation is the stage in which remedies become unavailing. At the same time, marvelous results sometimes follow treatment. I have seen general anasarca with effusions in the serous cavities disappear when least expected, so that one is never justified in giving an unqualifiedly unfavorable prognosis.

Treatment.—This is essentially that of valvular heart disease. Rest is even more important, while the heart tonics are, of course, indicated. Strychnin is an important remedy, and in dangerous stages may be given hypodermically in 1-30 grain (0.0022 gm.) doses every three or four hours or oftener for a short time. Digitalis in 7.5 minims (0.5 c. c.) or Merck's German digitalin, in doses of 1-10 to 1-2 grain (1.0066 to 0.033 gm.), may be given under like circumstances. Suitable nutritious food and, if the patient survives the primary danger, well-regulated exercise, are indicated. A timely blood-letting may save life if the signs of engorgement of the right ventricle are present—intense dyspnea, lividity.

It is in this condition that the Schott or Nauheim treatment is especially useful. It consists in the use of the carbonated saline baths at Bad Nauheim, associated with special exercises called "resistance" movements, originated by the brothers Schott. Fortunately, artificial baths may be substituted for the natural baths, or the treatment would have limited application. Ignoring for the present the rationale of the action of these baths, their therapeutic efficacy is undoubted. The waters at Nauheim have a temperature ranging from 82° F. (27° C.) to 95° F. (35° C.). Their important constituents are chlorid of sodium and chlorid of calcium.

The baths may be imitated at home by dissolving chlorid of sodium and chlorid of calcium in water, to which carbonic acid is added by decomposing bicarbonate of potassium by hydrochloric acid. Dr. K. N. B. Camac has calculated the required quantities of salt to each forty gallons of water for six different strengths of the baths. In the baths I recommend I have adopted the proportions of sodium chlorid and calcium chlorid calculated by Camac, but have slightly modified the proportions of carbonic-acid-forming constituents, making three strengths of the latter, after the method recommended by Bezley Thorne, of London:

Bath No. 1: Sodium chlorid, 4 pounds; calcium chlorid, 6 ounces.

Bath No. 2: Sodium chlorid, 5 pounds; calcium chlorid, 8 ounces.

Bath No. 3: Sodium chlorid, 6 pounds; calcium chlorid, 10 ounces.

Bath No. 4: Sodium chlorid, 7 pounds; calcium chlorid, 10 ounces; sodium bicarbonate, 1-2 pound; HCl (25 per cent.), 12 ounces.

Bath No. 5: Sodium chlorid, 9 pounds; calcium chlorid, 11 ounces; sodium bicarbonate, 1 pound; HCl, 1 1-2 pounds.

Bath No. 6: Sodium chlorid, 10 pounds; calcium chlorid, 12 ounces; sodium bicarbonate, 2 pounds; HCl, 3 pounds.

I rarely use anything beyond No. 4 bath.

The alkali should always be slightly in excess, unless a porcelain or paper tub is used.

In preparing the bath, the salts, including the right proportion of bi-

carbonate of sodium, are dissolved in the water. The bottle containing the hydrochloric acid is inverted and lowered until its mouth is below the surface, when the stopper is withdrawn and the bottle moved about so as to diffuse the acid as uniformly as possible through the water. In this way the bath is made ready in a few minutes. The carbonic acid is the most unsatisfactory feature of the artificial bath, since it is rapidly dissipated, and produces only feebly the effect of the acid in the natural baths. Hence the patient should be promptly put into the bath after the HCl is added, lest the CO₂ is lost before he can get the effect of it. My plan has been to give the baths on alternate days, using the weaker until its effects are exhausted, then passing on to Nos. 3 and 4 in the same manner. Nos. 5 and 6 are not often called for.*

As already stated, the baths are most efficient in cardiac disease, but they are also useful in renal affections. Their immediate effect is a diminished pulse-rate, intensified heart-sounds, diminished breathing-rate, while the dilated heart is reduced in size—under favorable circumstances to almost its natural limits. The effect is also to increase the action of the kidneys and that of the skin. These effects are apparent in a free flow of urine, which may continue for days and weeks. Metabolic changes are accelerated and improved; the deep-seated organs, especially the liver and pelvic viscera, are relieved of congestion; while the heart, relieved of its burden, and contracting strongly, derives from its improved coronary circulation material for the repair of weakened and damaged tissue.

I find in my experience that it is more satisfactory to give the baths on alternate days until about fifteen or twenty baths are taken, gradually passing from the weaker to the greater strengths, and gradually reducing the temperature from 95° F. (35° C.) to 82° F. (27° C.).

The exercises are not so easily described as shown by actual practice, but briefly they may be said to include every reasonable movement of the arms and legs, gently resisted by opposite pressure exerted by the physician or attendant. Thus, there is flexion of the arms on the forearm, carrying the arms forward until the palms are apposed, then backward from this position until they are in a line, and raising them from the sides upward until they touch the sides of the head. There are also radial movements of the arms alongside of the head, etc.—in all, nineteen movements. Similar movements are made with the legs, including flexion and extension at the knee-, ankle-, and hip-joints. They include also lateral and twisting movements of the trunk.

The exercises are not commenced until some very positive effect of the baths is secured, when they are associated with the baths or substituted after the latter are discontinued. The effects of these gymnastics are described as identical with those of the baths. The extremities become warm, the breathing is deepened, the sense of oppression is relieved, the pulse becomes slower, the dilated heart area reduced. Even the liver, which is so often enlarged in heart disease as a result of passive congestion, is said to be reduced in size.

* I have had constructed for use at the Hospital of the University of Pennsylvania an apparatus for introducing carbonic acid into the water of the bath, after a device suggested by Dr. Smitheman, when a student of medicine.

ATROPHY OF THE HEART—BROWN ATROPHY.

Definition.—Atrophy of the heart is the opposite state to hypertrophy—viz., a reduction in the muscular substance, with a corresponding reduction in the size of the cavities. It is associated with pigmentation, hence the term brown atrophy. It is limited clinically, being confined to the subjects of wasting diseases, like phthisis pulmonalis and carcinoma. It is the special result of senile marasmus. It is occasionally associated with chronic valvular disease. The muscular fasciculi undergo molecular death, the organ wastes, and is symmetrically reduced. It is dark red-brown in color and firm in consistence. By the microscope is recognized a peculiar arrangement of pigment granules about the nuclei and between the primitive fibrillæ. The source of the pigment is not precisely known. It may be the coloring matter of the muscle, or directly derived from the blood.

The **diagnosis** of such condition can only be based on a diminution in the normal area of cardiac percussion dullness associated with feeble pulse, and the long-continued presence of the causal disease. Reduced area of cardiac dullness must be unassociated with emphysema of the lungs or other causes which may diminish cardiac dullness by covering up the heart.

The **treatment** is that of the causal disease.

DEGENERATIONS OF THE CARDIAC MUSCLE.

The heart muscle is subject to parenchymatous degeneration, to fatty degeneration, to fatty infiltration, to amyloid degeneration, to the hyaline transformation of Zenker, to calcareous degeneration, and to the changes known as brown atrophy and yellow atrophy.

PARENCHYMATOUS OR ALBUMINOID DEGENERATION (CLOUDY SWELLING).—This is a change in which the sarcous substance is converted into granular matter of albuminoid composition, which produces also more or less indistinctness in the striated appearance of the fasciculi. The albuminoid composition of the product is attested by its solubility in acetic acid, and its insolubility in ether. The general effect is one of softening and flaccidity.

It is ascribed to some toxic agency, and occurs most frequently in the infectious fevers—typhoid fever, typhus fever, scarlet fever, diphtheria, and the like. It was at one time considered a consequence of high temperature, but this view is no longer held. It is believed also to be, at times, at least, the first stage of fatty degeneration, or to precede fatty degeneration. It is certainly at times associated with it. Cloudy swelling may disappear and the muscle resume its natural histology.

FATTY DEGENERATION OR FATTY METAMORPHOSIS.—In this change, also sometimes known as *yellow atrophy*, the sarcous substance of the muscular fasciculi is directly converted into globular fat, as contrasted with the condition of fatty infiltration, in which the fat is deposited between the fasciculi. The little fat drops—and they are very minute, as a rule—are seen in rows parallel to the fibrillæ of the fasciculus, and all transverse

striation has disappeared. As intimated, the cause of such degeneration is an interference with the proper nutrition of the heart-muscle.

It may be *general*, when it has its most frequent expression in the dilated heart which succeeds upon hypertrophy, involving the walls of one or more cavities. It is also a result of the impaired nutrition of old age, of the grave infectious diseases, and of cachectic states generally—such, for example, as pernicious anemia. In the infective diseases and cachexias it may be associated with parenchymatous degeneration or succeed upon it. It is also a result of the action of certain poisons, as phosphorus and arsenic, the effects of which may extend to other muscular organs. Under these circumstances, the heart is generally enlarged (dilated), flabby, and relaxed, of a light yellow or yellowish-brown color, and very friable, permitting the finger to be easily poked through it. The papillary muscles and the trabeculæ in the left ventricle may be the seat of circumscribed fatty degeneration, and be dotted and streaked with yellow, fatty matter. Unlike parenchymatous degeneration, fatty degeneration, when once established, is considered irremediable.

Fatty degeneration of the heart may also be *circumscribed* in small foci variously distributed. Thus, it may be confined to the superficial or sub-pericardial layers, when it is especially the result of pericarditis. Or there may be numerous pinhead-sized foci in the subendocardial layer in cases of extreme dilatation.

Finally, there may be a single focus in the substance of the left ventricle or the septum, due to total obstruction of one of the branches of the coronary artery, usually the anterior, by a thrombus or embolus. The product is an area of fatty degeneration known also as *anemic necrosis*, or *white infarct*. In the early stage the infarction is brownish-yellow or hemorrhagic. Minutely examined, the muscular fasciculi are without nuclei, and later they break up into a cheesy detritus. The infarct is not always thus made of fatty debris, but may present a hyaline appearance. It may be the seat of rupture, and thus cause hemorrhage into the pericardium, and immediate death.

Diagnosis.—The diagnosis of fatty degeneration, so far as recognizable, is that of dilatation, slight degrees and circumscribed fatty degeneration being unrecognizable, while considerable areas of partial degeneration may also exist without exhibiting symptoms. In fact, the presence of some dilatation of the cardiac cavities seems to be necessary to the production of symptoms—the feeble pulse, palpitation, and dyspnea being symptoms of the dilatation, rather than the fatty degeneration.

Prognosis.—This is grave. It is impossible to restore the degenerated muscular substance to its natural structure. With degeneration established death is liable to occur suddenly, and remedies which avail with an integral organ are useless here.

Treatment.—This embraces that of cardiac dilatation. Acute attacks should be met by stimulants, of which alcohol, aromatic spirit of ammonia, and digitalis are the type. Strychnin is also indicated, and may be used hypodermically.

Fatty Infiltration or Fatty Overgrowth.—Strictly speaking, this condition is not a degeneration of the heart muscle, though it leads ultimately to fatty metamorphosis. It is the *cor adiposum* of the older authors, and differs from fatty metamorphosis in that the fat is infiltrated *between* the muscular fasciculi. In the true *cor adiposum*, the fat extends deep into the

substance of the muscle, sometimes as far as the endocardium. It covers also the outside of the heart, at times so completely that the true muscular structure is invisible. This infiltration sooner or later interferes with the proper nutrition of the muscular substance, a true fatty degeneration results, with its symptoms, so far as any are manifested, and becomes ultimately also a cause of death.

The fatty infiltrated heart is commonly a part of general obesity, and occurs, therefore, at a time of life when this is usual,—that is, between the ages of forty and seventy years,—and is more than twice as frequent in men as in women.

The condition is inferred from the presence of extreme obesity associated with signs of cardiac weakness.

The **treatment** is that of obesity.

Amyloid infiltration invades the heart as it does other organs, attacking the blood-vessels and intermuscular connective tissue. Zenker's hyaline transformation attacks, on the other hand, the muscular fasciculi, causing them to appear swollen and transparent, and the striæ to be indistinct or absent.

Calcareous infiltration is a rare condition, in which the muscular fasciculi are infiltrated with lime salts.

MYOCARDITIS.

CHRONIC MYOCARDITIS OR FIBROMYOCARDITIS.

SYNONYMS.—*Fibroid Degeneration of the Myocardium; Fibroid Heart; Fibrous Myocarditis; Interstitial Myocarditis; Indurated Degeneration; Myodegeneration; Sclerosis of the Coronary Arteries.*

Definition.—A condition of the cardiac muscle in which there is more or less substitution of the normal substance by fibroid tissue, either localized in patches or diffused throughout the organ. It is analagous to fatty infiltration.

Etiology and Pathology.—The condition is not, strictly speaking, inflammatory, the patches representing transformed areas of anemic necrosis, due to obstructive disease of the coronary arteries and branches. The disease in the coronary arteries is endarteritis, resulting in arteriosclerosis. It not only diminishes the blood supply, but it causes degeneration of the muscular fasciculi, and their substitution by fibrous tissue. Only in the event of such diminished supply do the changes occur. Hence it is that arteriosclerosis of the coronary arteries is not always followed by fibroid change. The causes of arteriosclerosis of the coronary arteries, which in its turn gives rise to the fibroid change, are those of endarteritis elsewhere. They include all the causes which produce idiopathic hypertrophy (p. 603). The tendency to arteriosclerosis is often hereditary. It is a disease also which seldom occurs prior to middle life, though sometimes seen surprisingly early. It might be said that it is natural to old age—one of its evolutionary terminations. In pure, uncomplicated cases the valves are normal, while the muscle, on examination, is found dotted with white, shining areas present in varying numbers. Minutely examined, these are found made up of pure or partly fibroid tissue, the muscular fasciculi being correspondingly destroyed.

They are seated for the most part in *the left ventricle toward the apex* and in the *anterior wall*, though they may be found elsewhere. They may often be seen from the endocardial or pericardial surface as *cicatricial-like depressions*. Sometimes there is a single large patch known as a *fibroid patch*. The papillary muscles may exhibit the same fibroid change.

The fibroid change may also be associated with valvular disease, the mechanical impediment to the movement of blood in these conditions being the cause of a chronic venous congestion, which results in a fibroid infiltration; or the valvulitis may give rise to embolism of the coronary arteries or branches, thus cutting off nutrition. From the cardiac thrombosis which sometimes results there may arise cerebral, renal, and pulmonary embolism. Long-standing emphysema of the lungs results in similar congestion; so does obstruction of the pulmonary artery from any cause.

A further result of the fibroid change is dilatation of a part or of the whole of one of the heart cavities, producing in the former instance what is known as *cardiac aneurysm*. Fibrosis may also be associated with hypertrophy without valvular disease, though the recognition of such combination before death must be a matter of inference, based on the presence of arteriosclerosis elsewhere and of the causes of such hypertrophy.

Symptoms.—Slight degrees of fibroid change occasion no symptoms, while autopsies even disclose advanced stages of indurative myocarditis which were not suspected. In consequence of the frequent association, too, of endocarditis and pericarditis, the symptoms of these diseases are often combined and mask the distinctive symptoms of the fibroid change. Unmasked, the symptoms are, in a word, those of dilatation of the heart, including *dyspnea*, often so severe that the patient cannot lie down. With this may be associated *Cheyne-Stokes* breathing, commonly occurring during sleep. There may be *palpitation*, with *small, frequent, and irregular pulse*, or the pulse may be unnaturally slow. There is *precordial oppression*, with *attacks of faintness*, and, finally, *venous stasis* with *cyanosis, general edema, congestion of the liver, stomach, and kidneys, feeble digestion, scanty urine, and albuminuria*. These symptoms may set in gradually or suddenly. On such a heart, digitalis and other heart tonics are often without effect. A *persistently slow pulse* should be mentioned as an occasional symptom. *Angina pectoris* is also a symptom of indurative myocarditis, though it also occurs in other cardiac diseases, especially aortic stenosis. It will be described when treating of neuroses of the heart. The same symptoms may arise from fatty heart.

A very interesting train of nervous symptoms may arise, due to changed local distribution of blood in the brain, partly due to feeble cardiac action and partly to stenosis of the basilar vessels. They may include brief unconsciousness and various degrees of paralysis, and anesthesia resembling the symptoms of cerebral embolism.

Physical Signs.—Physical examination recognizes a *feeble impulse*, often scarcely appreciable, and, on percussion, either enlargement of the heart—dilatation—or the reverse. The first sound lacks its muscular element, and is more like the second—more purely valvular, and therefore short. Both sounds maintain for a time considerable distinctness, but ultimately grow feeble. Occasionally there may be a mitral murmur, which may be functional and transitory or permanent. Such murmur is explained by the experiments of Ludwig and Hesse, already alluded to, and more recently confirmed by Krehl. These go to show that a certain integrity of the

muscles about the mitral orifice or of the papillary muscles is necessary to a complete closure of the latter. Such integrity is impaired by myocarditis, and the resulting murmur increases the difficulty of diagnosis. There is, however, usually absence of accentuation of the pulmonic second sound characteristic of mitral regurgitation, though this may also be relatively present if the right ventricle happens to be less severely involved than the left. The second sound is also sometimes reduplicated. The mitral murmur in the fibroid heart is more variable and more subject to intermissions than that of mitral regurgitation. The sudden addition of a mitral systolic murmur in a fibroid heart previously without murmur may also indicate a lacerated valve.

Diagnosis.—This is often difficult, requiring the opportunity of prolonged study of the case for an accurate diagnosis. For the most part, we are compelled to rely on the absence of the symptoms and signs of valvular disease, and the presence of the symptoms of dilatation, the evidences of arteriosclerosis elsewhere, a persistently slow pulse, angina pectoris, the history of syphilis and of other causes, together with the age of the patient. When the fibroid condition is associated with murmurs, the diagnosis is still more difficult, and must, indeed, be a matter of probability, if even suggested, so much more likely are the signs to be interpreted as those of valvular disease, with which, however, the fibrosis may be associated. The presence of radial sclerosis is strongly confirmatory, but not essential.

Prognosis.—This is grave, or, to say the least, uncertain. Associated as it is with sclerosis and narrowing of the coronary arteries or branches, complete obstruction is liable to occur at any time, producing sudden death. On the other hand, the patient may live for many years with the heart the seat of considerable fibroid change.

Treatment.—This must mainly consist in treating the causes, and in a proper hygienic management. Habits of overeating and excessive drinking should be overcome. The avoidance of overexertion, associated with just sufficient exercise to develop the heart healthfully, should be observed. Outdoor life and a proper hygiene of the skin and body by bathing and massage are important.

Drugs which will remove the diseased condition of the coronary arteries and fibroid overgrowth probably do not exist. Still, the reputation of iodid of potassium as a remover of fibroid overgrowth and for the cure of syphilitic disease should be availed of. The iodid is also serviceable in producing vascular dilatation and facilitating the movement of the blood. For the symptoms of stasis and heart weakness, of dyspnea and of angina pectoris, the treatment is the same as that for these conditions under other circumstances. The judicious use of digitalis is indicated, and may accomplish much. Nitroglycerin may be associated with advantage or used alone.

ACUTE SUPPURATIVE MYOCARDITIS.

SYNONYM.—*Abscess of the Heart.*

This is a rare condition. It is always metastatic or pyemic in origin, in association with puerperal fever, malignant endocarditis, or other septic processes. It may occur in the septum, as well as the outer ventricular walls.

As such it is not recognizable before death, and is commonly discovered

at autopsies. It may, however, rupture into the heart cavities, causing other metastatic abscesses, or into the pericardium, causing septic pericarditis and early fatal termination.

ANEURYSM OF THE HEART.

This is a term given to two conditions :

1. A saccular projection from the ventricular surface of a sigmoid or cuspid leaflet, where the valve is weakened by ulceration through one of the lamellæ, the intravascular or intracardiac pressure furnishing the distending force. It is much more common in the aortic segments. The sacculæ may ultimately perforate, causing laceration of the valve.

2. Projection outward of a circumscribed portion of the muscular wall, which has been weakened by the fibroid patch or by an injury to the wall. Here, naturally, the left ventricle, too, suffers, and near the apex in more than half the cases. The resulting pullulation varies in size from 2-5 inch (1 cm.) or less to dimensions equal to those of the heart itself. The aneurysm may be sacculated or partitioned and even multiple.

There are no symptoms by which the condition may be recognized with any degree of probability. It may also terminate fatally by rupture into the pericardium.

RUPTURE OF THE HEART.

Rupture of the normally integral heart muscle does not occur. It is only when weakened by disease that such an event is possible. Fatty metamorphosis furnishes the most frequent predisposing condition. The softening due to obstruction of a branch of the coronary artery, as already described on page 610, and known as *massive softening*, is the most frequent cause of heart rupture, but the fibroid change, abscess, or ulceration are all conditions which at times precede rupture. Morbid growths in the heart-wall, such as gummy tumor and carcinoma, are also possible causes.

These preliminary conditions presupposed, any unusual strain is sufficient to produce rupture, though this is not always necessary, especially in the case of the white infarct, where the degeneration is so great as to admit rupture with the ordinary pressure. It is naturally an event of the second and third half-centuries of life.

The anterior portion of the left ventricular-wall near the septum is the favorite seat. Rupture is rarely recognized before death, which usually follows in the course of a few hours. The symptoms are precordial pain, a sense of oppression, dyspnea, pulselessness, and collapse. There may be enlargement of the cardiac area of dullness, owing to filling up of the pericardial sac.

NEUROSES OF THE HEART.

NERVOUS PALPITATION.

Definition.—By this is meant an unnaturally frequent, regular, or irregular beating of the heart, of which the patient is uncomfortably conscious, but which is unattended by any physical evidence of organic disease of the organ. This does not mean that there may not be functional or accidental murmurs, because these are especially prone to be present in the different varieties of anemia which are commonly associated with palpitation. *Such murmurs are always, however, systolic, a diastolic murmur always indicating organic disease.* Palpitation, or uncomfortable heart-beating, also occurs in connection with organic disease of the heart, but this is not nervous palpitation.

Etiology.—There are numerous causes of palpitation. In the first place, it is much more frequent in women than in men. Again, it is prone to occur at the time of puberty in girls, and at the menstrual period and climacteric in women. Anemia is at once a predisposing and an exciting cause; indigestion is a very frequent causal agent. Mental emotion, including fright, anxiety, and grief, diseases of the uterus and stomach, the exhaustion of protracted illness, sexual excesses, overwork, the abuse of alcohol, tobacco, tea, and coffee, are all active etiological elements. The "irritable heart" described by Da Costa, based on observations made on soldiers in the late War of the Rebellion in America, has for its most striking symptom palpitation; yet this dare not be called nervous palpitation, as dilatation of the heart was probably here present. Overwork and excitement were its chief causes, abetted by exhaustion from illness.

Symptoms.—The "*beating*" referred to is, of course, the chief symptom. It varies greatly, however, in degree and duration. At times there is a mere fluttering, lasting for a few minutes. At other times the pulse-rate may reach 160 or more and be scarcely countable. When the character last described is attained, and continues for a variable time of hours to days, but finally ceasing, the term *paroxysmal tachycardia* is applied. The rapid heart-action is sometimes associated with a sense of *weakness* or "*gone-ness*" in the epigastrium, and sometimes with *nausea*. The face is usually pale, but is sometimes flushed. The physical signs usually add nothing to the undue beating noted on auscultation, though, as already mentioned, there may be functional murmurs systolic in time at the base of the heart, more rarely at the apex. The normal heart-sounds may be somewhat sharper and clearer, or they may be more blurred.

Diagnosis.—The only two conditions with which nervous palpitation may be confounded are *myocarditis* and *fatty degeneration of the heart and dilatation*, the symptoms of which, it will be remembered, are similar. The nervous affection is, however, a less serious affection, characterized by intermissions during which the heart is quiet. Its subjects are also of the anemic nervous type, whose history greatly aids the diagnosis, and they are commonly younger.

Treatment.—This is by rest, nerve sedatives, and a suitable moral treatment of encouraging words and a confident manner. A few drops of

tincture of digitalis, with a few more grains of sodium bromid, repeated every hour, may be useful. When the patient is weak and anemic, he should be built up and strengthened by iron, quinin, and strychnin.

TACHYCARDIA AND BRADYCARDIA.

Paroxysmal Tachycardia.—This term is applied to conditions of the heart in which, without evident cause, there appears paroxysmally an inordinate increase in the number of heart-beats a minute, of which also the patient is conscious. The number of beats may reach 200 or more. The paroxysm may last for a few minutes only, or for hours. The intervals between two attacks vary greatly, and their recurrence may extend over many years.

Bradycardia; Brachycardia; Slow Heart.—The term bradycardia is applied to unnatural slowness of pulse. It is to be remembered, however, that some healthy persons naturally have a slow pulse, as others have one whose rate is more rapid than the typical 72. A rate of from 50 to 60 is not unusual. It may even be slower, as in the case of a patient of mine whose habitual pulse for many years of my observation was from 36 to 40. I do not know, however, what it was in youth. Of abnormally infrequent rates, cases with 20 beats are reported, some even at 12, 9, and 7. These instances of extremely slow rate are apt to be associated with fibroid heart, and there can be no doubt that the nervous condition is often confounded with the organic one.

In the study of an apparently slow pulse, care must be taken that the actual count is based on a corresponding heart-rate, for it sometimes happens that in consequence of the weakness of an alternate systole the heart-beat does not reach the wrist.

Bradycardia occurs under a variety of conditions, which have been carefully collected by Riegel. They include the following:

1. Convalescence from acute fevers, such as typhoid, pneumonia, diphtheria, acute rheumatism, and the like.
2. Diseases of the digestive apparatus, especially dyspepsia, but also ulcer and cancer of the stomach.
3. Rarely in diseases of the respiratory system.
4. Diseases of the circulatory system, more frequently those involving the muscular structure of the heart, and associated with deficient nutritive supply, especially conditions succeeding obstruction to the coronary artery.
5. In nephritis.
6. From the action of toxic agents, including the uremic poison, lead, alcohol, coffee, and digitalis.
7. Certain diseases of the nervous system, including apoplexy, brain tumors, especially those involving the medulla and cervical cord. (To these may be added epilepsy and catalepsy.—*Author.*)
8. Finally, affections of the skin and sexual organs.

Explanation of Tachycardia and Bradycardia.—The rationale of the production of tachycardia and bradycardia has excited much discussion and cannot be said to be settled. The heart's action is accelerated by stimulating the accelerator branch of the sympathetic or by paralysis of the inhibitory root of the pneumogastric, and slowed by stimulation of the latter, directly or reflexly. Direct stimulation of the latter is caused by pressure on its root,

which may be exerted through the cerebrospinal fluid, which in turn may be excited by brain tumor, hemorrhage, and meningitis of the dura or pia. Such irritation may be caused by toxic constituents of the blood, as in uremia.

Increased arterial pressure—such, for example, as occurs in *acute* nephritis—is said also to produce cerebral vagus irritation. On the other hand, such slowing is not maintained if the arterial tension is kept up, as in *chronic* Bright's disease and arterial sclerosis. Under such circumstances the excitability of the pneumogastric center may be said to be exhausted. Deficient nourishment to the heart substance, such as is caused by atheroma and obstruction of the coronary artery, leads also to a slow pulse. Reflexly, the pneumogastric may be stimulated by diseases of the abdominal organs—as, for example, the stomach, bowels, and peritoneum. The effect of disease of the muscular substance of the heart in reducing its rate has often been mentioned in the foregoing section. On the other hand, poisons and high temperature increase the pulse-rate. In this way the infectious diseases may produce acceleration. Other poisons slow the pulse, possibly by acting on the nerve endings in the heart. Such are the salts of the biliary acids and the uremic poison, whatever it may be.

It is well known that in the course of acute infectious diseases, especially typhoid fever, slowing of the pulse occurs at times very strikingly. This is not uncommon in the beginning of convalescence. It has been observed also in typhus fever, in croupous pneumonia, erysipelas, diphtheria, and measles. I have met it as slow as 18 in typhoid fever. In explanation of this phenomenon one may suppose a lesion of the cardiac ganglia by the toxic substances circulating with the blood, or a consequent weakness of the heart muscle due to the long continued fever.*

His and Romberg, in their studies on the innervation of the heart, were led to believe that the cardiac ganglia are sensory in function and that they share the increased sensitiveness of the entire nervous system, variously caused, and thence reflexly may excite the violent cardiac action of tachycardia. Not unlike this is the explanation of H. C. Wood, who suggests that the paroxysms of tachycardia are due to "discharging lesions" affecting the centers of the accelerator nerves. In some one of these views, perhaps, must be sought the required explanation. On the other hand, anesthesia of the cardiac ganglia, however induced, would be expected to have the opposite effect of a bradycardia. By recalling these facts many of the cases of bradycardia may be explained.

IRREGULAR PULSE.

SYNONYM.—*Arrhythmia*.

Description of the Different Varieties, Peculiarities, and Explanation.—The simplest form of irregular heart is that in which there is an occasional drop or *intermission* in the beat, while the pulse in the intervals is perfectly regular. This may occur once only in twenty or more beats, and from this rate may increase until it happens once in six or four beats, or it may be every second or third beat; or the pulse may be altogether irregular—*arrhythmical*. A striking feature of even the simplest form of intermittent pulse or

* See a very full paper "Ueber Bradycardie," by Dr. F. Grob, "Deutsches Archiv für klinische Medicin," vol. xxii., 1888, p. 574.

heart is that the omitted beat is commonly recognized by the patient himself, and often it becomes a matter of intense annoyance to him. Here, again, it is quite important to decide whether the dropped beat at the wrist is the consequence of an omitted systole recognized by absence of the first sound in the auscultated heart, or whether it is a simple weak systole which does not send the pulse to the radial artery at the wrist. It is more apt to be the former, if the patient recognizes it. It may be constant or occur at regular intervals or only occasionally.

In the latter event it may be associated with some such disturbing cause as dyspepsia and, especially, flatulence. It follows the use of tea, coffee, or tobacco, and is in rather frequent association with chronic gout. It follows also mental shock, and is especially prone to occur in nervous, hysterical persons. The intermittent pulse thus occurring is vaguely ascribed to nervous influences, and nothing more definite can at present be confidently suggested for its causation. It may be due to some influences of the causes named on the cardiac ganglia of the sympathetic nerve. It is probably at times directly due to organic changes in the heart muscle, especially in fatty degeneration, in which event it is a more serious symptom.

It is characteristic of the more purely functional variety of intermittent pulse that it may be removed by exercise or excitement, while it often disappears during pyrexia. On the other hand, the effect of exertion on the intermittent pulse of fatty heart is to increase the intermission or convert it into an irregularity.

The *irregular pulse* is indicated by its name. It is associated with a corresponding degree of irregularity of the heart's action, the highest degree of which is known as *delirium cordis*. This irregularity varies also, may be habitual or occasional, and produced by the same causes as intermission. It may also be induced by temporary or permanent derangements of the respiratory organs through changes in pressure on the large arteries in the chest. This, be it noted, is not an influence on the heart. Irregularity of the pulse and heart is a distinctive symptom of mitral insufficiency. This is very reasonably ascribed by W. H. Broadbent not to nervous influence, but to *variations in pressure due* to traction of the lungs during the inspiratory act on the cavities of the heart. This is favored by the thin, flabby, and feebly resisting walls of a dilated auricle, incapable of resisting variations of external pressure. In mitral stenosis, though the auricle is dilated, the narrow auriculo-ventricular orifice prevents the disturbing effect of the varying pressure of the respiratory movements.

In like manner may be explained the *pulsus bigeminus* and *trigeminus*, also common in mitral disease, more especially mitral stenosis. In these two and three beats follow each other in rapid succession, separated by a longer interval. The *pulsus paradoxus* of Kussmaul, in which the beats during inspiration are more frequent, but less full than during expiration, may also be explained in this way, occurring as it does in weak heart, chronic pericarditis, and other conditions in which the normal relation of respiration to the heart's dilatation and contraction is interfered with.

Other modifications of the cardiac rhythm are the *gallop rhythm* and *embryocardia*. The former consists of three sounds, and is so called because it resembles the footfall of a horse in canter. It occurs especially in the hypertrophy which accompanies interstitial nephritis with arteriosclerosis, and in fatty dilated heart. It is variously ascribed to an (1) abnormal "clacking," produced by the contraction of a hypertrophied auricle, preceding the ven-

tricular shock (Charcelay); (2) to a presystolic impulse which immediately precedes the precordial shock; (3) to the contraction of a hypertrophied auricle and powerful tension of the ventricular wall produced by the rushing of the column of blood into the ventricles in connection with the elastic resistance due to the muscular tonicity of the hypertrophied wall (Potain); (4.) Cuffer and Barbillion suggest, in explanation of the variety occurring in the feeble myocardium of ataxic fevers and dilatation, that the ventricular contraction and consequently the first sound is broken into two parts succeeding the precordial shock.* *Embryocardia*, first described by Stokes, is a condition in which the first sound is shortened, and therefore more like the second, the resultant being a sound similar to that of the fetal heart. It occurs especially in the latter stages of dilated heart, in which the muscular element of the first sound has become lost because of weakness and the sound is purely valvular.

The *dicrotic pulse* is a double beat, and is found in every normal sphygmogram. It is the effect of the elastic recoil of the overdistended aorta on the contained blood immediately succeeding the closure of the aortic valve, and is shown at *f* in the catacrotic or descending portion of the normal sphyg-

Fig. 57.—Showing Normal Pulse-tracing.

mogram appended. It is preceded by the aortic notch *e*; this by the *tidal* wave *d* and the percussion wave *b*, the apex of the curve. Only when exaggerated is it felt by the fingers. It may occur abnormally wherever there are a forcible systole and unobstructed arterioles, especially in aortic regurgitation, and although here the incompetent aortic valves do not furnish the requisite resistance, this is furnished by the full ventricle behind them, so that while the dicrotic factor may be delayed, it is marked when it occurs. This is seen in the sphygmogram on page 583. It occurs also in anemia after venesection, the necessary atony of the arterial system being thus produced; after the administration of amyl nitrite and nitroglycerin; also in uncompensated mitral regurgitation, when the emptiness of the arterial system is produced in a different way—that is, by diminishing the amount of blood which enters the aorta with each systole.

Another variety of double beat is the *pulsus bisferiens*, most frequently noticed in aortic stenosis, but also in senile degeneration of the arteries. This resembles the dicrotic pulse, though quite different in its etiology. In it the second beat is a reinforcement near its close of a prolonged systole. Under these circumstances the dicrotic wave will be absent.

Mention should be made in passing of the *anacrotic pulse*, though this is

* For an elaboration of these and further explanations see Barth and Roger, "Traité Pratique d'Auscultation," thirteenth edition, Paris, 1898.

not appreciable to the finger. It is similar to the *pulsus bisferiens*. An anacrotic pulse-wave is one in which a more or less marked notch occurs in the ascending limb, as in Figure 59. It is the pulse of high arterial tension, and occurs when the arteries are rigid and do not expand promptly to receive the contents of the ventricle during systole. The walls yield slowly, the pressure is prolonged, broadens the top of the sphygmogram, and throws the highest part of the tracing toward the end of the systole and nearer the diastolic

Fig. 58.—Pulsus Bisferiens (Broadbent).

wave, which is usually ill developed. So, too, the percussion wave is practically abolished and the tidal wave forms the apex of the curve. The pulse of prolonged arterial tension is produced by anything which restricts the motion of the blood through the capillaries and arterioles, and such causes are numerous. Chronic renal disease, especially interstitial nephritis, is one of them; so are gout, lead poisoning, constipation, atheroma, or calcification of the arterial walls. The anacrotic pulse is also produced in aortic stenosis, where it is of diagnostic value.

TREATMENT OF PALPITATION, TACHYCARDIA, AND ARRHYTHMIA.—It is of the greatest importance that the cause of nervous *palpitation* should be

Fig. 59.—Anacrotic Pulse-Curves—Pulse of High Arterial Tension.
(Landois and Sterling)

ascertained, for with its removal recovery may be expected. Indigestion, distant causes of reflex irritation, such as uterine and ovarian disease in women, anemia, chlorosis, and the like should be carefully sought and eliminated by a proper treatment. During an attack the strictest quiet should be enjoined, and the patient should be kept in the recumbent posture. It is much more important that this should be done than that heart tonics or heart sedatives should be administered. Yet at this time it may be helpful to give small doses of digitalis, frequently repeated, say three to five minims (0.18 to

0.3 c. c.), or five to ten drops, every hour, combined with the bromids in ten- to fifteen-grain (0.66 to 1 gm.) doses, or aconite and veratrum viride in one-minim (0.06 c. c.) doses as often. When the palpitation is prolonged, a belladonna plaster may be applied to the heart, or cold may be applied over the cardiac region.

The treatment of an attack of *tachycardia* is similar. Every conceivable remedy has been tried by those subject to these attacks and their advisers, with results apparently satisfactory at one time and totally disappointing at another. In one remarkable case, a dear medical friend of my own, a glass of ice-water rapidly drunk almost always stopped a paroxysm. I have seen this effect in his case follow in a few minutes. This remedy he arrived at after fifty years' trial of everything he could think of. *Bradycardia* is perhaps best left alone, unless some evident, easily removable cause be found.

As to treatment between attacks, the continuous use of strychnin may be expected to be useful. It should be combined with iron and quinin in moderate doses. A very elegant and convenient preparation is the elixir of iron, quinin, and strychnin of the U. S. P. On the other hand, strychnin sometimes causes nervousness. The dose must be regulated to avoid this. The tincture of *nux vomica* has been commended as especially suitable in these cases, given in ascending doses until thirty minims (2 c. c.) or more are reached. Outdoor life and exercise, walking, riding, cycling if not too violent, and mountain-climbing, all contribute to improve the general health and strengthen the heart at the same time. Cold bathing is one of the best measures for the same purpose, either at home or at the seaside.

The same principles of treatment apply to *intermittent heart and arrhythmia*. When these are the result of organic cardiac disease, their treatment is that of the disease. In the treatment of the simple slow pulse any cause of pneumogastric irritation should be sought for and removed, such as dyspeptic states, torpor of the liver, poisoning with retained bile salts, and the like. In the absence, however, of certain knowledge of the presence of such cause, the condition is best left alone, as treatment under such circumstances may do more harm than good.

ANGINA PECTORIS, OR STENOCARDIA.

Definition.—An affection of the heart characterized by intense paroxysmal pain, at first usually substernal, extending thence down the arms, especially the left, and up into the neck. It is a symptom rather than a disease, as it is commonly associated with some recognizable organic change in the heart or great vessels, though not always the same change. Often, however, such change cannot be found, and it may be that in rare instances it is a purely functional state.

Etiology.—The immediate cause of angina pectoris is deficient cardiac nutrition, however induced. It may be on account of obstructive disease of the coronary arteries, aortic stenosis or insufficiency, pressure by a tumor or other cause, dilatation or enlargement of the heart beyond the capacity of the coronary arteries to nourish, or any cause which produces cardiac ischemia. Adhesive pericarditis may act in this way. It may be that the excessive use of tobacco, which has been accredited with the direct effect of causing angina, may operate in this way. The exciting cause of the attack is usually some

overexertion or mental emotion calling for some additional effort from an already crippled ischemic heart. These events after a meal are more apt to produce this effect because a full stomach encroaches on the heart. Thus, the taking of food alone, even in moderate amount, may excite an attack. Still more, excessive eating and indigestion, however caused, become exciting causes.

It must be admitted that all explanations of the pain are purely speculative, for though total obstruction of the coronary arteries experimentally produced is followed by death, pain has not been found an associated symptom. On the other hand, the pain which succeeds the obstruction of an artery, leading to gangrene of a part, as the leg, is precisely analogous to the anginose pain which succeeds obstruction of the coronary arteries, while the results of experimental closure of these arteries have their parallel in recognized cases of *angina sine dolore*. Again, neuralgic pain of the ordinary kind occurs in a nerve which is badly nourished. May one not explain the pain of angina in the same way, since a defective nutrition is the one acknowledged condition of angina? Mention should be made of the view recently announced by Clifford Allbutt* that the agonizing pain and dread characteristic of angina pectoris may be produced by an acute aortitis.

Angina pectoris is a disease of adults, and of men rather than women, and though it may happen in early life, 80 per cent. of all cases occur after the fortieth year.

Morbid Anatomy.—Atheroma of the coronary arteries is the most constant anatomical change found associated with angina pectoris. It is well known, also, that obstruction of these arteries experimentally produced results fatally, though such death is not attended by the pain of angina. On the other hand, many cases of advanced sclerosis of the coronary arteries occur without angina. In these it must be concluded that the nutrition of the heart has not seriously suffered. The other associated conditions named in considering the etiology must also be regarded as a part of the morbid anatomy. A fair estimate of the frequency of such associations may be obtained from W. H. Walshe's statement that in every one of twenty-four cases he examined during life distinct signs of changes in the heart, the aorta, or in both coexisted. The testimony of G. W. Balfour and P. W. Latham is similar. Acute aortitis has been found. (See Clifford Allbutt's paper previously mentioned.)

Symptoms.—The cardinal symptom is agonizing *pain*—pain beginning beneath the sternum in the region of the heart, extending up into the neck, sometimes the jaws, and down the arms, especially the left, following the distribution of the ulnar nerve. Associated with this are *shortness of breath*, *precordial oppression*, and a *sense of impending dissolution*. The pulse is often strikingly natural, though it is also at times unnaturally small, frequent, and irregular. The pain is often associated with a *numbness* or *tingling in the fingers* or *over the cardiac region*. There are usually *extreme pallor* and an *agony of expression* which are not soon forgotten. The *skin is pale* or *ashen gray*, and often the *perspiration* stands out in huge beads. This ashen-gray color of the skin is not confined to the period of the paroxysm. It is, in my experience, quite a characteristic symptom, and when associated with atheromatous arteries, is of diagnostic value. The duration of the paroxysm varies from a few seconds to a half hour. At the end of this time, or earlier,

* "Angina Pectoris," by Clifford Allbutt, M. D., "Philadelphia Med. Jour.," vol. v., June 30, 1890, p. 1464.

the patient either passes out of the attack or dies in it. The paroxysms occur at widely different intervals, sometimes once in a few months, sometimes oftener, and sometimes at intervals of a year or more. Neither are they always so painful as described, and it is more than likely that the slighter attacks of cardiac pain associated with aortic stenosis and sometimes with aneurysm are of the same nature.

Diagnosis.—The only condition with which true angina pectoris is liable to be confounded is the hysterical form known as *pseudo-angina*. It is not often, however, that practical difficulty occurs in separating the two conditions. The hysterical form is more common in younger women, in nervous and hysterical persons, than the true form, and is associated with other nervous symptoms. In all instances careful examination should be made of the vascular system with a view to detecting alterations in it, such as arterial sclerosis and enlargement of the heart. These will generally be found in some one of their modes of manifestation in true angina. In false angina, as in other manifestations of hysteria, there is something indescribable which will guide the experienced physician aright. In cases of doubt the patient should have the benefit of it.

Intercostal neuralgia in the neighborhood of the heart resembles the pain of angina somewhat. It is, however, more circumscribed. It does not radiate into the neck and arms, and the heart and blood-vessels are normal. The pain is not so severe, and the anxious expression of the face is wanting.

The Adams-Stokes Syndrome may be here alluded to. It is a condition allied to true angina which may or may not, however, be associated with it. It was first described by Robert Adams of Dublin in 1827* and later more fully by Stokes in 1846.†

The syndrome consists of vertigo with repeated apoplectic or syncopal seizures with unconsciousness, usually preceded for a few days by hebetude and a loss of memory; slow pulse—permanently slow, but slower at the time of the attacks. These were the symptoms in Adams' case. Stokes suggested the name false or pseudo-apoplexy, laid stress on the syncopal character of the attacks, their frequency, the absence of paralysis, and the good effect of a stimulating rather than a depleting plan of treatment. Both Adams and Stokes' patients were sixty-eight years of age.

There is myocardial change, fatty or fibroid, and the visible arteries, especially the radials and temporals, are sclerotic.

Slowness of heart-rate and vertigo are distinctive symptoms. The former may fall to 40, 30, 20, or even 10 and 5. The slowness must be of the heart's action and not of the pulse. The latter may be only 20, while the heart-rate may be 40, because the intermediate pulse does not reach the radial, producing in sphygmogram the so-called bigeminal pulse.

Prognosis.—True angina is a very grave condition because, although fully three-fourths of all persons attacked recover from the first paroxysm, sooner or later a fatal ending may be expected, and no one knows what attack is going to be the last. In some instances paroxysms recur at intervals of considerable length throughout a lifetime, while in others the first proves fatal. G. W. Balfour mentions the case of an old gentleman who had a final fatal attack after an interval of ten years, in which he had enjoyed excellent health. Many instances of death in the first paroxysms are reported.

* "Dublin Hospital Reports," vol. iv., 1827.

† "Observations on Some Cases of Permanently Slow Pulse." "Dublin Quarterly Journal," 1846.

Treatment.—Treatment naturally resolves itself into that of the paroxysm and that for prevention or cure. For the first, morphin is the most efficient remedy, and if at hand, should be used hypodermically in not less than 1-4-grain (0.016 gm.) doses for an adult, combined with atropin. Nitrite of amyl has come to be an acknowledged remedy, first suggested by Lauder Brunton. A few drops may be placed upon a handkerchief or on cotton and inhaled, or, more conveniently, pearls of glass filled with the nitrite are crushed in a handkerchief. The pearls recommend themselves further because they can be conveniently carried, and it is desirable that persons subject to angina pectoris should always have the drug at hand. Chloroform may also be used instead of nitrite of amyl, if more convenient. Nitroglycerin is used for the same purpose in doses of 1-100 to 1-50 grain (0.00065 to 0.0013 gm.) at short intervals, say 15 minutes. Counterirritation should be simultaneously applied. The ordinary mustard plaster is a most convenient and efficient measure for the purpose.

Prophylaxis is exceedingly important, and is best accomplished by avoiding the exciting causes commonly responsible for the paroxysms—overexertion, overeating, and mental excitement. The patient subject to angina should never hurry or get into a passion or become excited in any way. The use of all indigestible articles of food should be carefully avoided. Nitroglycerin is sometimes efficient as a prophylactic as well as for the paroxysm in the same doses once in four hours or oftener. The alcoholic solution, of such strength that one minim represents 1-100 grain (0.0006 gm.), is the best preparation. Nitrite of sodium may be used in from three to five-grain (0.1944 to 0.32 gm.) doses. Other remedies recommended with a view to averting the attack are arsenic, nitrate of silver, the bromids, and especially iodid of potassium, the long-continued use of full doses of which has apparently sufficed to prevent the recurrence of attacks previously present. Its effect in this disease is comparable to that produced by it in aneurysm. As heart tonics, arsenic and strychnin in doses of 1-50 to 1-25 grain (0.0012 to 0.024 gm.) should be given. While sudden exertion and overexertion are to be avoided, carefully graduated exercise is to be recommended, for like all organs, the heart is strengthened and invigorated by exercise properly regulated. When moderate exertion, if borne at all, brings on an attack, even this should be avoided.

Could we correct the faulty nutrition of the heart we could hope for a cure, and though this may be impossible, we may do that which promotes it. Angina pectoris is one of the conditions in which the Nauheim hot bath may be expected to be beneficial. So it might, so far as the hot baths are used, but the cold bath in any form is harmful. Iodid of potassium should be used with the same end in view as in arteriosclerosis.

The treatment of *hysterical* or *pseudo-angina* is that of hysteria under other circumstances.

DISEASES OF THE BLOOD-VESSELS.

ARTERIOSCLEROSIS.

SYNONYMS.—*Endarteritis chronica deformans; Atheroma of the Blood-vessels; Arterio-capillary Fibrosis.*

Definition.—A disease chiefly of arteries, consisting of inflammation first of the intima, but extending also to the media and adventitia.

Etiology.—There is a tendency to atheroma in the arteries of the old, as an evolution process quite independent of exciting causes. This tendency also varies greatly in different families, being very strong in some and absent in others. Men are decidedly more liable than women. There are, however, many exciting causes, among which are overeating and drinking, with consequent accumulation of irritating matters in the blood, syphilis, the gouty poison, and lead. Chronic Bright's disease is especially frequently succeeded by it; more rarely acute articular rheumatism. In the latter the rheumatic poison is probably the responsible agent, and in Bright's disease it may be retained excrementitious matter. Two classes of cases may, however, be associated with Bright's disease, in one of which the arteriosclerosis is general and primary, causing interstitial nephritis, and in the other it is secondary, the result of the Bright's disease. One set of observers regard all cases of interstitial nephritis as secondary. Among these the late Sir William Gull and Henry D. Sutton, of England, and Arthur V. Meigs, of Philadelphia, have been conspicuous by their writings. Still another cause of arteriosclerosis is increased arterial tension due to prolonged muscular exertion.

Morbid Anatomy.—The aorta is the most frequent and conspicuous seat of the changes ascribed to chronic endarteritis, but the carotids, subclavians, brachials, radials, and ulnars, the iliacs, femorals, and especially the arteries of the brain and coronary arteries of the heart, are frequently involved. The arteries to viscera, like the stomach and liver, are rarely affected, while the pulmonary arteries take an intermediate place. On the other hand, the latter are sometimes invaded to the exclusion of the aorta. Whatever invites high tension in the lesser circulation tends to produce sclerosis in these vessels. The portal vein may also be invaded. The superficial arteries thus affected are easily recognized. They are tortuous, stand out conspicuously, and feel hard to the finger, under which they may be made to roll. These features are often recognizable in the temporals and less plainly in the radials. The smaller arteries and veins with transparent walls, especially in the brain, exhibit to the naked eye white patches which are the seat of the atheroma. On slitting them open, the inner surface of these and other arteries will be found to have lost its natural smoothness, to be rough and uneven, while the lumen is more or less encroached upon.

Minutely examined, the appearances vary with the stage. The first stage is that of cellular infiltration, represented by the translucent yellowish areas of intima thickened to three or four times its natural thickness. Later these young cells are in part converted into connective tissue, causing the primary hardness of the vessel-walls. In the second stage the cells of the connective tissue and the surface cells of the intima undergo fatty degeneration, and the intercellular substance liquefies. In the third stage, which is

not reached in the smaller arteries, or, indeed, usually in those below the aorta, there occurs a further liquefaction with the formation of the so-called atheromatous abscess, whose contents are not pus, but the well-known atheromatous pulp, representing the débris of fattily degenerated cells, including fat drops and cholesterin crystals. Alongside of the atheromatous patches appear also plates or scales of calcareous infiltration of the intima, produced by a deposit of lime salts in the intercellular substance of the deeper layers. The atheromatous abscess sometimes undermines the intima, forming sinuous cavities, and after evacuation there results the atheromatous ulcer. Both the limy plates and ulcers furnish inequalities which favor thrombosis. In the later stages of the more diffuse form of arteriosclerosis, especially studied by Councilman, the media or muscular coat and the adventitia are also invaded, the former mainly by atrophic changes, alongside of which, at times, is a homogeneous hyaline infiltration. In this form the capillary walls are also thickened, especially those of the glomeruli of the kidneys, in some of which the vessels become obliterated.

A *calcareous* infiltration of the *muscular* coat without previous inflammation may be found in old age in arteries like the radial, crural, and temporal. Still another primary degeneration is the *fatty erosion* of Virchow, extending through the intima and media as a transverse fissure thought to be the starting-point at times of dissecting aneurysm.

The effect of these changes is to produce rigidity and narrowing of the vessel, a loss of the propulsive power residing in the elastic coat, a slowing of the current, and increased intravascular pressure. These events tax the compensating power of the left ventricle, which therefore hypertrophies. This hypertrophy keeps up so long as its nutrition is maintained.

But another effect of obstructed circulation is defective local nutrition, some of the consequences of which have already been considered in the study of the fibroid heart. Similar interstitial overgrowth and contraction may be met in the kidney and have been referred to. Localized softening of the brain also succeeds upon atheroma, though this event is usually preceded by thrombotic obstruction favored by the sclerosis. A more frequent accident to the brain is rupture of one of these atheromatous vessels, succeeded by the symptoms of apoplexy and hemiplegia. Such rupture may be preceded by an aneurysmal dilatation. Finally, aneurysm of the larger vessels has for its almost indispensable condition, except in traumatic cases, atheroma of the dilated vessel. Both events—the primary atheroma and the subsequent dilatation—are favored by the increased intravascular pressure.

Symptoms.—Superficial vessels in a state of atheroma are easily detected by their *dilated, tortuous, pulsating appearance* in the temples, while in other situations, as at the wrist, antibrachial and popliteal spaces, they may be recognized more or less by the touch. Distinction should be made between simple increase of tension and thickening of vessel-walls, though the two are constantly associated. The vessel in both instances is hard and requires some force to compress it, and between beats it is still full and can be rolled under the finger, but the artery with the thickened wall, if firmly enough compressed to obliterate the blood current, can still be felt beyond the seat of compression. In many instances, on the other hand, the changes escape detection until a fatal apoplexy gives notice of their presence. In most of these cases, however, if attention had been directed to the patient, the previously described condition of the arteries would probably have been recognized, while a certain degree of hypertrophy of the left ventricle would also, perhaps, have been detected. It

does not follow, however, that the absence of atheroma in one place implies its absence in another, since fatal rupture of an artery in the brain has occurred when there has been no sign of sclerosis in the radials. Prolonged hypertrophy and the increased tension incident to it may produce atheroma, or the two may be the result of the same cause—as, for example, contracted kidney.

Cardiac hypertrophy is not always demonstrable to percussion, as the enlarged heart may be covered by an emphysematous lung, also often present in the aged, in whom atheroma is most prone to occur. On the other hand, the usual sharp accentuation of the aortic second sound is present if the hypertrophy has not given way to dilatation or fibroid induration. Cardiac murmurs do not occur unless the atheroma invades the valves to produce insufficiency, stenosis, or roughening of the aortic orifice or aorta near the orifice. This is not so very rare in old persons, apart from the relative insufficiency due to aortic dilatation.

For the reasons mentioned, the pulse is prolonged, hard, and tense,—the *pulsus tardus*,—while its sphygmogram is very characteristic: a slow, oblique ascent, a broad top; a slow descent and absence of the dicrotic rise, which in the normal state depends on an elasticity absent in the diseased vessel. Owing to the same slow transmission of the pulse-wave the pulse is some-

Fig. 60.—Sphygmogram of an Atheromatous Vessel—The Pulsus Tardus.

times retarded at the wrist, while the rate is also slow. At other times it is frequent and irregular, especially toward the end of life when the heart begins to fail.

The *arcus senilis* is often an associate of arteriosclerosis, and strongly confirmatory of its presence.

One of the most annoying consequences of atheroma of the blood-vessels of the brain is *dizziness* or vertigo, and this symptom, when present in the aged, is very apt to be caused by it.

The consequences of atheroma of vessels of the lower extremities include *muscular weakness, stiffness*, and a *tottering* gait. In extreme cases gangrene of the lower extremities may result from obstruction to their arteries due to thrombosis invited by the atheroma. Such termination is not very rare in contracted kidney.

With the supervention of cardiac dilatation and heart failure there appear paralysis, precordial oppression on slight exertion, dyspnea, edema, pulmonary congestion, scanty urine, aggravated vertigo, angina pectoris—in a word, all the symptoms of chronic heart disease. Finally, other symptoms are those of the morbid states it causes—*i. e.*, apoplexy, contracted or senile kidney, atheroma of the coronary artery and its consequences.

Treatment.—Treatment is mainly the removal of conditions causing it, such as too free living, gout, lead poisoning, and syphilis; together with rest and quiet, the avoidance of excitement, also the free use of diluent drinks and aperients to lower the arterial tension, a slight increase of which is often the last straw required to produce an apoplexy. The iodid of potassium is highly recommended by G. W. Balfour as a vascular stimulant in the sense that it promotes the flow of blood through the vessels and lowers the blood

pressure. As such, it ought to be useful in arterial sclerosis and probably is. Moderate doses should be continued a long time. In conjunction with this the usual cardiac tonics should be employed with a view to promoting a proper circulation of the blood.

ANEURYSM.

Definition.—An aneurysm is a more or less circumscribed dilatation of a blood-vessel. Aneurysm is known as true or false. A *true* aneurysm is one in which, at the outset, all three coats of the blood-vessel share in the dilatation, though one or two may disappear later in the course of its growth. A *false* aneurysm, on the other hand, starts at the outset with a laceration of one of the coats.

I. True aneurysm may be saccular, fusiform or spindle-shaped, cylindrical and cirroid. The "cirroid" or varicose aneurysm is one in which a blood-vessel—one of medium size—and its branches are irregularly dilated and contorted like a varicose vein, whence the name "varix," a dilated vein. The "invaginating" aneurysm is a rare form of cylindrical aneurysm, in which the cylindrical sac overlaps at either or both ends the main trunk of the artery involved. Saccular and fusiform aneurysms are for the most part frequent. The "neck" of an aneurysm is a constricted portion by which a saccular aneurysm is attached to the main trunk.

2. False aneurysm includes two varieties, traumatic and dissecting.

(a) Traumatic aneurysm. In traumatic aneurysm the initial event is some injury from without to one or more of the coats of the vessels, as the result of which the resistance to intravascular pressure is diminished and a protrusion of the intima through the yielding media takes place, the latter being the most passive of all the coats. The simplest illustration of this form of aneurysm is the antebrachial aneurysm caused by accidental wounding of the brachial artery in venesection of the median vein. The blood pushes out the intima and antebrachial fascia and forms a sac communicating with the artery through the wound.

A second form is the aneurysmal varix or anastomotic aneurysm, in which the blood from the wounded artery passes directly into the adjacent vein through the wound made at the same time, causing a dilatation of the vein. This is resisted by the valves, which, however, give way to the extent of two, three, and even more pairs before the current is successfully resisted.

(b) Dissecting aneurysm. This involves the aorta, in which, in consequence of a perforation through the intima and media, the blood dissects between them and the adventitia. The initial slit is found most frequently in the inner and posterior portion, about one inch (2.5 cm.) above the semi-lunar valves. The blood may dissect from this point around the arch of the aorta, even as low as the diaphragm, before it returns to the lumen of the vessel. Even the visceral pericardium has been thus separated by an aneurysm which projects into the pericardium, rupturing finally into the pericardial sac.

Etiology.—The aneurysm most frequently encountered by the physician is the saccular and fusiform form. Its most frequent essential cause is endarteritis and its consequences, including the more acute stage of cellular infiltration, as well as atheroma. The coats thus weakened yield to the intravascular pressure. The intima is capable of a considerable degree of expansion without rupture, while the media is entirely passive

and yields very soon to the distending force. The adventitia alone seeks to guard the sac against rupture by reactive overgrowth. The causes of endarteritis, already discussed, such as syphilis, alcohol, and other toxic substances variously introduced into the blood, are responsible for the more usual forms of arteriosclerosis which furnish the initial lesion of aneurysm. But weakening of the coats is caused also in the smaller vessels by emboli, after the lodgment of which the proximal part of the vessel often becomes dilated. Such embolus may excite an endarteritis, or may occasion direct violence to the vessel-walls if it be hard or sharp, as is often the case with a fragment of a calcified valve. Muscular compression exerted by muscles in certain situations may also produce it. Such may be the origin of popliteal aneurysms so frequent in footmen, who maintain a rigidly erect position. Finally, disturbances of innervation are considered capable of causing dilatation, and to such influence are ascribed the varicose aneurysms of the arteries of the scalp, of the temporal, and of the popliteal.

ANEURYSM OF THE THORACIC AORTA.

Thoracic aneurysm occurs in the arch of the aorta, in its ascending transverse and descending portions, and in the thoracic aorta below the arch. Such aneurysm may but slightly exceed the normal caliber of the vessel, or it may be six inches (12 cm.) or more in diameter.

The greater frequency of aneurysm in the male sex and during early middle life is recognized. To the pre-existing conditions of atheroma there may be added the effect of extreme exertion in lifting, or muscular strain of any kind, the effect of which is always to increase intravascular pressure. Partly because they are points of least resistance, and partly because they are in the line of successive impingement of the whirling blood stream, there are certain points of selection in the aorta which are quite constantly seats for beginning aneurysm. These are shown in the appended illustration.

The first point (1) of election is the beginning of the aorta directly behind the trunk of the pulmonary artery. Aneurysm originating there may produce early hypertrophy of the right ventricle because of the resistance to the outward flow of the blood through this vessel, a basic murmur in the pulmonary area, relative insufficiency of the tricuspid valve and venous pulse, with a possible ultimate perforation into the pericardium or pulmonary artery. The second point (2) is the favorite seat of aneurysm of the ascending limb of the arch, behind the sternum, at the manubrio-gladiolar junction, at which place it often bores its way through the sternum as a sacculated aneurysm, which may finally burst through the external integument. The third seat (3) is at the convexity of the arch toward the apex of the right lung. The pleural cavity at this point is soon obliterated by adhesive inflammation, through which the aneurysm bores its way, rupturing into the bronchioles of the apex of the lung, producing fatal hemoptysis. The fourth (4) is between the innominate and left carotid at the apex of the arch behind the trachea. It may perforate into the trachea before attaining very large size. The fifth position (5) is posterior in the descending limb of the arch, between the left subclavian and the isthmus of the aorta to the left of the vertebral column. The aneurysm here is more commonly a cylindrical dilatation. It may also rupture into the larynx. The remaining aneurysms of the aorta all point more or less toward the vertebræ, but the greater resist-

ance to their formation in that direction favors lateral development. Ultimately they rupture, with hemorrhage into the pleural or abdominal cavity. As much as seven pounds (3.17 kilos.) of blood have been found in the pleural cavity after a fatal hemorrhage. Aneurysms of the thoracic aorta lying close upon the diaphragm may bore their way between the trunk muscles behind, attaining often large size without perforation.

Symptoms of Thoracic Aneurysm.—Apart from the physical signs, the most important of the symptoms due to thoracic aneurysm are the result of pressure of the growing aneurysm, hence they are called *pressure symptoms*.

The first of these is *pain*, which may be sharp and acute when nerves are directly involved, or dull and boring when the result of pressure on bone. In the latter case, too, it is localized; in the former it may extend all over

Fig. 61.—Showing Sites of Election for Aneurysms in the Aorta—(after Rindfleisch).
a, b. Line of impingement of the whirling blood current—the continuous line is supposed to be on the anterior surface of the aorta, the dotted line on the posterior.

the chest and down the arms, simulating angina pectoris. It may be unilateral. It may occur in aneurysm of any part of the arch, but is more frequent in that of the ascending limb.

Shortness of breath, especially on exertion, is a frequent symptom. It may be due to pressure of the aneurysm on the trachea, or on a bronchus, especially the left. Dyspnea may be increased on changing position. *Dysphagia* from pressure of the tumor on the esophagus is a frequent symptom, especially in aneurysm of the descending aorta, anywhere in the thorax. Such pressure may be strikingly demonstrated by Schnell's* method of introducing into the esophagus a stomach-tube, of which the lower end is closed, attaching to the outer end a glass tube, and filling the

*"Münch. med. Woch.," xxxvi., "Der Diagnose des Aneurysma der Aorta descendens."

whole with water, and watching the rise and fall of the water in the glass tube, corresponding to the pulsation.

Cough and alterations in the voice are important symptoms. The latter include hoarseness, aphonia, and stridor. Some of these symptoms may be produced by direct pressure on the trachea itself, others by pressure upon the left recurrent laryngeal nerve. A stridulous voice, unaccompanied by dysphagia or aphonia, was early pointed out by Thomas Jolliffe Tufnell as indicating that the pressure is on the right side of the trachea and does not affect the esophagus or recurrent laryngeal nerve. Cough may be caused by tracheal pressure or by a resulting tracheo-bronchitis with copious thin or mucous expectoration, sometimes bloody. It is often brassy in character.

On the other hand, hoarseness, aphonia and various degrees of paralysis of the vocal cord are due to paralysis of the recurrent laryngeal nerve, commonly the left, which passes around the arch of the aorta and is, therefore, more likely to be involved than the right. The paralytic phenomena may be present without other laryngeal symptoms, hence any alteration of voice in a person exhibiting palpitation or dyspnea calls for a laryngoscopic examination. When paralysis is total, such examination may show little alteration in the position of the vocal cords in *ordinary* breathing, or the left may be a little nearer the median line. On *deep inspiration* the right vocal cord is well abducted, the left remaining quiescent in the so-called cadaveric position, midway between that of inspiration and phonation. The attempt at *phonation* is more or less abortive. During it, the right vocal cord may go to the median line, leaving a small opening between it and the motionless left cord, or it may even cross the line to its paralyzed neighbor.

Partial recurrent paralysis results if only the twigs distributed to the abductor muscle—*i. e.*, the posterior crico-thyroid—are involved in the pressure. There ensues gradually a permanent shortening or “paralytic contracture” of the antagonistic *adductors* of the same side, and the affected cord is drawn by this into a position of constant phonation—that is, to the median line. The result is that the voice may be entirely natural, the paralyzed cord being in the position of adduction, while its tension is mainly regulated by the external branch of the superior laryngeal nerve, which is uninfluenced in aortic aneurysm.* In these cases quiet breathing is also unimpeded.

These phenomena imply, of course, a destructive lesion, a wasting of the nerve, the result of pressure, which may be preceded by a primary neuritis. Such neuritis and resulting irritation of the entire pneumogastric may account for certain attacks of extreme *dyspnea* sometimes experienced by subjects of aortic aneurysm. Associated with the neural degeneration is also found atrophy of the left abductor muscle, the crico-arytenoid, while the adductors remain nearly intact. Constant dyspnea is more likely to be due to direct compression of the trachea.

Other *nerves* may also be *compressed*, especially the intercostal, vagus, and sympathetic. By compression of the intercostal nerves, pain may be caused; of the vagus, vomiting; and of the sympathetic, inequality of the pupils and unilateral sweating. I remember well a very stubborn case of intercostal neuralgia in my own practice which turned out to be caused by aneurysm of the descending aorta, confirmed by autopsy.

* For the muscles involved see Diseases of the Larynx.

Then, there is the *tracheal tugging* of aneurysm first described by Surgeon-Major Oliver, and further studied by Ross and McDonnell, in Canada.* It is generally indorsed by English clinicians as a valuable sign. Recently Fränkel, from the German side, confirms the importance of this symptom.† This is a dragging downward of the larynx with each systole of the heart. In Ewart's method the patient sits with his mouth closed, his head well bent backward, steadied against the chest of the examiner, standing behind him. The trachea is drawn up gently by inserting the ends of the fingers under the edge of the cricoid cartilage, when with each impulse the larynx is felt to be pulled downward. Oliver directs, with the patient in the upright position, the mouth closed, and chin elevated, grasping the cricoid cartilage between the fingers and the thumb and pressing it steadily upward, when, if aneurysm exists, the pulsation of the aorta will be distinctly felt. It is said that it may be the sole sign of aneurysm, and a sign, also, that the position of the aneurysm is such as to involve the posterior aspect of the arch—4 in Fig. 61. It should be a distinct tug downward, as light degrees of tracheal tugging are found in healthy persons. Cardarelli's sign of *lateral* movement of the larynx is similar, with an obvious difference. It is said never to be present in aneurysm of the innominate.

J. N. Hall called attention ‡ to a sign of aneurysm not previously described, which he calls *tracheal shock*, consisting in a distinct sharp impulse, diastolic in time, transmitted through the aneurysm to the trachea just after the tracheal tug, when the latter is present.

Alteration in the pulse in distal arteries is also a sign of considerable diagnostic value. It is chiefly when the aneurysm involves the origin of blood-vessels leading to those arteries, as the innominate on the right and the carotid or subclavian on the left. If the right radial pulse is enfeebled or delayed, the aneurysm will be on the right, involving the origin of the innominate; if the left radial is influenced, the aneurysm is probably in the neighborhood of the left subclavian. Great care should be taken in the examination, and it should be made from the center to the periphery—that is, the carotids, the subclavians, the brachials, and the radials should be successively examined, as recommended by Sansom. These effects are variously produced. Thus, the aneurysm may narrow or distort the orifice of the blood-vessel by traction on it; or there may be atheromatous change in the branch vessel analogous to that in the aorta itself, which may cause narrowing of the orifice, while the possibility of this, in the absence of aneurysm, is also to be remembered; or the aneurysmal sac may act as the elastic air-chamber in a pump, diminishing thus the pulsatile force in the vessel and branches beyond. It is particularly in the arteries of the lower extremities, by aneurysm of the descending thoracic and abdominal aorta, that this air-chamber effect is seen, and the pulse, even in the abdominal aorta and its branches, has been thus obliterated by a large thoracic aneurysm. *Capillary pulse* is occasionally present, and is probably favored by the recoil of the blood into the aneurysmal sac.

Pressure of the aneurysm on a bronchus may lead to retention of secretion and fetid bronchitis and bronchiectasis, and favor the inoculation of tubercular phthisis, thus accounting for the frequent association of tuberculosis of the lungs and aneurysm.

* "London Lancet," 1891.

‡ "Amer. Jour. of the Med. Sci.," January, 1901.

Spitting of blood is an occasional symptom, which may be the forerunner of larger and more dangerous hemorrhage.

Still rarer is pressure on the thoracic duct, causing emaciation. Though this symptom is more frequently due to mediastinal tumor.

Physical Signs.—*Inspection* does not always discover changes, but if the sac grows outwardly, sooner or later a swelling makes its appearance, to the right of the sternum if in the ascending limb, possibly raising a rib or the end of the clavicle; above and behind the sternum if in the transverse portion, raising the manubrium or boring its way through it; and to the left of the sternum if in the descending limb of the arch. As the tumor protrudes, the skin becomes smooth, shining, and tense over it, and may become gangrenous previous to rupture. Such a tumor may pulsate or not. The aneurysm is, as it were, a rudimental heart, dilating in all directions with every jet of blood that is shot into it, and contracting on the withdrawal of the intravascular pressure so long as any elasticity remains. Should this property be lost, either as the result of calcification or the lining of the sac with successive layers of coagulum, such dilatation becomes impossible, and pulsation does not occur. The pulsation is, however, of great importance in the diagnosis. When present, it is synchronous with the systole of the ventricles. The heart itself is sometimes displaced downward, as seen from the lowering of the apex sometimes as low as the sixth interspace and outside the mammillary line. Less frequent is hypertrophy of the left ventricle, and when present, not so extreme as in aortic valve disease.

If the aneurysmal tumor press upon the great veins of the neck, there may be venous engorgement and edema on one side of the neck or both, according as the innominate of one side only is compressed or the descending cava itself. The aneurysm may rarely rupture into the descending cava, resulting in a form of varicose aneurysm, producing, in addition to the ordinary signs of aneurysm, sudden distention of the veins in the upper half of the body, edema of the face, hands, and arms, cyanosis, systolic venous pulse, and purring thrill.

Palpation also appreciates the impulse of the aneurysm if it is visible, and sometimes when it is not visible. This beating is peculiar, being *expansile*, and differs thus from the rising of a tumor over a pulsating blood-vessel. Sometimes there is a double beat, the second and weaker being the usual recoil following closure of the aortic valves. A *thrill* is also often felt, a vibration in the walls of the sac caused by the whirl of the blood in it. It is by no means, however, invariable, and it may come and go. Very great *tenderness* is sometimes present over the seat of the protruding aneurysm. Palpation may also recognize the “diastolic shock,” or recoil blow of the aneurysm on the closed aortic valve, if this be competent—to be again referred to.

Percussion over the swelling of an aneurysm invariably elicits impaired resonance, varying greatly in degree and extent. On the other hand, the adjacent lung may be compressed, producing an area of dullness beyond the tumor itself. The dullness is usually in the right upper intercostal spaces, especially if the aneurysm is in the ascending limb of the arch. Aneurysms in the transverse portion produce dullness in the middle line under the manubrium and toward the left of the sternum, while aneurysms of the descending part may produce dullness in the left interscapular and scapular regions posteriorly. Sometimes the impairment of resonance

precedes the pulsation, though such dullness is of uncertain significance.

Auscultation is no exception, as compared with the other modes of physical investigation, as to the inconstancy of its information, sometimes furnishing the most distinctive signs, while at other times it is totally negative.

The murmur of bruit heard over an aneurysm varies. Sometimes but one murmur is produced—systolic, corresponding with the first sound over the ventricles, but more intense; more rarely it is diastolic only. Not infrequently there is a combined or double murmur, both systolic and diastolic, the first intense and prolonged, the second fainter and shorter. It varies greatly, being sometimes rough, sometimes soft, and sometimes musical. The murmur is not infrequently absent. The mechanism of these sounds is not settled. The systolic is most easily explained. There can be little doubt that it is produced by the inequalities which meet the entrance of the blood into the sac. When the aneurysm is at the beginning of the aorta, the diastolic murmur will probably be an aortic regurgitant murmur, due to relative insufficiency of the aortic valves. When the aneurysm is distant from the aortic orifice, the diastolic murmur may be due to the recoil of the distended sac, propelling the blood through the outlet with additional force, or the whirling of the blood through the sac. Rarely in these distant situations there is a diastolic murmur only, probably thus caused.

A much more constant symptom is an accentuated aortic second sound, which is, in fact, rarely absent in aneurysm of the arch where the aortic valves are intact and which constitutes the so-called diastolic shock. It is an exaggeration of the second sound, recognizable by the ear and due to the elastic recoil of the aneurysmal sac. "It is the shock of the second sound that is heard and the recoil that is felt." It is not always present, and requires a sound aortic valve to produce it in its most marked degree. Sir Douglas Powell holds that it is best studied with the wooden stethoscope, and that the binaural fails to observe it. Ernest Sansom considers it best investigated by the ear direct, with only a slight intervening chest covering. It may be accompanied by or replaced by the diastolic murmur referred to. It is rarely, if ever, present with mediastinal growths, even when they perforate the sternum and produce pulsation. J. N. Hall* calls attention to what he names *tracheal shock* in aneurysm—a communication of the diastolic shock to the trachea.

Occasionally a peculiar *whiffing* interruption of the breath-sounds may be heard by the stethoscope or ear placed near the open mouth, due to the expansile pulsation of the aneurysm. Similarly caused is *Drummond's sign*, produced by having the patient take a full inspiration and allowing the air to pass out slowly through one nostril, the other being compressed by the finger, while the clinician listens with the stethoscope over the manubrium. *Perez's sign* is a creaking sound heard when auscultating over the sternum when the patient raises and lowers the arm. It is caused by traction on adhesions, which may have formed in the anterior mediastinum in cases of aneurysm of the first and second parts of the aorta. *Glasgow's sign* is a systolic thud audible by the stethoscope in the brachial or similar large artery like that heard in aortic regurgitation. *Scheele's sign* is a momentary disappearance of the systolic murmur, accompanied by severe pain, produced by pressing over the crural arteries of the two sides. It is an experiment not altogether without danger, as death occurred in one instance on

* "Tracheal Diastolic Shock in the Diagnosis of Aortic Aneurysm," "Amer. Jour. of the Med. Sci.," vol. cxix., 1900, p. 10.

practicing it. Enlargement of the tumor mass may also arise by the pressure on the crurals.*

But any one or all of these signs may be wanting. Particularly is this the case where the aneurysm occurs just after the aorta has left the heart. The most valuable is the pulsation distinct and separate from that of the heart, or, as graphically put by Da Costa, "what is more essential is to find two points of pulsation in the chest—two hearts, apparently each with its own distinct beat, its own distinct sounds." †

The X-ray has been brought to bear on the diagnosis of aneurysm, and commonly a distinct demonstration of the tumor can be made, both by the fluoroscope and skiagraphy, but it is scarcely available to the practicing physician, because of the costliness of the apparatus.

Is it possible to determine the portion of the aorta involved by aneurysm? Yes, with a certain degree of probability:

In aneurysm of the ASCENDING AORTA there is more apt to be pain like that of angina pectoris, dyspnea, dullness to the *right* of the manubrium sterni from the second intercostal space upward, pulsation in the same region, displacement of the heart downward and to the left, delayed pulse in the peripheral arteries as contrasted with the heart's impulse, compression symptoms involving the sympathetic and the area of the superior cava, pressure upon the pulmonary artery producing a pulmonic systolic murmur, with hypertrophy and dilatation of the right ventricle if the aneurysm compress the pulmonary artery.

Aneurysm of the TRANSVERSE PART OF THE ARCH furnishes more particularly pulsation in the *fossa jugularis*, dullness on percussion over the manubrium and to its *left* in the first intercostal space, with possible narrowing of the orifices of the innominate, the left carotid, or left subclavian, and resulting inequality of the pulse in the head and arm, pressure on the *left* innominate vein, with resulting congestion and edema of the *left* half of the neck and head. It is when in this situation that aneurysm compresses the left recurrent laryngeal nerve and causes paralysis of the left vocal cord, presses on the trachea, with resulting stridor and cough, and on the left bronchus, producing inspiratory dyspnea.

In aneurysm of the DESCENDING LIMB OF THE ARCH OF THE AORTA ‡ we look for the pulsation posteriorly to the left of the vertebral column opposite the angle of the scapula or below. The bruit is faint or absent. In the *thoracic aorta below the arch*, in consequence of the air-chamber effect, we may find smallness of the crural pulse as contrasted with the radial, and symptoms of pressure upon the left lower azygos or hemiazygos vein—*i. e.*, edema of the upper part of the abdomen and pleuritic effusion; also pressure on the esophagus and left bronchus. The intercostal nerves may be compressed, producing intense pain in the course of their distribution, the vertebral column may also be eroded, the spinal canal opened, and the cord compressed, with resulting paraplegia. If the aneurysm project forward, which is rarely the case, it may press upon and displace the heart, causing palpitation, or it may also compress the esophagus, causing painful deglutition. It sometimes ulcerates and breaks into the esophagus. Obscure symp-

† Da Costa, "Medical Diagnosis," eighth ed., 1875, p. 507.

‡ The *descending part of the arch* of the aorta is somewhat arbitrarily terminated by anatomists at the lower end of the fifth dorsal vertebra, below which it is called the *descending thoracic aorta*, which terminates at the opening of the diaphragm in front of the last dorsal vertebra, below which it is the abdominal aorta. The symptoms of aneurysm of the descending part of the arch and the descending thoracic aorta do not differ widely.

toms of this variety of aneurysm may exist for a long time before a tumor shows itself posteriorly between the shoulders, which is unmistakable at this late stage.

Aneurysm of the ABDOMINAL AORTA furnishes a pulsating tumor to the left of the vertebral column, to the left and above the umbilicus. The bifurcation of the aorta takes place on the fourth lumbar vertebra, which point corresponds to the umbilicus. Sometimes a thrill may be felt and a systolic murmur heard, rarely a double murmur. Here, too, the smallness of the crural pulses, as contrasted with the heart's impulse and the radial pulse, may be observed, while in some cases the crural pulses disappear altogether. The symptoms vary somewhat, according as the aneurysm grows backward or toward the front. In the former case pain is also a striking symptom, and may be of two kinds, a fixed and constant pain in the back, caused by the pressure of the tumor on the solar plexus and splanchnic nerves, or a sharp lancinating pain radiating along the branches of the compressed lumbar nerves, whence pain in the loins, testes, hypogastrium, and in the lower limb, usually of the left side. If the sac grows anteriorly, gastro-intestinal symptoms may be present, such as vomiting, gastralgia, diarrhea, and even symptoms of obstruction. Pain is also present, but is more likely to be fixed in the loins, epigastrium, or some part of the abdomen. Erosion of the spine is much rarer in abdominal aneurysm than in thoracic. In emaciated persons the abdominal aorta sometimes pulsates so plainly that one is strongly reminded of aneurysm, and I have myself been misled by such pulsation, but under these circumstances there is absence of the systolic murmur and of the alterations in the pulse of the arteries of the lower extremity, and none of the pain described. Indeed, evident abdominal pulsation occurs far more frequently without aneurysm than with it.

ANEURYSM OF THE BRANCHES OF THE ABDOMINAL AORTA.—Of these, aneurysm of the *celiac axis* is most often mentioned and diagnosed, though not always confirmed by the necropsy. The symptoms may be said to be a pulsating epigastric tumor, associated with pain in the same neighborhood, and often vomiting. The pain and vomiting may precede the pulsation and tumor by some months. These aneurysms are sometimes traumatic, and have been referred to railroad accidents in which sudden and powerful compression has been exerted upon the abdomen. As intimated, their diagnosis is not always easy. Two illustrative cases have come to my knowledge. In one, an aneurysm diagnosed as being of the celiac axis was at the autopsy proved to be in the abdominal aorta. In another case of supposed aneurysm the celiac axis was excluded, and the necropsy disclosed an aneurysm of that axis.

Aneurysm of the SPLENIC ARTERY is sometimes met. Ten cases have been collected by Lebert out of thirty-nine involving various branches of the abdominal aorta. Osler reports, in his book, one in a patient aged thirty. The aneurysm was as large as a cocoanut, and was found at autopsy between the stomach above and the transverse colon below, and extended to the left as far as the level of the navel. The sac contained densely laminated fibrin and had perforated the colon. The symptoms were a deep-seated tumor in the left hypochondriac region, with dullness, which merged into that of the spleen. There was no pulsation, but a bruit was *thought* once to have been heard. The symptoms were vomiting, epigastric pain, occasional hematemesis, and, finally, hemorrhage from the bowels.

Aneurysm of the HEPATIC ARTERY is a rare lesion, some ten or twelve cases having been recorded. These aneurysms are not usually large, while the liver has been found greatly enlarged.

Aneurysms of the SUPERIOR MESENTERIC ARTERY have been found at necropsies.

Aneurysms of the RENAL ARTERY are more numerous. They are generally small, but may terminate in rupture and retroperitoneal hemorrhage.

Aneurysm of the INNOMINATE is especially indicated by its murmur, thrill, and impulse in the vicinity of the inner end of the right clavicle, which is sometimes raised by the resulting tumor; also by the comparative absence of signs of pressure on the larynx or esophagus. The differences in the right radial pulse alluded to are especially present here. Compression of the right subclavian and right carotid diminishes the force beat of the innominate aneurysm, but is without effect in aortic aneurysm. Nor are there percussion signs of enlargement of the aorta.

If the SUBCLAVIAN is involved, the signs are further outward, on the outer side of the sternocleidomastoid, while in aneurysm of the innominate they are found on the inner or tracheal side. To those named may be added pressure symptoms upon the subclavian vein, producing swelling of the arm and neck; upon the right recurrent laryngeal, producing defective speech and dyspnea; on the sympathetic, producing contraction of the pupil, and on the brachial plexus of nerves, pain. Especially would these signs point to aneurysm of the subclavian if the pulse of the carotids is uninfluenced while the right or left radial pulse is influenced.

The very rare condition of aneurysm of the PULMONARY ARTERY may produce a swelling, with the other local symptoms described, to the left of the sternum, in the second interspace. A murmur is less constant and is not conducted into the vessels of the neck, while the superficial pressure signs are more conspicuous. There is lividity of the face, with dropsy, and the dyspnea is naturally very great. There is no cough or voice alteration. It is to be remembered, however, that the swelling of an aneurysm of the arch of the aorta may extend to the left of the sternum. Such an aneurysm may break into the pulmonary artery.

An aneurysm of the HEART is not recognizable, though it may be suspected if there is bulging succeeding the signs of fibroid disease of the organ.

Differential Diagnosis of Aneurysm of the Arch.—Further diagnosis distinguishes aneurysm of the aorta mainly from *mediastinal tumors*. There may be the same percussion signs, and there is often similar pain; there is also pulsation, but instead of the expansile pulsation extending in all directions, there is in mediastinal tumor more upheaving. Percussion dullness is more irregular in mediastinal tumor. Murmurs are not usual in the latter. The ringing, or accentuated second sound—diastolic shock—which may be present in aneurysm when the aortic valves are intact, or substituted by the diastolic murmur when the valves are incompetent, is absent in mediastinal tumor. Tracheal tugging does not occur in mediastinal tumor, nor do differences in the pulse or changes in the voice. The state of the blood-vessels usually associated with aneurysm must be ascertained. Fever is often present in mediastinal tumor; very rarely in aneurysm. A differential diagnosis is often impossible, and experts have held opposite opinions on the same case. Should the patient develop a cachectic state and secondary glandular enlargements appear, presumption is in favor of mediastinal disease.

The resemblance of some of the symptoms of aneurysm of the ascending aorta to some of those of *aortic incompetency* is very close. The same pulsating aorta, the same double basic murmur with impaired resonance at the right of the sternum, may be present. I have seen a case diagnosed as aortic regurgitation, with stenosis, in which the autopsy disclosed perfect semilunar valves with, however, aneurysm and relative insufficiency, which caused the diastolic murmur. In aneurysm there is less hypertrophy of the heart than in aortic valvular disease. The age of the patient, if under forty, especially the history of heart disease in early life, the history of rheumatism, and the absence of the causes of atheromatous vessels, point to valvular disease. Though there may be pulsation at the root of the neck in both, in aortic incompetency the same strong pulse-beat extends to the wrists. Traube's double sound in the femorals and popliteals, though possibly otherwise caused, is still more frequently associated with aortic incompetency than any other lesion. Simple dilatation may, indeed, be present in aortic incompetency, but the pressure signs are wanting.

A *pulsating empyema* on either side of the upper sternum sometimes closely resembles a pulsating aneurysm, and the illusion is more complete because the pulsation is expansile. I well remember a case of my own in which the pulsation to the left of the sternum was so like that of an aneurysm that I hesitated to use the exploring needle. Pulsating empyemas are generally further to the left of the sternum than aneurysmal pulsation. Other signs of aneurysm are also wanting, unless it be tenderness, which may be present. A rare condition is a *narrowing of the aorta* below the remains of the ductus arteriosus at the junction of the arch with the thoracic aorta, which produces small delayed pulse in the femorals, a thrill and murmur over the upper part of the sternum, but the extraordinary enlargement of the collateral vessels, especially the mammary and epigastric arteries, should set the question at rest.

How shall the symptoms, which also so much resemble those of a *laryngitis*, be recognized as due to aneurysm instead of the latter affection in the absence of the physical signs of aneurysm?

In acute laryngitis we have often the cause—exposure to cold—to help us, though in the chronic form we have not. In laryngitis there is usually more huskiness and less stridor in the voice, nor is the cough so brassy, or the voice so uniformly changed; it is more likely to alternate with normal voice. In aneurysm the voice grows progressively weak until aphonia results. The dyspnea in aneurysm is more often attended with wheezing, and is sometimes relieved for a time by coughing. Stokes called attention to the fact that in aneurysm the stridor of the voice seems to come from the notch of the sternum, rather than from the larynx itself. In aneurysm the breathing sounds are more likely to differ in the two lungs. Then we have the laryngoscopic picture. There is no swelling of the cords in aneurysm, while there may be the paralytic phenomena detailed. Finally, in laryngitis there may be fever.

Prognosis.—Aneurysm is not infrequently found at necropsy without having been suspected. In other cases the fatal termination is the first notification of its presence. When an aneurysm of the aorta is so developed as to exhibit its usual signs plainly, it is sooner or later fatal in some one of the modes already described. To foretell in which of the directions pointed out perforation will occur depends upon the accuracy with which diagnosis of its position can be made, and such diagnosis is at

best a matter of probability. Only in cases in which aneurysm slowly erodes the anterior wall of the chest is there a gradual termination. Then there are sometimes repeated small hemorrhages, which gradually reduce the strength of the patient, who finally dies of exhaustion or of an ultimately fatal large hemorrhage. Perforation into the vena cava, pulmonary artery, and right side of the heart is a rare termination. The course of the disease may, however, be prolonged many months, and if treatment is instituted early, it may contribute to such prolongation. When death does not occur from sudden hemorrhage, the symptoms may assume the type of chronic heart disease, for which, indeed, the condition is sometimes mistaken by the untrained observer. With failing heart, come dyspnea, palpitation, dropsy, and death.

Treatment.—We seek in the treatment of aneurysm to *diminish intravascular pressure* and *restore the integrity of the vessel*. The former may be accomplished in a degree by placing the patient under conditions which will avert the causes of such increased intravascular pressure, which is constantly co-operating with the disease of the artery to produce further dilatation and ultimate rupture of the blood-vessel. This is, of course, best accomplished by absolute rest. It is plain the less frequently the heart beats and throws the weight of its blood against the weak blood-vessel, the longer will that blood-vessel last, while it is known to every student that the heart beats less frequently in the sitting than in the standing posture, and less in the recumbent than in the sitting position. On the other hand, it is evident that absolute rest is an impossibility. Yet it may be approximated in various degrees. It is impossible also to restore the integrity of the vessel, but to this end also measures are suggested which have for their immediate purpose coagulation of the blood in the vessel and obliteration of the sac. That this sometimes occurs numerous autopsies also attest.

The method which has met most favor is that now known as Tufnell's treatment, though Valsalva originally suggested a restricted diet and practiced frequent venesections. Bellingham advised starvation without bleeding. It was, however, revived by the late T. Jolliffe Tufnell and modified by W. G. Balfour. Tufnell's treatment consists in absolute mental and physical rest in the recumbent position, together with a moderate dry diet. The object of this is to diminish the blood pressure and volume of blood, to increase the proportion of fibrin in the latter, and to promote its coagulation. The diet is as follows:

For breakfast, two ounces of bread and butter and two ounces of milk; for dinner, two or three ounces of meat and three or four ounces of milk or claret; for supper, two ounces of bread and two ounces of milk. Thus it is hoped to diminish the blood volume and reduce the pressure within the sac, to render the blood more fibrinous and to favor coagulation. The addition of iodid of potassium is Balfour's modification. The proper maximum dose is from five to twenty grains (0.33 to 1.3 gm.) three times a day. An additional effect of the iodid of potassium is the relief it affords to pain. To its efficacy in this direction I think I may add my testimony. It is supposed also to act by increasing secretions, thus thickening the blood. Dr. Balfour also claims that it lowers the blood pressure by promoting the flow of blood through the arterioles. It may be expected, also, that cases of syphilitic origin will be those especially benefited, but it is said that experience does not confirm such expectation. Occasional small bleedings are said to contribute to a favorable result. Evidences of improvement are reduction in the size of the tumor,

diminished force of pulsation, and relief of pain. It should be kept up for several months, or as long as the patient will submit to it. It is said to be useful more particularly in saccular aneurysm communicating by a small orifice with the aorta. It is doubtful whether it is worth while to subject a patient with large aneurysm communicating with the aorta by a large orifice to the inconvenience of such a treatment, and whether it may not be better to advise him to live a life as quiet as possible and to await the inevitable, while we relieve symptoms as they arise, and remember especially that iodid of potassium is often one of the best remedies for pain.

Small venesections—to the amount of a few ounces—are also recommended for the relief of pain in aneurysm. Acupuncture as a means of securing coagulation and contraction of the clot was suggested by Velpeau. It consists in placing an iron wire or needle into the aneurysm with the hope that the blood will coagulate on it. Filling the aneurysm with *horsehair or fine wire* has been suggested for the same purpose. The wire is introduced through a hypodermic needle. Galvanopuncture, suggested by Loretta, furnishes perhaps the most satisfactory results. Two needles are introduced into the sac, and a mild current of electricity is passed through them. In this way a combined electrolytic and mechanical effect is obtained. The introduction of astringent substances, as solution of acetate of lead or persulphate of iron, into the aneurysm may be mentioned only to be discouraged, since the danger of producing embolism far exceeds the chance of benefit. Ligation of the carotid or subclavian, or both, has also been done for aneurysm of the aorta with satisfactory results. It is, however, a formidable operation.

The latest method of inducing coagulation for the cure of aneurysm is by the subcutaneous injection of gelatin, suggested by Lancereaux.* Two hundred and fifty cubic centimeters of a solution of two grams of gelatin in 100 grams of saline solution are injected under the skin of the thigh. This is renewed at varying intervals from every two to fifteen days. It has been claimed that, as a rule, ten, fifteen, or twenty injections produce complete cure. They act by increasing the coagulability of the blood. Recently, Professor Shoicesco of Bucharest reported † six cases treated in this way with good results in five cases. On the other hand, Osler treated ten cases at Johns Hopkins Hospital without a single cure.

No other internal treatment for aneurysm other than that suggested—by iodid of potassium—has ever been of any use. As a part of the medicinal treatment of thoracic aneurysm it should be added that where there is violent action of the heart, *cardiac sedatives* are sometimes indicated to allay this, in addition, of course, to the enjoined rest. Among these sedatives we include aconite and veratrum viride in extreme cases, also cold to the seat of the swelling and to the cardiac region.

The treatment of *peripheral aneurysm*, as of the popliteal and femoral, is usually relegated to the surgeon, who will treat it by ligation or compression. The *injection of ergotin* in the vicinity of the aneurysm, as suggested by Langenbeck, may be tried. From two to five grains (0.132 to 0.33 gm.) of the aqueous extract dissolved in water or glycerin are injected every two days. Tufnell's method is also applied to peripheral aneurysm, for which indeed, it was originally recommended.

The treatment of peripheral aneurysm by *compression* has long been an

* "The Lancet," October 22, 1890.

† "Journal de Médecine Interne," July 1, 1899.

acknowledged method for the purpose, and though looked upon as a surgical procedure, is as medical as surgical. The method adopted which has been most successful is digital compression, which is exerted by relays of students or others available for the purpose. The effect is that in the course of forty-eight hours coagulation has taken place and the aneurysm is cured. Failing in these measures, ligation is practiced in case of the smaller arteries, but all details of this operation belong to the province of surgery.

SECTION V.

DISEASES OF THE BLOOD AND BLOOD-MAKING ORGANS.

DISEASES OF THE BLOOD.

THE MINUTE STRUCTURE OF THE BLOOD.

An accurate knowledge of the histology of the blood has become so important to an intelligent study of its diseases that a brief statement of its minute constitution seems justified. It is more especially since the practice of staining blood preparations has come into use that our present more intimate knowledge has been acquired.

The *red blood disc* needed these aids least, but it is nevertheless a more interesting object thus studied. Thus, when stained with a solution of orange G, contained in the Ehrlich triple stain, it assumes a beautiful yellow or pale-orange color. By means of this stain the expert observer may even measure a diminution in the amount of hemoglobin, indicated by a diminished intensity of the central coloring. Only in high degrees of loss of hemoglobin do the edges of the cell become paler. Eosin solutions stain the red disc a brilliant red.* (See F in plate opposite p. 662.) The average number of red discs in a cubic millimeter in the male is 5,000,000, in the adult female 4,500,000; previous to menstruation, the number is somewhat larger.

The *blood plaques*, though a constituent of normal blood, are not rendered visible by staining. They are most readily demonstrated by placing a drop of fresh blood at the edge of a thin cover previously placed on the slide, whence the blood is drawn in by capillary attraction. The plaques may be recognized as dotted bodies of irregular outline *half the diameter* of a red blood disc and often coherent. *Fibrin* is not stainable, but its delicate threads may be seen after a time in specimens prepared as previously directed.

* The student is referred to works on diagnosis for technical methods, but it may not be amiss to add directions for making and using Ehrlich's triple stain. The formula is as follows:

Saturated aqueous solution orange G,	120-135 c. c.
Saturated aqueous solution acid fuchsin,	80-165 c. c.
Saturated aqueous solution methyl-green,	125 c. c.

Add—

Water,	300 c. c.
Absolute alcohol,	200 c. c.
Glycerin,	100 c. c.

Or the colors previously mixed, constituting the Ehrlich-Biondi or Ehrlich-Biondi-Heidenheim powder, may be used as follows:

Ehrlich-Biondi powder,	1.70 gm.
Acid fuchsin,	0.05 gm.
Absolute alcohol,	2.00 c. c.
Distilled water,	18.00 c. c.

To Stain.—After cleansing the finger thoroughly with soap and water and alcohol, it is pricked with a clean needle and a clean cover-slip touched to the blood as it flows from the puncture. Drop this cover-slip on another, draw the two apart and dry in the air. At any time within a few days fix by heating at 230° F. (110° C.) for ten minutes, or by placing in absolute alcohol or alcohol and ether. Then place for four minutes in the Ehrlich tricolor mixture. Dry and mount. Better success in the differential staining is obtained, according to Henry F. Hewes, if the specimen is washed after treatment with the Ehrlich tricolor mixture and treated for from one-half a second to ten seconds in Löffler's solution of methylene-blue (saturated alcoholic solution of methylene-blue 30 c.c., potassium hydrate—1: 10,000 solution—100 c.c.). Wash, dry, and mount in balsam. The second alkaline basic stain is recommended because it completes the conditions necessary for acid, neutral and basic staining, the last being furnished imperfectly by Ehrlich's stain, which does furnish perfectly acid and neutral staining.

It is the study of the *colorless corpuscle* which is most facilitated by the staining process. By it are differentiated first the different varieties of white cells. They include the following:

1. *The Small Lymphocyte* (C, plate opposite p. 662).—This consists of a greenish blue nucleus as stained by the acid fuchsin of Ehrlich's triple solution. It is about as large as a red disc, surrounded by a thin, slightly stained, scarcely visible or even invisible ring of protoplasm. The small lymphocyte is from 5 to 10 μ in diameter.

2. *The Large Lymphocyte or Large Mononuclear Cell*.—This presents the same characters as the small lymphocyte, but is larger and paler. Both nucleus and protoplasm have increased in size, but the former more than the latter. The protoplasm continues free of granules, as a rule, but fine and pale granules may be brought out by intense basic stain like methylene-blue. Between the small and large lymphocyte are intermediate forms. These cells have a common origin and represent different stages of development. It was formerly erroneously supposed that the large mononuclear cell arose from the spleen and the small one from the lymph glands. The large lymphocyte may have a diameter of 13 to 15 μ . Both large and small cells sometimes show a disposition to division of the nucleus.

3. *Transitional Leukocytes*.—These differ from the large mononuclear cells only in the fact that the nucleus is indented or horseshoe shaped, and are a still more mature cell than the large lymphocyte. Its protoplasm is like that of the large mononuclear leukocyte, but neutrophilic. The protoplasm of the three varieties described is therefore quite similar.

4. *Polymorphonuclear or Polynuclear Cells*.—These include three subdivisions:

(a) *Polymorphonuclear Neutrophiles* (B, plate opposite p. 662).—These are regarded as matured leukocytes. They make up the majority of the white cells of the blood and of pus. They are large, possessed of an irregular nucleus, often bent or twisted into fantastic shapes, which stain a green or greenish-blue in Ehrlich's tricolor fluid. Different parts of the nucleus are variously distinct, according to the distance of such parts from the surface, and thus the impression of a polynuclear cell is often produced, though a multiple nucleus is not present. Two or more nuclei are, however, sometimes found. The cell is further characterized by the presence within the nucleus and the protoplasm surrounding it of minute granules which stain well only in neutral solutions like Ehrlich's, whence the name *neutrophilic* or ϵ granules. In this fluid they stain violet or purple. Between the granules may be seen a pinkish matrix. Occasionally the nucleus of a neutrophile appears to have a round or oval nucleolus, but this is said to be an optical effect caused by the arrangement of the nucleus or point of view whence it is seen. The presence of these neutrophilic granules constitutes the chief difference between this variety and the three forms previously described.

(b) *The Eosinophiles* (A, plate opposite p. 662).—These are also large polymorphonuclear cells, slightly smaller than the neutrophiles, with granules much larger, which stain in acid stains such as eosin and the acid fuchsin of Ehrlich's triple stain: hence they are called *oxyphiles* or α granules. With eosin they assume a brilliant pink color, with acid fuchsin in the Ehrlich-Biondi a copper red. The nucleus stains bluish, and there may be more than one. The eosinophiles are actively ameboid, and are regarded as overmature cells, as contrasted with the adult or mature neutrophile.

(c) *The Basophilic or "Mast" Cell.*—Occasionally is found in normal blood a *polymorphonuclear* cell whose granules either do not come out with Ehrlich's fluid or appear as white spots. They stain, however, in a basic solution of the anilin dyes,—as, for example, dahlia in glacial acetic acid and water,—and are hence called basophilic. The large basophilic granules are called γ granules; the fine, δ granules. The relation of the "mast" cells to the other leukocytes is not known.

The *proportion* of the different varieties of colorless cells in normal blood is approximately as follows:

Small lymphocytes (young),	20	to 30	per cent.
Large lymphocytes (young),	4	to 8	"
Polymorphonuclear neutrophiles (adult), . .	62	to 70	"
Eosinophiles (old),	0.5	to 4	"
Coarsely Granular Basophilic or "Mast" cells	0.25	to 0.5	"

These proportions are not absolute in health. Thus, in infancy the percentage of young cells represented by small and large leukocytes may be from 40 to 60 per cent., while the adult cells, or polymorphonuclear cells, may be as low as from 18 to 40 per cent. A similar ratio is at times found in conditions of debility without actual disease. The eosinophiles are more abundant in various parts of the body, as in the marrow of bones and in the thymus gland, while their number often varies in an unexplainable way in the blood. The total mean number of leukocytes in health is 6000 per cubic millimeter.

Cell Forms Rarely or not at all Found in Normal Blood.—(a) *The myelocyte of Ehrlich, or marrow cell; Cornil's "cellules medullaires"* (A, plate opposite p. 662).—Certain large leukocytes twice or three times as large as a red blood disc and corresponding in all respects to the large granular cells of the bone-marrow are thus named. They are the variety of leukocyte most numerous in the bone-marrow, in which lymphocytes, polymorphonuclear cells, as well as eosinophiles, are also found. Their protoplasmic granules are commonly neutrophilic, but occasionally eosinophilic. They are recognizable only by the Ehrlich staining methods. The nucleus stains pale in the Ehrlich-Biondi stain, is large, single, at times smooth, at others irregular, and sometimes showing a tendency to degeneration. Smaller cells exhibiting all the characteristic features of true myelocytes are sometimes met associated with the large variety. Myelocytes resemble the large lymphocytes, differing, however, in the presence of granules. They differ also from the polymorphonuclear cells in the shape of the nucleus. They may be an intermediate stage between these last mentioned cells. Rarely if at all found in normal blood, these cells are numerous in certain varieties of leukemia and occur also in pernicious anemia and in some infectious diseases. There is every reason to believe they are the cells originally described by Cornil as "*cellules medullaires*."

(b) *Nucleated Red Corpuscles* (D, plate opposite p. 662).—These are red cells possessed of a nucleus. They are usually divided into three classes: (a) *Normoblasts*, about the size of a normal red corpuscle; (b) *megaloblasts*, large and irregular cells; (c) *microblasts*, very small cells, smaller than a normal corpuscle.

These cells are regarded as pointing to regenerative change. The *normoblast*, representing an immature red corpuscle, is found normally in the bone-marrow, whence it may be prematurely ejected before it has expelled its nucleus. Its nucleus stains deep blue, almost black with the

Ehrlich-Biondi fluid. It is found in severe anemias, occasionally in large numbers. The megaloblast is very large, with a large nucleus, staining pale green or a robin's-egg blue with Ehrlich-Biondi fluid. It is found nowhere in the normal adult body, but it does occur in fetal marrow and in grave forms of anemia along with the normoblast. Ehrlich regarded it as degenerate, while the normoblast is regenerate. The *microblast* is still smaller than the normoblast. It is variously regarded as degenerate and as a younger normoblast. It is found in the blood in anemias. Irregular or atypical forms are also met. The smaller forms of nucleated cells appear in the earlier stages of anemia, the megaloblasts and irregular forms in the more advanced stages.

Muller's * "blood dust" (hemoconien) is the latest discovered constituent of normal and pathological blood. It consists of small, round colorless granules resembling the smallest fat drops, about 1-4 to 1 μ in diameter, highly refracting and characterized by molecular movement. According to Stokes and Weyforth † they may be the extruded granules of neutrophilic and eosinophilic leukocytes.

THE ANEMIAS.

Broadly defined, anemia means "bad blood." It is further subdivided into *local* and *general*. The former is known also as *ischemia*. Its special consideration requires but brief treatment in a text-book of medicine. It is illustrated by the pallor of the fainting person, and by that interesting disease known as Raynaud's disease, which will be considered with diseases of the nervous system.

By *general anemia* is meant any state of the blood in which there is a diminution of its total bulk, its red corpuscles, its hemoglobin—any one or all of these. The first is the condition which ensues from a large hemorrhage of any kind, as from the rupturing of an aneurysm, erosion of a blood-vessel, such as sometimes happens in ulcer of the stomach or in tuberculosis of the lung, or from a blood-vessel wounded in any way. In all instances, however, where the hemorrhage is not fatal the original bulk of the blood is rapidly restored by the absorption of water and salts from the tissues, while the hemoglobin and albumin remain deficient until they can be restored by suitable nourishment. Practically, therefore, anemias resolve themselves for study into conditions in which there is a reduction in the amount of hemoglobin through a diminution in the total number of red corpuscles or in the proportion of coloring-matter in each corpuscle, or both.

Anemias are further divided into *primary* or *essential*, and *secondary* anemias. The former, strictly speaking, should include only those which are the direct result of a defect in the blood-making apparatus, while secondary anemias are those due to loss of blood, or some one of its important constituents, or from a defective supply of blood-making material. Richard C. Cabot defines primary anemia as an anemia "in which the causal factors are entirely unknown or are insufficient to cause so severe a disease." That such a definition has some foundation will appear from the facts to be adduced as our study proceeds.

* "Centralblatt f. allg. Path.," viii., 1896.

† "Johns Hopkins Hospital Bulletin," December, 1897.

Among primary anemias are commonly included chlorosis, pernicious anemia, leukocythemia, lymphatic anemia or Hodgkin's disease, and splenic anemia. It is not conceded by all observers that pernicious anemia is the result of a defect in blood-making. In fact, each year adds more evidence to show that the conclusion of Quincke and William Hunter that it is a hemolysis, or disintegration of the red blood-corpuscles in the circulation or certain parts of it, especially in the liver, is the correct one. Particularly noteworthy are the studies of J. P. C. Griffith and C. W. Burr,* favoring such view. As the chain of evidence is not, however, complete, I shall for the present consider it among the essential anemias.

The secondary anemias are numerous, including those due to hemorrhage and other drains of various kinds on the economy, inadequate food, and defects in the digestive apparatus; also those due to the action of poisons on the blood—the toxanemias, including lead-poisoning and uremia.

SECONDARY OR SYMPTOMATIC ANEMIA.

This form of anemia is the direct result of trauma, accidental hemorrhage, chronic disease, or toxic agents. I may again refer to the fact mentioned in the preliminary remarks on the anemias, that reasons are being found to show that some, at least, of the so-called essential anemias may be due to agencies tending to destroy the corpuscles, rather than to diseases of the blood-making apparatus. The secondary anemias include:

1. *Anemias Due to Hemorrhage, however caused.*—Traumatic hemorrhage, postpartum hemorrhage, lung hemorrhage, and gastric and intestinal hemorrhages comprise most of these; ruptured aneurysms, purpura, and the bleeding habit furnish others. Parasites invading the intestinal canal may be causes of hemorrhage and consequent anemia. So may parasites elsewhere, as the *distoma hematobium* in the kidney.

In non-fatal hemorrhages from these causes the immediate loss of blood in bulk is rapidly made up by the absorption of water from the gastrointestinal tract, but a long time is required, even under favorable circumstances, before the corpuscles and hemoglobin are restored. At other times regeneration is quite rapid, restoration being complete in ten days. The hemoglobin is always rather more reduced than the corpuscles, but both increase for a time *pari passu*, as shown in the appended chart. The albuminous constituents are more rapidly restored.

2. *Anemias Due to the Drain of Chronic Disease.*—Such are chronic Bright's disease, suppurative processes, cancer, or prolonged lactation, or chronic diarrhea. In this group belong the anemias of malaria, in which the corpuscle is directly consumed by the plasmodium.

3. *Anemia from Inanition.*—This results from starvation, which may be the practical consequence of diseases which interfere with the successful ingestion and assimilation of food, such as obstruction of the esophagus by cancer or otherwise, or chronic and prolonged dyspepsia. Carcinoma of the stomach may also be included in this group. The last two groups (2 and 3) overlap.

Under these circumstances, the blood mass is greatly reduced, but it is by a reduction in the blood plasma, rather than in the corpuscles, for the

* "Pathology of Pernicious Anemia," "Transactions of the Association of American Physicians," vol. vi., 1897.

latter, though reduced, are not markedly so, and may even be relatively increased.

4. *Toxic Anemias*.—Finally, there remain the toxic anemias. These are the result of the presence in the blood of such substances as lead, acquired by painters or workers in lead-paint factories, type-setters, and type-founders; also arsenic from dress fabrics, wallpaper, and furniture coverings; mercury, and certain disease poisons, among which that of chronic malaria is the most conspicuous. Syphilis is also one of these, producing what is sometimes known as syphilitic chlorosis. The blood-chart (Fig. 62) is from a case of syphilis.

Fig. 62.—The Blood in Simple Anemia. Hemoglobin Red, Corpuscles Black. From a Case of Syphilis.

In the true toxic anemias the poisonous substance acts directly upon the red corpuscles, destroying them, or perhaps also by increasing their consumption in the ordinary way.

Among the toxic anemias must, perhaps, be included those due to unsanitary surroundings; also those due to infectious diseases, the organisms causing which generate toxins. Among these is the anemia of tuberculosis. Similar products, generated by intestinal and other parasites, are responsible for the anemias associated with them. Such intestinal parasites are the *anchylostoma duodenale*, *bothrioccephalus latus*, and *anguilulla intestinalis*. The latter also contributes to anemia by causing hemorrhage.

Symptoms.—The most commonly recognized symptom of anemia is a paleness of the skin, and this is undoubtedly present in the vast majority of cases. Yet a total reliance dare not be placed on it, for it sometimes happens that the skin and even the lips are pale, and yet no anemia is found

when the blood is examined. On the other hand, the skin and lips may have a good color, and yet anemia be actually present. Weakness, faintness, and palpitation are also symptoms. In addition to these are the blood changes, which vary with the degree of anemia. Both corpuscles and hemoglobin are reduced, the latter in somewhat larger proportion. The disproportionate lowering of the hemoglobin is explained by a more than natural paleness of the red corpuscles. Their average size is reduced, while there is also a moderate poikilocytosis. Nucleated red corpuscles also make their appearance soon after a hemorrhage. The normoblasts and microblasts are the prevailing forms. They exhibit, after staining with hematoxylin, a deep-blue nucleus, while free nuclei are occasionally found. Microcytes, megalocytes, and poikilocytes are present in advanced cases.

The colorless corpuscles are moderately increased, such increase being represented by the multinuclear neutrophiles, while the small mononuclear lymphocytes are diminished. The leukocytosis gradually disappears with the return of the blood to its normal state. The presence of leukocytes as well as of the nucleated corpuscles is evidence of regenerative activity. The proportion of the different varieties is nearly normal. In severe cases the lymphocytes may be in excess and the polymorphous leukocytes be reduced. Myelocytes are exceptionally present.

Diagnosis.—In addition to the blood changes more or less common to all of these causes of anemia, the same general symptoms of pallor, lassitude, debility, and faintness which characterize the essential anemias are also present in less degree.

The distinctive feature of simple anemia is the nearly coequal reduction of the hemoglobin and corpuscles. The history of the case in the presence of one of the causes named is of itself sufficient to determine the diagnosis in many cases. The simple anemias are not always, however, sudden or rapid in their occurrence, and a study of the blood is often necessary to clear up a doubtful case.

Treatment.—The treatment of simple anemia is eminently satisfactory. The administration of nourishing food with rest is followed by a very rapid coequal rise in the hemoglobin and corpuscles, as is beautifully shown in the foregoing chart (Fig. 62) made from one of my cases in the Philadelphia Hospital. And when to the treatment by nourishing food we add the use of iron, there is nothing more to be desired. Full doses of iron are well borne in these cases, and we have the choice of almost any of the preparations, including Bland's pills of the carbonate, reduced iron, tincture of the chlorid, Basham's mixture, and the vegetable salts. Though full doses are here indicated, it is still unnecessary to give the massive doses recommended by some, as they are not absorbed and produce constipation. The rapidity of the cure in some of these is surprising.

THE PRIMARY OR ESSENTIAL ANEMIAS.

These include chlorosis, *for the present* pernicious anemia, leukocythemia, lymphatic anemia, or Hodgkin's disease, or pseudoleukemia, and splenic anemia.

I. CHLOROSIS.

SYNONYMS.—*Morbus virginicus; Green Sickness; Chloremia; Chloranemia.*

Definition.—An essential anemia most frequently met in young women, characterized by a very marked relative reduction in the hemoglobin of the blood.

Etiology.—As stated in the definition, it is a disease of women, and especially of young women. Yet its occurrence is not impossible in men having the habits and occupations of women, among whom Hermann Eichhorst especially instances tailors. Moreover, while it is especially a disease of young women from about the age of puberty to twenty-four years, it is also possible in those who are older, as well as those who are younger. In the former it is known as *chlorosis tarda*, and as such is met in women between thirty and forty. Rather more frequent is its occurrence in children who have not reached the age of puberty. Niemeyer held that girls who menstruated at thirteen or fourteen, in whom there was, as yet, no development of pubis or breasts, most invariably become chlorotic. The disease occurs the world over, and is apt to be recurrent in the same individual. It is more common in blondes than in brunettes, in the weak and delicate, rather than the strong and vigorous. Yet this general truth is not without exception.

Among predisposing causes are overwork, especially in closely confined and ill-ventilated rooms, insufficient nourishment, exhausting drains, such as prolonged lactation and profuse menstruation. Menstrual derangement is, however, also a consequence as well as a cause. Sustained or repeated emotion, especially such as arises from sexual excitement and masturbation, is a cause. Homesickness and grief are included among causes.

The frequent association of constipation with chlorosis led Sir Andrew Clark to suggest that it might really be a copremia, or poisoned blood due to absorption from the large bowel of poisons of the nature of ptomaines and leukomains. Such poisons may readily interfere with the proper development of the hemoglobin of the blood disc, without in a great degree causing its destruction. Similar is the hypothesis of Bunge that intestinal putrefaction due to imperfect stomach digestion is the cause of chlorosis. These views explain what seems to me a closer relation between chlorosis and pernicious anemia than has commonly been admitted, a relation consistent with the newer etiology of pernicious anemia, as well as with features in its clinical course, and with the results of treatment, to which attention will be called when considering the latter affection.

Morbid Anatomy.—Other than the changes in the blood, to be considered under symptoms, there is no essential morbid anatomy in chlorosis. Many years ago Virchow pointed out an imperfect development of the circulatory apparatus as more or less characteristic—that the heart was small, the right ventricle sometimes dilated, the aorta and its larger branches

were poorly developed and thin-walled. Such a condition, when present, is probably an accidental coincidence. There is no enlargement of the spleen or lymphatic glands. Imperfect development of the uterus and other genitalia has been noticed. The rarity of fatal termination in chlorosis may limit our knowledge of the morbid anatomy, uncertain at best.

Symptoms.—Of these, the *blood changes* may be regarded as fundamental, though not absolutely constant. They consist in a decided reduction in the hemoglobin, with a moderate oligocythemia, or reduction in the number of red corpuscles. Thus, the hemoglobin value of each red disc is diminished. The usual range may be put at from 3,500,000 to little less than normal. Thus, Thayer, in 63 consecutive cases in Osler's clinic, found the average 4,096,544, or over 80 per cent., and Lembeck found the maximum in one of 15 cases to be but 3,600,000. In a few instances, however, in cases of acknowledged chlorosis, there has been found a more decided reduction in the erythrocytes. One has been reported in which they were reduced as low as 1,190,000 in a cubic millimeter.

The hemoglobin, on the other hand, is much reduced, the average of Thayer's cases referred to being 42.3 per cent., which may be regarded as a fair average. This disproportionate fall in the hemoglobin, while not invariable, remains, however, a tolerably constant feature, producing sometimes a recognizable diminished intensity of color when the blood is seen *en masse*. Along with the lowering of hemoglobin, as would be expected, since it is a constituent of the hemoglobin, the iron of the blood falls. An increase of alkalescence, announced by Graeber* as a constant symptom, has not been found by Kraus† in his more exact methods of testing. Increased coagulability of the blood has been observed.

As to remaining changes, the red corpuscles may be *altered in shape* to a moderate extent, constituting a small degree of *poikilocytosis*, a term suggested by Quincke, or they may be larger than in health, when they are known as *megalocytes*. More frequent is an undue reduction in size of the corpuscles—a *microcytosis*. The red discs are sometimes appreciably paler than in health. A very *slight* degree of *leukocytosis* may be rarely present, an average of 8467 in Thayer's counts, as contrasted with a mean normal of 6000 in cubic millimeter, while the *blood plaques* in severe cases may also be increased. *Nucleated red corpuscles* are sometimes met, especially in the later stages, represented by the smaller forms (microblasts) which sometimes appear in crops. In this stage the corpuscles may assume irregular shapes. Myelocytes have rarely been met.

While the blood alterations in chlorosis are scarcely distinctive enough to be considered diagnostic, the *other symptoms* help greatly to the formation of a correct conclusion. The patient is almost invariably a girl, generally between sixteen and twenty, who, although she may have been overworked, does not seem badly nourished; certainly she is not emaciated. There is often derangement of menstruation, and sometimes the girl is hysterical.

Most striking, though not invariable, is a peculiar pallor, often exhibiting a yellowish-green tinge, extending to the lips, and especially the mucous membranes, and which is responsible for one of the names of the affection—*green sickness*. The patient is extremely weak, especially on exertion, and short of breath. She is subject to vertigo, palpitation of the heart, and even

* "Zur klin. Diagnostik d. Blutkrankheiten," Leipsic, 1888.

† "Zeitschrift f. Heilkunde," Bd. ii.

irregularity of the heart's action. Physical examination will sometimes discover functional cardiac murmurs; also a systolic murmur at the apex, ascribed by Balfour to a relative insufficiency of the mitral valve due to dilatation of the left ventricle. Rarely, a compensatory hypertrophy of the left ventricle has been noticed, but never actual valvular disease. Sometimes a *bruit de diable*, or humming-top murmur, may be heard over the right

Red Corpuscles—Black. Hemoglobin—Red. Colorless Corpuscles—Blue.

Fig. 63.—Blood in Chlorosis.

jugular. Epigastric pain is also a symptom at times. It must not be forgotten that a chlorosis late in life, or *chlorosis tarda*, does sometimes occur. Fever is not rarely present. On the other hand, the hands and feet are often cold.

Diagnosis.—The diagnosis is based chiefly upon the age and sex of the patient, the peculiar greenish-yellow color, the paleness of the lips, and the decidedly diminished hemoglobin, unaccompanied, as a rule, with a

proportionate reduction in the number of erythrocytes. The same lost normal ratio between the hemoglobin and the corpuscles is also a characteristic of *lead-poisoning*, which has, however, superadded its own characteristic symptoms, and is almost restricted to adult males.

The epigastric pain mentioned as occurring in chlorosis resembles that more common in *ulcer of the stomach*. The anemia which so constantly attends ulcer of the stomach, often in a high degree, is, however, different from that of chlorosis, there being a proportionate decline in the number of the erythrocytes and their coloring-matter. At least, the reduction is not so widely disproportionate as in chlorosis. It dare not be said, as it once was, that there is subacidity, as a rule, in the gastric fluid in chlorosis, nor is there motor deficiency.

A not infrequent error of diagnosis in connection with chlorosis is the mistaking of it for a "decline," a *pulmonary consumption*, which it resembles in the pallor, the feebleness, and shortness of breath of the patient. The absence of emaciation, of cough, and of the physical signs of consumption exclude that disease. On the other hand, evidences of tuberculosis should always be sought where the symptoms of chlorosis prevail. Latent *cancer* is also sometimes responsible for similar symptoms.

Most frequently chlorosis is confounded with *secondary anemia*, and with reason. Close observation will recognize in chlorosis the yellowish tinge of the skin and mucous membranes, while the sclerotic remains white or bluish. The most constant difference is in the reduction of hemoglobin, which is disproportionately large in chlorosis. Leukocytosis is less frequent in chlorosis; so are nucleated red cells. In advanced degrees of chlorosis the blood approaches nearer that of *pernicious anemia*, in which, however, the blood coagulates more slowly. The question whether a chlorosis will be transformed into that more serious variety of anemia known as pernicious anemia has been raised. This seems not impossible. If the view of Sir Andrew Clark be accepted, that chlorosis may result from the absorption of poisonous substances from the larger bowel, and if pernicious anemia be due to the absorption of more intense poisons from the small intestine, the difference is only one of degree. Both are characterized by defects in the cellular constituents of the blood. In the one, chlorosis, the coloring-matter is chiefly wanting, although associated with this is usually found a small degree of morphological defect. In pernicious anemia both cell-shapes and coloring-matter are defective. In both diseases the oxygen-carrying office of the blood is interfered with, and thus important vital processes are embarrassed, the total suspension of which must be fatal.

Prognosis.—The prognosis is nearly always favorable when the disease is recognized and the proper treatment instituted. There are few results more satisfactory in therapeutics than those of a properly treated case of chlorosis. Time is, however, required, and too rapid a cure must not be promised, several months and even longer being sometimes required.

Treatment.—The treatment is pre-eminently by iron, and it matters not very much what preparation is used. The tincture of the chlorid well diluted is probably the most easily assimilable, but the carbonate, in the shape of Blaud's pill, made by a double decomposition between the carbonate of potassium and the sulphate of iron, maintains its popularity, one to five grains (0.06 to 0.2 gm.) being given at a dose three times a day. Reduced iron or one of the vegetable salts may be given. Much larger doses are sometimes given, as much as 45 grains (3 gms.) a day. I have

many times said that iron is given in too large doses in the majority of cases for which it is prescribed. Most of it is unabsorbed, and therefore wasted. Nay, worse, that which is unabsorbed locks up the intestinal secretions by its astringency, produces headache, and makes the patient otherwise uncomfortable. But chlorosis is one of the few diseases in which large doses of iron are well borne. The reason is plain. It is the iron-holding constituent of the blood which is wanting, and the iron is needed to replace it. The blood is, as it were, hungry for it. Next to iron comes arsenic. The efficiency of iron is greatly aided by union with arsenic, which should be given in increasing doses, but short of toxic effect.

Hydrochloric acid in full doses, originally suggested by Zander on the ground of supposed deficiency of this acid in the digestive fluid in chlorosis, is useful also in promoting the solubility of iron, as well as for its tonic and antiseptic properties.

But to give these drugs is not alone sufficient. *Rest* in bed, at first continuous, is imperative to secure a rapid result, and this must be associated with an abundance of good food. Daily massage, except during menstruation, is also a useful adjuvant. There is no condition in which the so-called "rest cure" is more efficient than in chlorosis. With a return of color to the lips, or, better, with the growing increase in the hemoglobin as measured by the hemoglobinometer, the patient should be permitted to be out of bed at first from a half-hour to an hour only, but this should be gradually increased until she is up most of the day. For a long time, however, fatigue should be avoided. To those who can afford it, a residence at the seaside materially aids convalescence. Indeed, I know of no condition so rapidly improved at the proper time by sea air as chlorosis. To the poor, a well-regulated hospital treatment is a boon for which there is scarcely a substitute.

II. PROGRESSIVE PERNICIOUS ANEMIA.

SYNONYMS.—*Idiopathic Anemia; Pernicious Anemia.*

A second variety of essential anemia is *pernicious* or idiopathic anemia, originally described by Addison in 1855 in his celebrated paper on "Diseases of the Suprarenal Capsules." Interest in the subject was revived by Biermer in 1868, and since then it has been thoroughly studied anatomically and clinically. It is, however, still the least understood of all the anemias. Fortunately, it is an infrequent disease.

Definition.—Pernicious anemia is an anemia in which the red corpuscles have been destroyed and reduced in number, along with a reduction of the hemoglobin, while the ratio of the latter to the remaining corpuscles is one of excess.

Etiology.—The etiology of pernicious anemia is very obscure. Pregnancy seems to be in some way responsible for a certain number of cases. Such a condition, associated with the puerperal state and with functional disease of the uterus, was first described by Walter Channing* in 1842. The symptoms described by him are evidently those of pernicious anemia, though he called the condition simply "anhemia." A. Gusserow † published, in

* "New England Quarterly Jour. of Medicine and Surgery," Boston, 1842-43.

† "Ueber hochgrädigste Anämie bei Schwangerer," "Archiv für Gynäkologie," Berlin, 1871.

1871, a number of cases in pregnant women. It has also followed lactation. Other causes are cited, such as atrophy of the stomach, early noted by Flint and Fenwick, profound and long-continued gastro-intestinal disease, and intestinal parasites, especially the *anchylostomum duodenale* and *bothriocephalus latus*, which undoubtedly produce symptoms clinically indistinguishable from the general anemia which Addison characterized as "occurring without any discoverable cause whatever—cases in which there had been no previous loss of blood, no exhausting diarrhea, no chlorosis, no purpura, no renal, splenic, miasmatic, glandular, strumous, or malignant disease." I have already expressed my partiality toward the view of Quincke and others, who ascribe the state of the blood to a hemolysis, in proof of which they point to the enormous accumulation of iron in the liver noted by Quincke in 1876 and confirmed by Rosenstein in 1877. To these, William Hunter added a pathological increase of the urobilin in the urine. In a noteworthy paper, Griffith and Burr take the same view.* Figs. 64 and 65 are from Griffith and Burr's paper, and show the deposit of iron in

Fig. 64—Liver Lobules in a Case of Pernicious Anemia, Showing Distribution of Iron Pigment—(after Griffith and Burr).

the liver cells demonstrated by ferro-cyanid of potassium. Such a hemolysis is most satisfactorily explained on the supposition of absorption from the intestine or elsewhere of poisonous products engendered under any of the circumstances named. Among these may be included the products of imperfect digestion, such as may be expected to arise when there is atrophy of the gastric tubules.

The disease is widespread, being quite common in this country. It affects mostly those past middle age, but children also have it, and Griffith mentions ten cases occurring under twelve. It is more frequent in males.

Symptoms.—The approach of the symptoms of pernicious anemia is most insidious, beginning with a gradual *progressive weakness*. What is first interpreted as a causeless weariness or languor grows slowly into an extreme debility, with faintness on the slightest exertion, and thence into a state of thorough muscular weakness, which ultimately prostrates the patient, and he is too weak to rise from bed. To this succeeds a state of

* *Loc. cit.*

mental hebetude and bodily torpor. *Yet there is no emaciation.* The body bulk is well preserved. The *skin* acquires gradually a *lemon-yellow* hue, and sometimes an actual jaundice, whence the disease has been mistaken for the slower form of yellow atrophy of the liver, a mistake not altogether unsustained by other symptoms. In fact, the jaundice is similarly caused. It is probably a hematogenous jaundice, a matter of blood disintegration, although it has also been ascribed to defective cell action on the part of the liver. The mucous membranes, on the other hand, are blanched, as may be noticed in the lips, gums, and mouth.

Cardiovascular symptoms are especially conspicuous in progressive pernicious anemia. Hemic murmurs, visibly pulsating and throbbing arteries, even pulsating veins, have been noticed. The large, but soft, jerky pulse,

Fig. 65.—Cells from Liver in Pernicious Anemia, More Highly Magnified, Showing Position of the Iron Pigment within them—(after Griffith and Burr).

resembling that of aortic regurgitation, was mentioned by Addison. The capillary pulse is also frequently seen, and hemorrhages, cutaneous and retinal, occur.

Digestive derangements form an important part of the symptomatology of pernicious anemia. Indisposition to take food, or, rather, a disgust for food, nausea, vomiting, and diarrhea are often troublesome symptoms. *Hydrochloric acid* is constantly deficient in gastric digestion. *Moderate elevation of temperature*, irregular and intermittent, is also noticed, while *nervous symptoms*, including numbness, languor, and even paralysis, are sometimes present.

The urine exhibits no constant changes, being sometimes pale and sometimes dark-hued. The dark color is ascribed by Mott and Hunter to an excess of urobilin.

Blood Changes.—The changes in the blood are more distinctive than in chlorosis, although it is true also that there is no single constant character-

istic feature. It may be pale and watery. The most constant feature is a very decided oligocythemia, without a corresponding reduction in the hemoglobin, although the hemoglobin, *in toto*, is much reduced. Rarely it has been found increased. Quincke found as few as 143,000 corpuscles in a cubic millimeter of blood, while it is not uncommon to find less than half a million. Frederick P. Henry found 315,000 a few hours before death, and Laaché 360,000. In a case under my own care at the Philadelphia Hospital, in 1898, the red discs fell to 437,000, and the hemoglobin to 9 per cent., death taking place two days after the count was made. The inevitable conclusion from the average of cases observed is that either the hemoglobin value of each corpuscle must be increased, or there is a hemoglobinemia, which has its seat in the plasma. This latter view Silbermann

Fig. 66.—Pernicious Anemia.

has adopted, because he has been able to produce, by the administration of blood-corpuscle-dissolving substances, as pyrogallol, to animals, a complex of symptoms like those of pernicious anemia. If pernicious anemia be a hemolysis, as seems likely, rather than a defective hematogenesis, we would expect such a hemoglobinemia to result.

A further striking peculiarity in the blood of pernicious anemia is an increase in the size of the red corpuscles. They become *megalocytes*, from ten to fifteen micromillimeters in diameter, as compared with a normal of from 6.5 to 9.4. The majority may be so enlarged. They are often also ovoid in form. On the other hand, there are also *microcytes*—cells smaller than normal—and *poikilocytes*—corpuscles characterized by great irregularity in shape. While these irregular shapes were first demonstrated in connection with pernicious anemia, and although they are more or less characteristic, cases of the disease have been described by Grainger Stewart, Lepine, Hermann Müller, and others, in which poikilocytosis was altogether

absent. Neither megalocytosis, microcytosis, nor poikilocytosis is therefore a pathognomonic feature.

Nucleated red corpuscles are a constant constituent of the blood of pernicious anemia, and have also been regarded by their discoverer, Ehrlich, as almost pathognomonic. Two kinds are found—first, the small, normalized corpuscle, with its deeply stained nucleus (normoblasts), and certain large forms with pale nuclei (megaloblasts). They are not confined to this disease. Blood plaques are either absent or very scanty. *Leukocytes* are usually slightly diminished in number, while there is a tendency to an increase of the mononuclear white cells, as compared with health. F. P. Henry* has called attention to a fact which condenses the peculiarities of the blood changes, by saying that in this disease the red corpuscles “approach those of the lower animals in many, if not all, of their chief characteristics—namely, in their number, their size, their shape, and the amount of hemoglobin they carry.”

There are also sometimes found in the blood numerous minute highly colored spherical bodies, called *Eichhorst's corpuscles*. Eichhorst regarded them as pathognomonic, but they, too, are sometimes absent. When present they contribute to the hemoglobin in the blood, but as they are not included in the blood-count, they get no credit for their effect. The relative excess of the hemoglobin may, in a measure, be thus accounted for.

Morbid Anatomy.—Various tissues have been studied in the effort to find a morbid anatomy for pernicious anemia. In the absence of lymphatic involvement or enlargement of the spleen, except sometimes in small degree, the *marrow of bones* has claimed close study. H. C. Wood described the red condition of the marrow of long bones in 1871. It was further studied in this country by William Pepper † and myself,‡ and abroad especially by Cohnheim.§

Although the appearances described by these observers are not identical, they are sufficiently constant to justify their association as more than accidental. *Summed up*, they amount to this: Marrow dark red; consistency less soft; fat vesicles absent; specific lymphoid cells increased, including marrow cells of various sizes, containing one or more nuclei; numerous nucleated red corpuscles present, especially the larger forms, the gigantoblasts of Ehrlich. These studies were made before the days of differential staining and counting. More recent studies add neutrophiles and eosinophiles. These appearances are now commonly interpreted as due to an effort of the blood-making apparatus to reproduce the disintegrated erythrocytes. They are not, however, constant, as the marrow is sometimes pale or yellow.

The deposition of *iron in the liver cells* has already been alluded to. It is found in the outer and middle zones of the lobules, and may be so distributed as to outline the bile capillaries. It is regarded by Hunter as characteristic. I have myself examined the preparations of Griffith and Burr, and they are striking and seem unmistakable. The liver itself is often fatty and is sometimes enlarged. The iron is, in like manner, sometimes increased in the kidney, but not in the spleen, and these organs are not

* “Anemia,” Philadelphia, 1887.

† “Progressive Pernicious Anemia,” “American Journal of the Medical Sciences,” October, 1895.

‡ “Die Beteiligung des Knochenmarkes bei pernicioser Anaemie,” “Virchow's Archiv,” 1877, lxxi. 118–126.

§ “Virchow's Archiv,” October, 1876.

otherwise essentially changed. The spleen also has its iron pigment increased, and has been found reduced in size.

The *heart muscle* is fatty, while the other muscles are unusually red. Other *morbid changes* are described, but they cannot be regarded as essential. Such are changes in the ganglion cells of the sympathetic, and sclerosis of the posterior columns of the cord, first studied by Lichtheim.* Softening of the upper part of the lumbar cord has also been reported by Sir Dyce Duckworth.† While the association of the changes in the posterior columns are so constant that they cannot be regarded as accidental, experimental studies by Burr and Griffith intended to determine this relation to pernicious anemia resulted in nothing definite. Complete atrophy of the secreting tubules of the *stomach* has been described by Fenwick, and by William Osler and F. P. Henry in one case studied jointly by them.

Diagnosis.—The diagnosis of pernicious anemia may be uncertain at first, but the true nature of the disease soon declares itself. The intense anemia, extreme weakness, digestive derangements, and cardiovascular symptoms, in connection with a blood-count of 1,000,000 or below, with a relative increase, or at least no proportionate diminution, in the hemoglobin, and an admixture of megalocytes, microcytes, and poikilocytes, point to a condition scarcely mistakable. It may be said, moreover, that almost never in the case of a pernicious anemia do the number of corpuscles fail to fall below 1,000,000. The large forms of nucleated red corpuscles have been regarded as characteristic, but are also found in leukemia (see also diagnosis of Cancer of the Stomach, p. 371).

Prognosis.—The prognosis is to-day regarded as less unfavorable than it was a few years ago, since recent experience has developed the fact that temporary improvement is not uncommon, and it is said that recovery sometimes takes place. Still, Addison's original prognosis, of a termination sooner or later fatal, is seldom astray.

Treatment.—Treatment of this form of anemia is, moreover, not fruitless. The same measures which are almost a specific for chlorosis are not without effect in pernicious anemia. Accordingly, arsenic, to a less degree iron, good food, and favorable hygienic surroundings, are to be adopted. The arsenic treatment has been followed by results which justify the words "temporary cure," and it is said that permanent cure has followed. Such temporary cures have covered a period of three years. The best preparation appears to be Fowler's solution, in gradually increasing doses, until twenty and even thirty minims (1.3 to 2 c. c.) are reached, and this three times a day. It should be continued for a long time, for weeks or months, with intermissions of a few days if unpleasant results appear, to be again resumed. Arsenic is not a specific for pernicious anemia, but the results of its use are often surprisingly gratifying. Cakodylate of sodium has been recommended for other preparations of arsenic. It is said to be less irritating and suitable for hypodermic use. The dose is half a grain (0.033 gm.), three times a day. Inhalation of oxygen has also been recommended, as advised in leukemia. The relation between chlorosis and pernicious anemia, already referred to, is sustained by therapeutic results. Certain cases of chlorosis very closely resemble pernicious anemia, especially when not arrested by treatment. The arsenic, administered as directed, is wonderfully well borne, nausea and vomiting being rare. Rest in bed is

* "Congress für innere Medicin," 1887.

† "British Medical Journal," November 10, 1900.

indispensable, but should be supplemented with massage, if possible. Food should be in easily assimilable shape, such as beef-juice, beef-peptonoids, and peptonized milk. Pernicious anemia is one of the diseases in which much was expected from the use of *bone-marrow*, originally suggested by Thomas R. Fraser.* Fraser used three ounces (90 gm.) daily of beef-marrow, in addition to iron and arsenic, with apparent cure. At the present day the glycerids are used in doses of half an ounce (15 c. c.), three times a day. I have had some experience with it, but my results have not been very encouraging. Salol has been suggested as an intestinal antiseptic, from the standpoint that the disease may be due to toxins absorbed from that canal. Recently, too, Dr. William Hunter has suggested the use of antistreptococcus serum to counteract possible general infection.

Transfusion of blood and of milk, which seemed at one time to give promise of favorable results, has been discontinued. At the present day, hypodermoclysis would probably answer the same purpose, and is much easier done.

III. LEUKEMIA.

Definition.—A disease characterized by an enormous increase in the colorless corpuscles of the blood, by hyperplastic changes in the spleen, in the lymphatic glands, or bone-marrow, any one or more of these.

It has been called *leukocythemia* as well as *leukemia*, the former of these words meaning white-cell blood, the latter simply white blood. From the etymological and histological standpoint, leukocythemia, suggested by Hughes-Bennett, is the more accurate term, but Virchow's term, leukemia, has become the one in common use.

Historical.—The history of the development of our knowledge of leukemia possesses unusual interest. The older observers spoke of a purulent blood, ascribed to an inflammation of this tissue, while Piorry and Rokitsansky spoke of a hematitis as the cause of a literal pyemia. Craigie undoubtedly saw a case of the disease in Edinburgh in 1841. He did not, however, publish the case until John Hughes-Bennett published his on October 1, 1845, in the "Edinburgh Monthly Journal of Medicine." Both Craigie and Bennett noted enlargement of the spleen. Rudolph Virchow published his case in Froriep's "*Notizen*" in the second or third week of November, 1845. The matter of priority between Bennett and Virchow has given rise to much discussion. There can be no doubt that Bennett's case was published first; also that he declared it unconnected with inflammation of any of the tissues, and especially unconnected with phlebitis, and that he attributed the condition to the development of white corpuscles in the blood. Craigie, on the other hand, ascribed it to the absorption of pus from an inflammatory lesion either in the mesenteric veins or the spleen. Virchow confirmed all the observations made by Bennett and published new cases, especially one of great importance, in which there was *enlargement of the lymphatic glands without enlargement of the spleen*. Virchow also said the blood changes consisted essentially in an increase of the colorless cells of the blood, and that these cells originated in the lymphatic glands. He also suggested the name *leukemia*, while Bennett did not suggest that of *leucocythemia* until 1851 in a series of papers, and again in 1852 in a separate work. It appears to me that Bennett is clearly entitled to priority, and was the first to interpret the condition as an increase in the colorless corpuscles of the blood, though he speaks of it as *pus*. Virchow's added point was ascribing the formation of the cells to the lymphatic glands.

Vogel first recognized a case during life in 1849. Virchow described two forms of the disease in his "Cellular Pathology," in one of which the smaller forms of leukocytes predominated and in which there was marked involvement of the lymph glands. In the second the larger white blood cells predominated, and there was marked enlargement of the spleen; hence he inferred that the lymphatic glands were at fault when the smaller cells predominated, and the spleen when larger cells prevailed. Varieties thus characterized do exist, but we dare not draw conclusions as to the organs involved as sharply as Virchow did. Large cells predominate in the

* "British Medical Journal," June 2, 1894.

lienomedullary form, while small cells characterize the lymphatic variety. Intermediate forms, however, interfere with sharp distinctions. It was many years later that Neumann described a case in which the *bone-marrow* was markedly altered. Pure splenic and pure medullary forms scarcely exist, though a case or two of the latter is described. The pure *lymphatic form* does occur, but even this is rare. Most common is the mixed *lienomedullary* or *lienomyelogenous*.

The extremely rapid course of certain cases of leukemia justifies its division into an *acute* and *chronic* form. An instance of the former was a fatal case reported by Ebstein, in which the whole duration of the disease, including a prodromal stage, was but six weeks. Similar cases are reported by others, eleven by Fraenkel.* M. H. Fussel and A. E. Taylor collected fifty-six cases. The duration of the chronic form may extend over years. Leukemic women have been repeatedly pregnant and have borne children at term.

Etiology.—Nothing definite is known of the cause of leukemia. It occurs in all countries, in both sexes, and at all ages, although it is more common in middle life and in males. Cases have occurred in the eighth week and seventieth year. It is sometimes hereditary, but leukemic women have borne non-leukemic children. Malaria has been assigned as a cause, and certainly its association with this disease has been seemingly more than accidentally frequent. To a less degree this is true of syphilis. Pregnancy is said to favor it. It is said to have followed a blow or injury, and to have been found in the lower animals.

The idea of the infectious origin of leukemia, advanced by Klebs and supported by observations of Osterwold, Roux, Byrom Bramwell, Pawlowsky, Kelsch, Vaillard, and others, seems well founded, but no single micro-organism has been found associated. A case has, however, been reported where an attendant on a case of leukemia contracted the disease and died. The frequent association of leukemia with stomatitis and intestinal ulceration was pointed out by Hunterberger.

Morbid Anatomy.—Leukemia has a definite morbid anatomy, consisting in alterations in the blood and in the hemogenic apparatus, including the spleen, the lymphatic glands, and the marrow of bones, and it is called, accordingly, splenic, lymphatic, myelogenic, while combined or mixed forms are indicated by suitable compound terms, such as lieno-myelogenous. Most leukemias are mixed.

In the first place, the *spleen* is almost always enlarged. It may be adherent to the abdominal walls, the diaphragm, stomach, or other viscera. The splenic changes exhibit three stages in their development. In the first, the spleen is simply hyperemic, soft, and swollen, sometimes even ruptured. The Malpighian bodies share in the hyperemia, and may be slightly enlarged, but are overshadowed by the swollen pulp. In the second stage, hyperplastic changes make their appearance in the Malpighian bodies, and as these grow the pulp is intruded upon. They may reach such size as to be recognized by the naked eye as spherical gray nodules one to three lines in diameter, or they may be elongated or forked, following the course of the blood-vessels. The third stage furnishes the granitic spleen, in which white dots are separated by dark streaks representing the destroyed pulp, pigmented by the disintegrated blood. The spleen is now hard, and is cut with resistance. Its size may be enormous, and the organ may weigh from two to eighteen pounds (1 to 9 kilos).

* "Wiener klin. Wochenschrift," 1894.

The *lymphatic enlargement* is a true hyperplasia. Not only do the glands enlarge, but new foci of lymphatic tissue appear in various organs, as the liver and kidneys. These are regarded by some as simple extravasations of leukemic blood from the capillaries. All the more prominent groups may share in the enlargement—the cervical, axillary, inguinal, and perineal glands. The individual glands remain, however, soft. The lymphatic follicles in the tonsils and in the tongue, pharynx, and mouth may enlarge. This is also occasionally the case with the solitary glands of the intestine and the agminated glands of Peyer.

The *marrow changes* may be described, in a word, as reversion to the embryonal type of medullary tissue. The fat of the adult marrow has disappeared, and a mass of lymph cells mingled with nucleated red corpuscles in all stages of development takes its place. The marrow is often *pyoid*. The lymph cells include numerous large mononuclear cells, many in the act of division, also multinuclear leukocytes. There are also numerous marrow-cells or myelocytes and eosinophiles, like those found in the blood.

The *liver* is often enlarged, and, according to von Jaksch,* *pari passu* with the spleen, and it has this further peculiarity, that its edges are rounded, while in what he describes as *pseudoleukemia infantum* the edges are sharp, and the enlargement does not go hand in hand with that of the spleen. The liver is also at times infiltrated with leukemic patches and nodules, not unlike miliary tubercles. The same is occasionally true of the kidney.

The thymus gland has been found enlarged in some cases of acute lymphatic leukemia, and even the skin, stomach, and gastrosplenic omentum have been the seat of growths, presumably lymphatic. In fact, there is no situation in which such growths may not make their appearance. The possibility of their being blood extravasations, white in consequence of the large proportion of white cells, is always to be remembered.

The lungs and heart alone seem free from encroachment by the lymphatic tissue. The heart may, however, be dislocated by a large spleen.

The alterations in the *blood* constitute really a part of the morbid anatomy of leukemia, but are commonly treated under the head of symptomatology, where I, too, will consider them. An increase in the mass of the blood may, however, here be mentioned. The heart and vessels are commonly found gorged with blood, usually coagulated, sometimes whitish or yellow in color.

Symptoms.—The early symptoms of leukemia are precisely those of the other anemias, viz.: *Insidious onset, pallor, rapid breathing amounting to dyspnea* on exertion, *weakness and faintness, headache, indigestion, and loss of appetite*. The last two symptoms may precede all others. *Emaciation* is ultimately added. *Moderate fever*, with rapid pulse, is also present in the majority of cases, the temperature sometimes reaching 103° F. (39.4° C.). Headache, more or less continuous, is a symptom noticed. Lymphatic gland enlargements are evident. In a case recently under my care the first intimation of the presence of a *large spleen* was an attack of circumscribed *peritonitis*, favored, doubtless, by the presence of the splenic tumor and ascribed to exposure to cool air while perspiring. *Hemorrhages* from the nose and stomach are common, and dropsical swelling appears toward the close. *Nasal hemorrhages* are sometimes fatal. Thomas Oliver reported a case terminating fatally by sudden post-peritoneal hemorrhage.†

* See cases reported by J. Chalmers Cameron and Saenger, Sajous' "Annual" for 1891, E.
 † Sajous' "Annual" for 1890, vol. i., E, p. 12.

Hematemesis may be an early and almost initiatory fatal symptom. *Purpura hæmorrhagica* sometimes presents itself as a manifestation of the same tendency, as may also cerebral hemorrhage, producing coma. *Priapism* is an occasional symptom; it is sometimes persistent, and in a case of Edes was the first symptom noticed.

Black—Red Corpuscles. Red—Hemoglobin. Blue—Colorless Corpuscles.

Fig. 67—The Blood in Leukemia.

The *urine* often contains a small quantity of albumin, is highly colored and scanty, and deposits a copious sediment of uric acid.

Blood Changes.—The blood exhibits a most marked and diagnostic change consisting in an *enormous leukocytosis*. The mean number in normal blood is about 8000 colorless corpuscles to the cubic millimeter, which, with the red discs at 4,500,000, makes the proportion 1 to 580; or with these at 5,000,000, to 1 to 625. There is a physiological leukocytosis which, after a full meal, may reach 1 to 150, and even 1 to 100, while there are pathological

leukocytoses which quite equal those of many true leukemias. In leukemia, however, there may be 1 to 50, to 25, to 10, to 3, to 2, or the leukocytes may equal, and in rare cases even exceed, the red discs. The maximum proportion of colorless corpuscles impresses decidedly the color of the blood *en masse*, making it pink, or even the color of chocolate and milk, while aggregations of leukocytes may produce white streaks, and well justify the belief of the older pathologists that there was pus in the blood—a supuration of the blood, as they called it.

There is also a reduction in the total number of blood-cells, including white and colored, the quantity in a cubic millimeter being sometimes reduced to between 2,000,000 and 3,000,000. This reduction may be even more positive, as in a case reported by Suchannek,* in which there were 301,600 red discs and 306,100 colorless corpuscles.

Numerous *nucleated red discs* are present, and occasionally also *poikilocytes*. The hemoglobin falls below the normal proportion, so that the value of each disc is lowered. The blood plaques may be slightly increased. The beautiful plate opposite page 662 was made from the blood of a patient in the Hospital of the University of Pennsylvania. (See also Diagnosis.)

An early discovery in the study of leukemia was that of certain transparent octahedral crystals, known as Charcot's crystals, which form in blood which has been kept for some time on slides. Neumann referred these crystals to the bone-marrow, but they are commonly conceded to be the same as those sometimes found in the expectoration and in feces and in seminal fluid. There is reason to believe they are decomposition products, and that they hold no essential relation to leukemia.

That the alkalinity of the blood is sometimes diminished is true; that it is ever replaced by acidity is not true, as was at one time held. Its specific gravity is lowered to 1030 to 1050. Leukemic blood coagulates slowly, a feature which has been ascribed to the presence of albumoses.

Diagnosis.—The diagnosis of leukemia requires the aid of the microscope, but with it it becomes easy. (See Blood Changes.) A refinement of diagnosis, thus aided, attempts with partial success to separate the different varieties, which are known as simple or complex, according as one or more of the cytogenous organs are implicated. Most leukemias are, however, mixed. In his monograph Hermann Rieder says that, so far as he knows, *pure splenic* and *pure myelogenous* forms have never been observed, while the *pure lymphatic* form does occur.† Even the latter is rare. A case of the pure myelogenous variety reported by Fränkel, in a girl of fourteen,‡ is not now admitted to be a true instance. Another was reported by von Leube and Fleischer.§ On the other hand, Ehrlich prefers to call the most common form the splenomedullary, "myelogenous," because he thinks the spleen is purely passive.

I. For the present I shall retain the term *splenomedullary* or *lienomyelogenous* for the most usual form. The spleen is very large, and the leukocytosis is intense, the ratio of white to red corpuscles being 1 to 3, 1 to 2, or 1 to 1. The *lymphocytes*, while actually increased, are *relatively diminished*—that is, instead of representing 20 to 30 per cent. of all the leukocytes, they represent a smaller proportion, an average of 10.6 per cent. The *poly-*

morphonuclear cells are increased as to absolute number, but the percentage is reduced, particularly toward the close, to an average of 46 per cent., a range 17 to 72 per cent. *Eosinophiles* are increased, but not their percentage, and they are not now assigned any distinctive value, because so numerous in other conditions. But the most characteristic feature of this variety is the presence of the large *neutrophilic myelocytes*, and the more of these, the more likely is it that the leukemia is myelogenous. The percentage rises, sometimes as high as 60 per cent. and often above 20, with an average of 35 per cent. *Basophilic leukocytes*, including "mast" cells, are much more numerous than in normal blood.

The red corpuscles are those characteristic of anemic blood, and nucleated cells are numerous.

II. Pure *lymphatic leukemia* is less frequently met, probably less than 15 per cent. of all the cases. The external lymphatic glands are most involved. The leukocytosis is not nearly so marked, the colorless cells scarcely ever exceeding one in ten, often only one in forty. The lymphocytes predominate, equaling 90 per cent., including all forms, large and small and mixed. Myelocytes are infrequent. In a case reported by Uthemann, 93 per cent. of all the leukocytes were lymphocytes, as compared with 15 to 30 per cent. in normal blood; in one of Osler's, 98 per cent. Even in the combined form lymphatic involvement is found. The superficial groups of glands are usually involved, but never to the same degree as in Hodgkin's disease.

Caution should be observed, too, in basing the presence of leukemia solely on a *leukocytosis*, as some remarkable instances of this condition have been reported wherein leukemia did not supervene. Thus, von Jaksch, in his studies of the anemia of children, found such proportions as 1 white to 12 red corpuscles, 1 to 17, and 1 to 20; and in the case of an adult, 1 to 8, and still no leukemia followed.* Eighty thousand white corpuscles in a cubic millimeter are not unusual in leukocytosis, while 170,000 have been produced experimentally in the dog. The association of lymphatic or splenic or myelogenous change with the leukocytosis is therefore essential to a diagnosis. Nay, more, we must look to the proportions of the varieties of leukocytes. It will be remembered that in the most frequent form of leukemia at least, myelocytes predominate over lymphocytes and polymorphonuclear cells. But in most cases of non-leukemic leukocytosis the adult polymorphonuclear cells are in relative as well as actual excess—90 per cent. being made up of this form in leukocytosis. Rieder is also inclined to regard the cases of so-called acute leukemia as really acute inflammatory leukocytosis rather than leukemia.

Allusion has already been made to an anemia described by von Jaksch as *anæmia infantum pseudoleukæmia*, further studied by Loos and Luzet, which is not to be confounded with leukemia. Its essential feature is an enormous falling off in the red cells of the blood, often as low as 820,000. The proportion of leukocytes is always increased, but never to the same degree as in leukemia, nor is it so rapidly brought about. They have been found to the number of 54,666. On the other hand, the leukocytes are characterized by their varied shape and unusual size. The red cells display a high degree of poikilocytosis, while white cells inclosing red cells and fragments of red cells are also found, together with occasional eosinophilic leukocytes and large multinuclear neutrophilic leukocytes and nucleated red

* *Op. cit.*, p. 29.

cells. All of these modifications of the blood-corpuscles may occur in leukemia, but in the latter disease there is not so marked a reduction either in the hemoglobin or in the number of erythrocytes. The difference in the form of the liver and splenic enlargement in the two conditions has been referred to on page 659. It has been suggested that this is a form of disease intermediate between pseudo-leukemia, or Hodgkin's disease, and true leukemia.

Prognosis.—The prognosis of leukemia is unfavorable, the best that can be expected from treatment being the deferring of the fatal end. Some rather remarkable fluctuations are noted, and cases of cure are even reported, especially of late, by inhalations of oxygen. Osler saw a case ten years after the original diagnosis was made by Wm. H. Draper. The lymphatic leukemias are the more acute and more intractable.

Treatment.—The treatment has heretofore been mainly with iron, quinin, and arsenic, fresh air, and good food. Large doses of arsenic—as much as thirty drops (0.92 c. c.) of Fowler's solution, reached by gradual increment have been especially recommended and certainly should be tried.

Inhalations of oxygen, suggested in 1887, were used by Sticker and Pletzer with temporary benefit, and Da Costa and Hershey report the apparent cure of one case, a boy of thirteen, and such marked improvement in a man of thirty-five that he was thought for a time to be cured. This treatment deserves, therefore, to be tried along with that first named. Thirty to 100 liters (about 4 to 12 gallons) of oxygen are to be inhaled daily. *Bone-marrow* has been extensively used, but the results have been disappointing. It should, however, be tried in one fluidram (4 c. c.) doses of the glycerin solution, increased to half an ounce (16 c. c.), three or four times a day.

IV. LYMPHATIC ANEMIA—HODGKIN'S DISEASE.

SYNONYMS.—*Hodgkin's Disease; Pseudo-leukemia; Lymphadenosis; Lymphadenoma; Malignant Lymphoma (Billroth); Adénie and Lymphadénie.*

Definition.—The disease consists essentially in an anemia accompanied by a fibro-adenic enlargement of the lymphatic glands and the formation of lymphatic foci in the spleen and occasionally in other glandular organs, but unassociated with an increase in the colorless corpuscles of the blood.

Historical.—Hodgkin's paper, to which we are indebted for our first definite knowledge of the disease, appeared in 1832.

Etiology.—Its etiology is as undetermined as that of leukemia. Depressing influences of all kinds are believed to favor it. Scrofulosis has sometimes preceded it. The presence of an irritating substance in the blood has been suggested, and the necessity of local irritation, associated with a lymphatic diathesis, has been insisted upon by Trousseau. It may occur at any age, but more common in adult life, and in males.

Morbid Anatomy.—Its morbid anatomy is, however, definite. There is both lymphatic and splenic involvement, the latter secondary to the former. The tonsils, intestinal lymphatic structures, and even the liver and kidneys may be invaded. There is, moreover, a deposition of new foci of lymphatic tissues decidedly more marked than in leukemia. The lymphatic enlarge-

ment usually begins first in the more superficial groups, as those of the anterior and posterior cervical triangles, the glands of the axilla, and the groin, but the entire lymphatic system may be involved, including the retroperitoneal glands, resulting sometimes in marked abdominal enlargement. Occasionally the overgrowth is limited to the deep-seated glands. Of the abdominal, the retroperitoneal are most frequently involved, producing tumors which have been mistaken for myomata of the uterus. The bronchial glands may also be involved, and by their pressure produce dyspnea.

The *lymphatic* enlargement is a hyperplastic one, shared by the cellular and trabecular tissue in varying degrees. When the former predominates, the product is soft and exudes a milky juice on section; when the latter, it is firm and resisting. The individual glands are not disposed to fuse nor to become adherent to adjacent tissue, differing in this respect greatly from glands enlarged by the tubercular process. The enlargement also exceeds that in leukemia.

The alteration in the *spleen* is hyperplastic, involving the pulp and Malpighian bodies jointly or either alone. The enlarged Malpighian bodies furnish the most characteristic feature. They form grayish-white masses, varying in size from that of a lentil to that of a walnut, from two millimeters to as many centimeters in diameter, and contrast strongly with the dark-red parenchyma. The process in the Malpighian bodies is a true hypertrophy of the adenoid tissue, while in the pulp it is rather the trabecular tissue which is overgrown. The splenic enlargement is more limited than in leukemia, the organ rarely exceeding ten inches (25 cm.) in length, as contrasted with the colossal size of the leukemic spleen. The spleen is not always involved, though Gowers found splenic enlargement in 75 per cent. of the cases collected and the organ contained lymphoid growths in fifty-six of these.

There are, likewise, at times changes in the *marrow of bones*, which is converted into lymphoid tissue, sometimes pyoid in consistence.

The liver and kidney, and even the thymus gland and lungs, are sometimes the seat of lymphoid deposits; in fact, all organs and tissues may be invaded, including the nervous. Paraplegia has resulted from pressure on the cord by growths in the spinal canal. The posterior nares may be occluded by invasion of the tonsils and the numerous lymphoid follicles in the pharynx. In like manner the intestinal walls may be invaded, producing thickening, while even serous surfaces do not escape.

Symptoms.—The symptoms of Hodgkin's disease are, again, the *pallor*, *weakness*, *dyspnea*, *palpitation*, *dizziness*, and other signs of anemia, concurrent with or even sometimes in advance of the glandular enlargement. There is quite often *fever*, very irregular and variable in degree, and cases have been observed by Murchison and De Renzi in which there was *paroxysmal glandular enlargement* coinciding with fever, the enlargement subsiding with the decline of fever, but not reaching the degree present prior to the enlargement. In a case under my care in the wards of the Hospital of the University of Pennsylvania in which the glandular enlargement was not conspicuous, there occurred an intermittent rise of temperature ascribed to a concurrent peritonitis, but the autopsy discovered this to be so limited that it is perhaps more reasonable to ascribe it to the feverish tendency characteristic of the disease.

The external glandular growths are variously conspicuous; occasionally, however, they are wholly absent. There is no fixed order of involvement,

although the glands of the anterior and posterior cervical triangles commonly enlarge first, and with the acme of their growth produce a striking picture. The enlargement is not uniform, but at times remits and even ceases. It is said it may disappear altogether for a time. The glands are usually soft, sometimes there is even a sense of fluctuation.

The glandular enlargements themselves contribute further to the symptoms by their effects. Thus, in the case of the bronchial glands, *dyspnea from pressure* on bronchi or trachea may occur, and is apt also to be intermittent. Pressure elsewhere may lead to *pleuritic or abdominal effusions*, while the entanglement of nerves in the growth may cause *pain*. Erosion of bone may result. *Bronzing of the skin* has been found associated with enlargement of the abdominal glands. A *purpuric rash* is sometimes present in Hodgkin's disease, due perhaps to the hydremic state of the blood.

Macroscopically, the *blood* appears thin and pale. Minutely examined the red corpuscles are diminished in number, although not always. Minimum counts make 960,000 * to the cubic millimeter, while in a case reported by Henry,† that of a boy of five, with enormous enlargement of the right cervical glands, there were 5,462,000 to the cubic millimeter. Thus, the diminution is less than in pernicious anemia. The hemoglobin is, however, reduced to at least 60 per cent., furnishing thus one of the conditions essential to anemia. There are few nucleated red corpuscles and poikilocytes, and especially microcytes. The leukocytes may be slightly increased, occasionally decidedly so, but this is rare, and there is no approximation to the leukemic state of the blood, and the two states are distinct and separate. A combination of the two may be possible.

Diagnosis.—The diagnosis requires some care, as more than one condition is attended by similar glandular outgrowths. Chronic and even acute *adenitis* has been mistaken for the early manifestation of Hodgkin's disease, while the converse has obtained perhaps more frequently. Time is the arbiter of such uncertainty.

A group of *tubercular glands* resembles more closely the disease under consideration, but it is not usually difficult to distinguish between the two. Tubercular glands are adherent to each other and to adjacent tissues, while the lymphadenoid growths are loose and easily movable. Tuberculosis rarely involves more than one group of glands, is characterized by caseation and suppuration, while the lymphadenoid growths almost never suppurate. Yet the tubercular process is the slower. Tuberculosis is commonly found in young persons under twenty. Hodgkin's disease may occur at any age, but the average age is greater. It is more common in males. In Gowers' 100 cases, 75 were males and 25 females: 30 were under twenty, 34 between twenty and forty, and 36 above forty.

Sarcoma also involves groups of glands, and in the beginning the consistence of the glands is similar to that in Hodgkin's disease. But this disease rapidly invades surrounding tissues, fusing with them, and destructive ulceration soon makes its appearance.

Carcinoma of lymphatic glands should also be mentioned as producing a somewhat similar growth, associated also with cachexia, but it is for the most part secondary to cancer elsewhere than in lymphatic glands.

Finally, all the conditions named as possible to be mistaken for Hodg-

* Case reported by Richard Geigel, quoted by F. P. Henry ("Anemia," Philadelphia, 1837), from "Deutsches Archiv für klinische Med.," 1835, Bd. xxxvii. p. 59.

† *Op. cit.*, p. 67.

kin's disease are limited to single groups, while the latter always extends, and the fact of such limitation is of itself sufficient to preclude the disease.

From *leukocythemia* the disease is easily distinguished by the leukocytosis characteristic of the former.

Prognosis.—While the prognosis is ultimately fatal, the course of the disease varies greatly, and death seldom results in less than a year. F. P. Henry places the average duration of life at two years, but admits it is greatly modified by such circumstances as age and previous health of the patient.

Treatment.—Treatment, too, may avert the fatal termination for a long time. Extraordinary results in this respect have followed the administration of arsenic, and even recoveries have been reported. Large doses, arrived at by gradual increment, should be attained and kept up until some physiological effects are observed. Such doses are from fifteen to twenty minims (1 to 1.3 c. c.) of Fowler's solution. Particularly happy results are claimed for the injection of arsenic into the lymphoid masses. Especially is this recommended when arsenic is not well borne by the stomach. From eight to thirty minims (0.5 to 2 c. c.) of Fowler's solution have been injected daily in divided doses. Inunctions of iodine and iodid of potassium are also recommended. Supporting treatment of all kinds, including quinin, cod-liver oil, and the best of food, is necessary. Bone-marrow is indicated here as in other forms of anemia, if it possesses the qualities claimed for it.

Operative interference is sometimes necessary to avert danger to life, threatened by the encroachment of enlarged glands on vital organs and functions, such as respiration. It has even been claimed that the removal of a group of primarily enlarged glands has cut short the spread of the disease, but such an apparent result is rather an evidence of error in diagnosis. In view of the fact that at an early stage a diagnosis is impossible, the removal of a local group of glands should be recommended.

STATUS LYMPHATICUS.

SYNONYM.—*Lymphatism*.

Definition.—A hyperplastic state of the lymphoid tissues throughout the body, including the lymphatic glands, the spleen, the thymus, and the lymphoid marrow of bones, occurring chiefly in children and young persons.

This condition is rare in this country, and has never come under my observation. It has been described by Poltau and other Vienna physicians, and by James Ewing, of New York.*

Morbid Anatomy.—The lymphatic glands most frequently affected are the pharyngeal, thoracic, and abdominal; those of the cervical, axillary, and inguinal regions less frequently and in less degree, while the lymphatic elements of the tonsils and the upper pharynx, and the solitary and agminated follicles of the small and large intestines, are often much involved. The spleen is moderately enlarged, while the Malpighian bodies stand out distinctly. The thymus gland is enlarged and soft, and on section may exude a milky fluid. The bone-marrow may be hyperplastic, and the yellow marrow replaced by red marrow. Along with these anatomical changes have sometimes been found rickets, and, again, hyperplasia of the heart and aorta.

Symptoms.—The symptoms in addition to the anatomical changes noted are a lowered power of resistance, sometimes evidenced by sudden death or

* "New York Medical Journal," July 10, 1897.

death from insufficient cause. The subjects are said to be poorly developed and infantile in appearance. As might be expected, the recognition of the actual condition is not always easy, if it dare be assigned a separate place in the nosology.

So far as I may judge from my limited knowledge, a separation of it from Hodgkin's disease seems scarcely justified.

V. SPLENIC ANEMIA, OR SPLENIC PSEUDO-LEUKEMIA.

Definition.—This term is applied to a condition in many respects analogous to Hodgkin's disease, but differs especially in the absence of involvement of the lymphatic glands, the spleen being alone enlarged. Attention was first called to it as a separate variety of pseudo-leukemia by Horatio C. Wood * in 1871, although reports of cases corresponding to it had been previously made by others. It has been studied by Strümpell and Banti. More recently quite a number of cases have been reported, notably by Jarvin,† Alfred Stengel, and others. I retain the term not because I insist upon the etiological relation between the spleen and blood changes, but because the study of the subject is facilitated.

Etiology.—This is undetermined, except that there is reason to believe that the condition sometimes succeeds the infectious diseases. It is to be separated from the enlarged spleen sometimes associated with a moderate anemia, so often the result of chronic malaria. It occurs alike in old and young.

Morbid Anatomy.—Its morbid anatomy consists in the splenic changes. The organ is greatly enlarged, approaching that of the leukemic spleen rather than the spleen of Hodgkin's disease. It is three or four times its normal size, but retains its normal shape. It is indurated, and its incisures are deep. Its capsule is thickened and opaque in spots and sometimes adherent to adjacent tissues, as is often true of any large spleen. The histology of the organ differs from that of the leukemic enlargement and that of the enlarged spleen of Hodgkin's disease. There is no true overgrowth of the lymphatic tissue in the Malpighian body, but rather a destruction, it being replaced by an overgrowth of the reticulum, producing a white body as large as a pea. In addition to this the organ is often traversed by bands of thickened reticulum, visible to the naked eye. The change corresponds rather with that in the harder lymphatic glands of Hodgkin's disease than that in the spleen. In a word, as well stated by Banti, the histological alterations of the spleen consist of an *atrophy and sclerosis of the Malpighian corpuscles*. Marrow changes, like those described under pernicious anemia, are also sometimes present.

Symptoms.—The symptoms are analogous to those of pernicious anemia, and include *pallor, weakness, dyspnea, palpitation*, associated with the signs of *enlarged spleen*, evidence of which is sometimes shown by its weight and the pressure it exerts before other symptoms show themselves. Finally, there results the cachectic state characterized by *emaciation, a deeper yellow color of the skin and mucous membranes, a tendency to hemorrhage and pyrexia, edema, serous effusions, extreme muscular prostration, and mental*

* "Relations of Leukocythemia and Pseudoleukemia," "Amer. Jour. of the Med. Sci.," October, 1871.

† "Anemia Splenica," "Berliner klin. Wochenschrift," August 16, 1897.

hebetude. There is also said to be at times, as in lymphatic pseudo-leukemia, an intermittent or *per saltum* course in the symptoms to the extent of apparent complete restoration to health in the intervals.

The *blood* exhibits the changes one would expect in cases in which there is destruction of the tissue devoted to its reproduction. It is anemic. The red discs are notably diminished, from 5,000,000 to as low as even 1,000,000. The hemoglobin is diminished, in Jarvin's case especially, relatively less than the corpuscles. There are found also the other changes of the erythrocytes characteristic of pernicious anemia. There are poikilocytosis, megalocytosis, and microcytosis. Nucleated red blood-cells are numerous. The leukocytes are sometimes slightly more numerous; at other times they are in normal proportion, and are said to be generally mononuclear.

An *increase in the uræa* of the urine has been noted by Strümpell, and is regarded as evidence of increased albuminoid metamorphosis.

All clinical facts go to show that the spleen is responsible in some way for a destruction of erythrocytes and of their capacity for carrying oxygen.

The duration of the disease is from five to six months to three years.

Diagnosis.—The diagnosis of splenic anemia depends upon the presence of splenic enlargement associated with the phenomena of anemia previously described, and the absence of glandular enlargement, so conspicuous in Hodgkin's disease. Anemic symptoms attend the chronic malaria so often associated with enlarged spleen, but the history of malaria in such cases is invariably present, while the degree of anemia in malaria is not so high.

Prognosis.—The prognosis has been regarded as unfavorable, but may be modified by the results of splenectomy, which in the cases collected by Banti appears to have been successful in three out of four.

Treatment.—The treatment is that for the other anemias, by iron and arsenic and nutritious food. Bone-marrow may be tried. The propriety of splenectomy must be determined on the merits of each case.

SECTION VI.

DISEASES OF THE DUCTLESS GLANDS.

DISEASES OF THE THYROID GLAND.

GOITRE.

SIMPLE GOITRE OR STRUMA.

SYNONYMS.—*Bronchocele*; *Thyrocele*; *Thick Neck*; *Derbyshire Neck*.

Definition.—The name is derived from Latin, *guttur*, throat. Under this name are included all enlargements of the thyroid gland other than those due to inflammation, malignant disease, exophthalmic goitre, or parasites.

Distribution.—Simple goitre may occur endemically or sporadically, but in this country it is only sporadic. It is, however, quite prevalent about the eastern end of Lake Ontario and in the State of Michigan. It is still endemic in certain parts of Switzerland (cantons of Freiburg and Berne), in Italy (in the Southern Alps and in Savoy), in England, the Himalayas, in Asia, and in Siberia. In the cantons named as many as 80 and 90 per cent. of recruits are found goitrous. It has even occurred in *epidemic* form in Finland.

Etiology.—The exciting cause of goitre still remains unknown, although a belief has long prevailed as to the endemic form that some constituent of drinking-water is responsible for it. That locality is in some way responsible is shown by the fact that removal from a territory subject to it arrests its development, while, if a healthy family moves into a goitrous district, the disease develops in some one or more members. A change in the water-supply of a district where goitre has been prevalent has led to its disappearance, while the water in certain wells on the continent of Europe is known to produce it. In fact, certain water is said to be drunk by men who desire to develop in themselves a goitre in order that they may be exempt from military service. What the responsible constituent of the water is, is, however, unknown.

It is much more common in women than in men, according to different authorities seven to forty-one times as frequent. It has been suggested that this is because women drink more water. The disease generally develops after puberty, sometimes after fifty. Congenital cases are known. It is sometimes hereditary, but heredity must be separated from the operation of one cause on different members of the same family.

Morbid Anatomy.—All simple goitres start in a true hypertrophy of the gland follicles, but ultimately assume special peculiarities, on which are based anatomical varieties. According to anatomical peculiarities assumed after the goitre sets in, there occur: (1) *Struma mollis*, or parenchymatous or hypertrophic goitre, in which there is a true hypertrophic enlargement; (2) *struma aneurysmatica*, in which the vessels are enlarged and dilated; (3) *struma fibrosa*, in which there is an excessive development of fibroid tissue; (4) *struma colloides*, in which the follicles are enlarged and

filled with colloid matter; (5) *struma cystica*, when the follicles have enlarged to cysts with liquid contents; (6) *struma ossea*, characterized by calcareous infiltration; (7) *struma amyloidea*, in which there is a wax-like product caused by amyloid change. There are various combinations or intermediate types.

Symptoms.—It may be said of the majority of goitres that they cause no inconvenience, and are mainly objectionable through the deformity they cause. The size attained varies: the enlargement may but slightly exceed that of the normal gland, or the organ may be very large and pendulous. It may be one-sided or bilateral, or only affect the isthmus. It is characteristic of all goitres and enlargements of the thyroid of any kind that they rise up when the patient swallows, and tumors of doubtful locality may thus be located. The goitre is sometimes low down, behind the sternum, and can only be felt during deglutition.

A goitre may press on the trachea, causing dyspnea, or upon the esophagus, causing difficulty in swallowing. When behind the sternum, it may press upon the veins in the neck, causing swelling of the face and head, and sometimes headache and drowsiness. There may be pressure on nerves, especially the pneumogastric, causing spasm of the glottis, paralysis of the abductor, and even complete paralysis of one or both vocal cords.

Treatment.—The medical treatment of goitre consists principally in the topical application of tincture of iodine. It is undoubtedly efficient at times. The simple iodine ointment or ointment of the red iodide of mercury may be daily rubbed into the goitre. It is recommended that after applications of the latter the neck should be exposed to the rays of the sun. This treatment has been especially efficient in India. Injections of iodine into the cyst are also used—twenty to thirty minims (1.3 to 2 c. c.) of a solution of one part in twelve parts of alcohol twice a week, a new point being selected each time, care being taken not to wound any vessels or nerves.

Internal treatment is also recommended. Naturally, the iodide of potassium is conspicuous among remedies, in the usual doses—five to twenty grains (0.3 to 1.3 gm.) three times a day. Thyroid extract is also being used with disputed success. Bruns treated twelve cases with raw thyroid glands in doses of five to ten gm. (75 to 150 grains) twice a week at first and once a week afterward. Nine were benefited. Kocher, however, thinks that the results with thyroid extract are no better than with iodine.

When large and causing dangerous symptoms, goitre falls properly into the hands of the surgeon, who treats it as exigencies demand, sometimes extirpating it, though the operation is rather formidable at times and there is some risk of its being followed by myxedema. Cysts may be incised and drained or injected with iodine or perchloride of iron solution. Sir Morell Mackenzie injected the latter after tapping, using two drams (7.4 c. c.) of a 25 per cent. solution.

If the goitre is produced by local causes, a change of residence is, of course, desirable.

EXOPHTHALMIC GOITRE.

SYNONYMS.—*Struma exophthalmica*; *Graves' Disease*; *Basedow's Disease*; *Cardiothyroid Exophthalmos*; *Tachycardia strumosa*.

Definition.—A disease characterized especially by enlargement of the thyroid gland, protruding eyeballs, and frequent pulse, probably due to some perversion of function of the thyroid gland.

Historical.—In the early part of the nineteenth century cases in which exophthalmos was a symptom were published by different authors. Some of these were probably examples of exophthalmic goitre. In 1825 C. Parry published several instances of a disease not previously described which were evidently cases of exophthalmic goitre. In 1828 Adelman published a case declared on Virchow's authority to be one of exophthalmic goitre, and therefore the first described in Europe. In 1833 Trousseau reported the history of a woman affected with goitre, exophthalmos, and cardiac palpitation at the same time, of which he said afterward that he was far from supposing that this symptomatic triad constituted a special morbid entity. In 1835 Graves published the clinical lecture whence arose his association with the name of the disease, which will perhaps continue through all time. He also described it in his "System of Clinical Medicine," published in 1843. He was the first to emphasize the absence of *organic* cardiac disease. In 1840 von Basedow published the results of his study of four cases of exophthalmic goitre, and with it the most exact description of the disease which had yet been given. He gave to the disease the name *exophthalmic cachexia*. Although his name has also become associated with it, and the Germans insist on the priority of his studies, he seems to have been clearly anticipated by Graves. Others who described the disease were: Romberg in 1851; Shoch in 1854; and in 1855 Koeben, who first ascribed it to derangement of the sympathetic nervous system. In 1855, too, Stokes included the disease in his book on "Diseases of the Heart," and drew special attention also to the nervous phenomena. Charcot thoroughly described it in 1856 and 1857, and in 1857 von Graefe described the symptom known as Graefe's. In 1859 Fischer referred the symptoms to the remote effects of anemia. In 1860 Trousseau asserted the nervous origin of the disease, and that it should be classed as a neurosis. In the same year Aran ascribed the exophthalmos to a contraction of the muscular fibers of Müller supplied by the sympathetic. In 1862 a notable discussion in the Academy of Medicine of Paris took place, when Trousseau maintained that in all cases of exophthalmic goitre there was either an antecedent or a coincident derangement of the heart, and reasserted its nervous origin. Piorry denied the unity of the disease, and claimed that the prominence of the eyeballs was the result of retarded intracranial circulation due to pressure of the enlarged thyroid upon the external and internal jugular veins.

The neurotic nature of the disease has much in its favor, and most recently the medulla oblongata has been selected as the site for the lesion. This view has the support of some experimental evidence, and in a few autopsies changes have been found in the medulla. The view that it is a sympathetic neurosis has always commended itself, appearing as it does to explain the symptoms more satisfactorily than any other—the frequent pulse, the exophthalmos, the thyroid pulsation, the sweating, and the general nervousness being all thus accounted for.

Most recently the startling facts developed in connection with myxedema and the results of its treatment have drawn attention to a possible antithetic relationship between the two conditions. Thus we have, on the one hand, associated with exophthalmic goitre, excitability of the nervous system, manifested in restlessness of mind and body, a rapid action of the heart, and a moist, flushed skin; with myxedema the opposite conditions of dullness of intellect, torpor of body, slowness of pulse, dryness of skin. From this standpoint Moebius and Greenfield have taken the position that exophthalmic goitre is such an antithetic disease. Greenfield further adduces the fact that the changes in the gland are those of an organ in active evolution—*i. e.*, proliferation with production of new tubular spaces and absorption of the colloid matrix, to be replaced by a more mucous fluid. Further are the facts that thyroid extract in excess produces tachycardia, tremor, headache, sweating, and prostration, symptoms of Graves' disease; that when administered during the disease, it aggravates the symptoms—has, indeed, in an overdose caused it, as in a case of Beclère's; and that the most successful treatment has been such as reduces the bulk of the gland.

Etiology.—Exophthalmic goitre is more common in women than in men—according to Trousseau, as fifty to eight. Others make it twice as frequent, others ten times. It is also more common in the young adult and

in the middle-aged. The average age may be put down at from thirty to thirty-one years; Byrom Bramwell says fifteen to thirty for women and thirty to forty-five for men. The oldest patient I have ever seen was forty-four. It has been observed as early as two and a half years, and as late as sixty-eight. Heredity is a rare factor, but its influence cannot be denied. It sometimes happens that several members of a family are affected. Sometimes myxedema affects one member of a family, and exophthalmic goitre another. It occurs with especial frequency in neurotic families. Sudden mental shock, worry and grief, and physical fatigue are assigned as exciting causes. So are many acute diseases, of which rheumatism is especially cited, also typhoid fever. Some of these are more likely to be coincidences. W. H. Thomson ascribes Graves' disease to gastro-intestinal ptomain poisoning from excessive meat ingestion. Some perversion of function of the thyroid gland lies at the foundation of exophthalmic goitre.

Symptoms.—Of the cardinal symptoms mentioned in the definition, the cardiac and vascular usually appear first. The *palpitation* is extreme, delirious, as it were, the pulse-rate being commonly in the neighborhood of 120 to 140, and is said sometimes to reach 200. The slightest excitement augments the pulse-rate instantly. The *cardiac impulse* is strong, but the volume of the *pulse* small. The normal *heart-sounds* are loud, audible to the patient and even at a distance from the body, in one case described by Graves himself as far as four feet. A *systolic murmur* is often heard at the base, usually soft, but sometimes loud; more rarely at the apex, when it may be due to relative insufficiency of the mitral or tricuspid valve.

Exophthalmos is commonly described as the second of the cardinal symptoms to appear, but it is not far behind the palpitation. The degree of this protrusion varies very decidedly. It may be so slight as to be scarcely noticeable, while again the peculiar staring effect arising from it is conspicuous, and attracts attention instantly. The eyes show a large amount of white, and the eyelids when closed often cannot cover the eyes. It is in these extreme cases that *von Graefe's symptom* presents itself—a condition in which, when the eye is cast down or raised, the lid fails to follow it as it does in health. This symptom, of which so much has been said, is not a very frequent one. *Stellwag's sign*, which is less known, seems more frequently met. In it, the palpebral fissure is increased in width, owing to the persistent retraction of the upper lid. It may occur with or without von Graefe's. Retraction of the lower lid is occasionally seen. Moebius considers Graefe's symptom the result of *Stellwag's*. The patient *winks* less frequently than in health. *Pulsation of the retinal arteries* can be seen with the ophthalmoscope, but other changes in the retinae are rare. The same is true of the pupils. A *lack in convergence* of the two eyes was pointed out by Moebius.

The *thyroid enlargement* commonly presents itself at about the same time as exophthalmos. A patient of mine said, almost as early as she noticed swelling she observed her eyes began to protrude, showing that the events are not far apart, and that the three distinctive symptoms appear almost simultaneously. The goitre itself is in no way peculiar. It is usually of moderate size, almost never reaching the dimensions sometimes attained by a simple goitre. The tumor is largely contributed to by its vascularity, though there is also an overgrowth of the proper glandular tissue of the thyroid. Pulse and thrill are both palpable, while a loud systolic murmur may be heard on auscultation.

Another symptom, already alluded to, included by some as cardinal, is what is commonly known as "*nervousness*." It includes irritability, restlessness, a disposition to start at the slightest sound, and wakefulness at night. At a part of this, or as due to the same cause, at least, is "*tremor*," a highly important symptom, of such frequency as to be included by George R. Murray in his definition.* It does not, however, appear, as a rule, until the other symptoms have been present for some time. It may be best studied by holding out the hand with the palm downward; even better by laying the examiner's palm lightly upon the patient's fingers when the hand of the latter is held out. The tremor affects the flexor and extensor muscles of the wrist, and not the intrinsic muscles of the hand, so that the fingers do not vibrate independently, but the whole hand moves. It is rapid, regular, and uniform while it lasts. It occurs *eight or nine times* in a *second*. Its extent is small, but not always the same. It may be seen, too, in the foot, and in some instances the whole body appears to tremble. It is generally equal on the two sides of the body, but has been unilateral when goitre and exophthalmos have been on one side. It is variously modified by position—lying, sitting, or standing. It does not, as a rule, interfere with the movements of the hand, but when excessive may hinder sewing or writing. The tremor of general paralysis and alcoholism is less regular in extent, while the individual fingers tremble, the rate being practically the same. In the tremor of old age, the rate is only one-half as rapid; in disseminated sclerosis, it occurs from three to six times a second, and in paralysis agitans it is less regular. It resembles more the tremor of fatigue or that seen in recovery from long illness. Another symptom included in the same category is a *sudden giving way of the legs*, so that the patient falls to the ground without previous feeling of faintness or giddiness, and Charcot mentions also a weakness of the legs. *Painful cramps* sometimes occur. *Localized muscular atrophy* and that peculiar nervous symptom known as *astasia abasia*, in which there are inability to stand and inability to walk, are occasionally met.

Excessive *sweating* is a frequent symptom. It may be intermittent or irregular, or there may be a simple feeling of flushing without sweating. *Diminished electrical resistance* was pointed out by Vigouroux. This is a natural result of the constant moisture of the skin. *Polyuria* often occurs, caused, perhaps, as is the sweating. A dark *coloration of the skin* sometimes takes place, more decided in those situations in which the pigment is naturally more abundant, such as the face and arms. Yet the flexures of the joints, the axillæ, the genitals, and the inside of the thighs are also affected. The skin may be uniformly bronzed, or it may be darker in patches. Parts of the body which are subject to constant pressure are also disposed to take on pigmentation more deeply. *Edematous swellings* of the skin in various parts of the body may occur, and are to be carefully separated from edema the result of associated conditions, such as anemia, organic heart disease, etc. It manifests itself as swelling in the feet and ankles, and has been ascribed to vasomotor paralysis. The *nails* sometimes become thin, and occasionally have a corrugated appearance.

Gastro-intestinal symptoms are frequent, manifesting themselves by attacks of diarrhea, apparently of nervous origin, coming on suddenly without pain, with copious loose motions, of which there are two or three or

* "Twentieth Century Practice of Medicine," vol. iv., 1895.

more in a day. With this uncontrollable vomiting may be associated. Acute forms are sometimes thus ushered in. The *tongue*, however, *remains clean*, and there is, *as a rule no rise of temperature*. Sometimes there may be very slight fever. The skin discoloration and gastro-intestinal symptoms suggest those of Addison's disease, and it is not impossible it may have been associated. *Rapid breathing* is a frequent accompaniment, equaling thirty to forty respirations a minute. It may be associated with *cyanosis* of the face and swelling of the vessels of the neck. *Intermittent albuminuria* is frequent, as pointed out by Dr. Begbie. *Derangements of menstruation* are less frequent than might be expected, this function being normally maintained in the majority of instances. *Pregnancy is infrequent*.

The *mental condition* has been alluded to. It may be added that fits of depression alternate with buoyancy, while the moral nature may also be changed to a degree amounting to melancholia and mania. Active cerebral symptoms are sometimes present. This mania is of bad augury. Dullness or stupor seems to be entirely absent.

Among complications, *hysteria* and *chorea*, and even *epilepsy* are included.

Diagnosis.—This needs no description. The combination of the three cardinal symptoms named can receive no other interpretation. There may be some doubt at the beginning, which time will shortly remove.

Prognosis.—Exophthalmic goitre is rarely fatal in itself, the patient usually dying of some other disease. At times the condition remains permanent, with little change, but in the course of time the majority of cases improve greatly, and some get well. I have been watching for years a young woman who, nineteen years ago, had striking exophthalmic goitre, with its usual train of symptoms, who is now well, except that her eyes are slightly more prominent than is strictly natural. A physician of my acquaintance is in the same condition, attending actively to practice.

In some rare instances a rapidly fatal course ensues, death taking place in a few days after the onset. The majority of cases run a chronic course, the symptoms persisting more or less for years. When death occurs, it is from failure of the heart. It is generally preceded by an aggravation of all the symptoms. It may be sudden, as by syncope. Acute cases are reported, with characteristic symptoms, following one of the cited causes, in which the symptoms lasted a few days, and then disappeared completely.

Treatment.—Rest and protection from excitement are essential conditions to successful treatment. After this, the treatment is mainly directed to the symptoms. The remedies most used are the bromids and digitalis: digitalis to slow and steady the pulse; the bromids for two reasons—(1) as nervous sedatives, and (2) for their reputed action in producing anemia of the nerve centers.

In some cases, where there is no cardiac lesion and the pulse is good and strong, aconite with the bromids is of service. Ergot, for its power of contracting the caliber of blood-vessels, is also a rational remedy. There is a difference of opinion as to the propriety of administering iron. I believe the decision should be based on the condition of the patient and the presence or absence of anemia. By German writers, galvanism of the sympathetic is claimed to be of service. Theoretically, it should be. A constant current of from five to eight cells is used: the negative pole is placed on the fifth cervical vertebra, the positive pole along the sternum. Special efficiency has been claimed for the tincture of *nux vomica* by J. New-

ton Hunsberger, of Skippack, Pa., who called my attention to it. Dr. Hunsberger gave it to a well-marked case, beginning with doses of twenty-five drops, increased to fifty (0.77 to 1.54 c. c.). In three months after the treatment commenced the patient was able to do all her work, and has continued well ever since.

Consistent with his view as to its etiology, Prof. Thomson insists upon the absolute necessity of a milk diet, which he says should be kept up for two years. He suggests the fermented milks where the ordinary milk is not well borne.

Thyroid extract has not proved useful so far as tried—in fact, has appeared to be harmful. My friend, Dr. James C. Wilson, has used extract of suprarenal capsule with apparent advantage—five grains (0.33 gm.) in tablet form at a dose. The results of operative treatment have been somewhat satisfactory. Oppenheimer has collected 68 cases, of which 18 recovered completely, in 26 there was more or less improvement, in 9 there was no change, 5 died almost immediately, and 4 within twenty-four hours.

MYXEDEMA.*

SYNONYMS.—*Cachexie pachydermique* (Charcot); *Cachexia thyroidea vel strumipriva vel thyreopriva* (Kochler); *Athyrea*; *A Cretinoid State Supervening in Adult Life in Women* (Gull).

Definition.—A myxomatous infiltration of the subcutaneous connective tissue of the body, characterized also by dryness of the skin, subnormal temperature, mental failure, and atrophy of the thyroid gland.

Historical.—Nearly one hundred years ago King, of Guy's Hospital, London, showed experimentally that the colloid matter of the acini of the thyroid gland passed into the lymphatics and thus suggested the idea of what is called in modern times an internal secretion. Schiff showed in 1859, by experiment on carnivora, that the gland is important to life, and confirmed this in 1884 by showing that the removal of the organ alone in these animals is followed by striking symptoms preceding death. In 1884-85-86 Victor Horsley, experimenting on monkeys and later herbivorous animals, showed that myxedema could be produced in the monkey by removing the thyroid gland. The disease itself, as occurring in man, was first described by Sir William Gull in England in 1873 as a cretinoid change; further described by William M. Ord in 1877, and named by him myxedema. It was also studied by Charcot, who called it *cachexie pachydermique*. In 1882 Jacques L. Reverdin called the attention of the Medical Society of Geneva to the occurrence of the symptoms of myxedema after total extirpation of the thyroid in the human subject. Theodor Kocher states that in the autumn of 1882, previous to this event, he spoke to Professor Reverdin of the remarkable consequences of the operation, and that six days later Reverdin read a paper on the subject. In 1883 Kocher reported to the Twelfth Surgical Congress at Berlin similar results in patients from whom he had entirely removed the thyroid gland, calling the condition *cachexia strumipriva*, having previously known nothing of myxedema as a disease. He did not, therefore, attribute the condition to the loss of the thyroid, but to injuries received in the structures of the neck in the operation. In a succeeding paper the brothers Reverdin recognized the condition as identical with myxedema, and called it *myxedema operatoire*. Shortly afterward Felix Semon suggested that the loss of function in the thyroid gland was probably the common factor in the production of both. Victor Horsley's results were not published until 1890, the same year in which von Eisberg† announced that the removal of the thyroid caused tetany. Horsley ascribes the tetanic symptoms to the fact that the animals were kept at a temperature of 90° F. (32.2° C.) after

* The student is referred to five noteworthy papers on the subject of "Myxedema and Cretinism" in vol. viii., 1893. "Transactions of the Association of American Physicians," by Francis P. Kinnicut, James J. Putnam, M. Allen Starr, W. Gilman Thompson, and William Osler; to the "Atlas of Clinical Medicine," by Byrom Bramwell, for admirable illustrations; and to the exhaustive article on "Myxedema" by George R. Murray, of Newcastle, England, in the "Twentieth Century Practice of Medicine," vol. iv., 1895. Also to an Address by Victor Horsley on the "Physiology and Pathology of the Thyroid Gland," published in the "British Medical Journal," December 5, 1896.

† Von Eisberg's experiments were made chiefly on cats.

the operation. N. Weiss also pointed out that tetany is apt to follow operative extirpation of goitre. In 1890 Horsley published a note on the possibility of the successful treatment of myxedema, sporadic cretinism, and cachexia strumipriva by grafting with thyroid tissue from the necks of animals, though in this he was anticipated by Kocher in 1883 and Bircher in 1889. Kocher's graft was absorbed, but Bircher's patient was enabled to return to work. Victor Horsley's results were a part of a report by a committee of the Clinical Society of London, appointed in 1883, whose conclusions were as follows:

1. Myxedema is identical with cachexia strumipriva.
2. Sporadic cretinism is myxedema occurring in childhood.
3. Endemic cretinism is also closely allied to myxedema.
4. Further, that while these conditions are dependent on loss of function due to removal or disease of the thyroid gland, the ultimate cause of this loss of function in ordinary myxedema is not as yet explained. George R. Murray suggested the hypodermic injection of the gland extract in 1891 and Horwitz of Copenhagen, E. L. Fox, and H. Mackenzie its internal administration.

Etiology.—All forms of myxedema are the result of disease or removal of the thyroid gland, but what excites this disease is not known. It is much more common in girls. In the simple form, a minor rôle may be assigned to heredity, but in cretinism heredity plays no part, as cretins are not sexually developed. Yet it occurs in members of the same family, which only goes to show that one cause operates to produce it. Many are the children of neurotic persons, while Langdon Down considers that alcohol is responsible, especially if the alcohol habit is present at the time of procreation.

Morbid Anatomy.—The morbid changes in the myxedema after death are those described as characteristic in life, but autopsy has disclosed the thyroid absent in nine out of ten cases of cretinism examined, confirming the theory of its origin. Enlargement of the *hypophysis cerebri* was found in six cases of cretinism by different observers, and Horsley says that the convolutions of the brain are ill-defined, and the blood-vessels small, even in proportion to the rudimentary condition of the nervous system.

Symptoms.—Three groups of cases are recognizable:

1. Pure myxedema.
2. Myxedema associated with congenital or sporadic cretinism.
3. Operative myxedema or cachexia strumipriva.

1. *Pure Myxedema.*—This is much more frequent in women than in men,—at least as six to one,—and occurs usually between the ages of thirty and fifty, but is not confined to these ages, being found in those who are younger and older. Heredity is a recognized factor, acting usually through the mother. Several members of a family may be affected. The poor suffer most. It is said to have no relation to the catamenia, but has followed frequent pregnancies, injuries, severe hemorrhage, and mental disturbance. Most essential is some change in the thyroid gland. Formerly thought to be rare in this country, cases have multiplied since attention has been called to it.

The face is the chief seat, but the extremities, the trunk, the tongue, and even the internal organs may be involved. The *face is uniformly swollen, broadened, and flattened, the nose is broad, the mouth large, all lines are obliterated, and expression is gone. The skin of the neck above and below the clavicle is thrown into folds of fatty and myxomatous tissue. It is yellow, translucent or waxy, dry and scaly. The cheeks and sometimes the nose are flushed. True edema may be associated, and there are rarely albuminuria and glycosuria. The hands lose their natural shape, and were described by Gull as "spade-like"; the feet are also misshapen; the gait is slow and labored. The mind is feeble, slow in its action, memory is poor, while irritability and suspicion are added qualities, and sometimes there are*

delusions and hallucinations, ultimately often dementia. The organic functions are fairly well performed. *Atrophy of the optic nerve* is a rare but possible symptom, also *synovitis* from trifling causes. *Subnormal temperature* is characteristic, though in early stages the temperature may be normal or slightly above. In winter the patient always feels cold and hugs the stove. The course of the disease is slow, and the patient usually dies of some intercurrent affection.

2. *Myxedema Associated with Cretinism, Congenital or Acquired.*—(Cretinoid idiocy: Idiotie avec cachexie pachydermique.) Cretinism is a form of idiocy associated with absence of the thyroid or with a functionless thyroid. It is myxedema in childhood. There is almost complete *arrest of mental and bodily development*. The cretin is a dwarf. In the *congenital* form, there is congenital absence of the thyroid, and the child is further characterized by its thick neck, short arms and legs, and prominent belly. The face is large, the lips are thick, and the tongue is large and often protruding. All the bones of the skeleton are short and broad, the epiphyses swollen, but not ossified. The skull is short and broad, and the basosphenoid junction early ossified. The cretin resembles the rickety child, and may be confounded with it.

Acquired cretinism may start before birth and be barely appreciable at birth. More frequently the infant appears normal at birth, and the changes make their appearance between the *second* and *fifth* years. The arrest of development continues, or, rather, there is very slow development, so that at adult age the man or woman does not exceed in stature a child of from five to seven years. The myxedemic symptoms are similar to those described in pure myxedema.

From the fact, however, that the disease may start to develop later than infancy, there results a series of types intermediate between those represented by congenital and adult cretinism. This arrest of mental and physical development is, of course, greater the earlier the disease begins to develop; whence two cretins of the same age will differ materially if one has commenced to develop at or before birth, and the other not until seven or eight years of age.

True congenital cretinism—that is, cretinism which is evident at birth—is very rare. Some cases of supposed intra-uterine rickets may have been cretinism. In most cases, the child does not long survive its birth. In another form described by Horsley the disease is supposed to begin shortly before birth, but develops slowly, so that at birth it has not attained the degree incompatible with life, and the child can live. In this there is usually a goitre at birth.

Cretinism may be endemic, as in some parts of the continent of Europe; or sporadic, as in England, and America as well. The sporadic cases are, as a rule, without goitre, the thyroid glands being either undeveloped or atrophied, while one-third also of the endemic cretins are without goitre. In either event, the gland is functionally dead, even though it may appear natural in size, the original true gland tissue having been replaced by an indifferent element. Endemic cretinism occurs in localities where goitre is also endemic—in the shut-up valleys of mountainous districts of Europe and Asia, to which it is confined. At one time—in 1847—a number of cases—some 24 out of a population of 350—prevailed in Cheselborough, Somerset, England, but the disease has died out. The endemic form is commonly ascribed to the use of certain drinking waters, but no responsible

constituents have been isolated. The child, being normal at birth, remains so until the change begins in the thyroid, when it becomes less lively, development is arrested, and the conditions described on page 678 slowly develop. The cretin may reach the age of thirty or forty years, but ceases to change after the twentieth year, whether the case be sporadic or endemic.

3. *Operative Myxedema or Cachexia Strumipriva*.—By this is meant a condition of myxedema the result of removal of the thyroid (see History, p. 676). It is more likely to follow total than partial removal of the thyroid, but does not follow every case, having been observed in 69 out of 408 cases. Cases of operative myxedema are very rare in this country.

Diagnosis.—This is easy. The *edema of Bright's disease or heart disease* may be confounded, especially as albuminuria and casts are sometimes present in myxedema; but the peculiar flat face, the absence of pitting on pressure, and of the signs of heart disease are distinctive features of myxedema.

Prognosis.—This was regarded as unfavorable until the hypodermic use of thyroid extract was suggested by George R. Murray, of Newcastle, England, in 1891, based upon the satisfactory effect obtained by Bettencourt and Serrano, in 1890, in ingrafting sheep's thyroid in human subjects having myxedema, the idea being in this manner to substitute the juice or secretion of the gland. Every expectation was realized. In 1892, Howitz, of Copenhagen, and soon after, E. L. Fox and H. Mackenzie, in England, substituted for the hypodermic use the administration of the gland itself or some preparation of it by the mouth. At the present day, the effects of the administration of thyroid preparations in myxedema are among the marvelous results of medicine.

Treatment.—The treatment at the present day is, therefore, solely by the sheep's thyroid. The gland is best administered in the shape of glycerin extract or tablet. From fifteen minims (1 gm.) to thirty minims (2 gm.) of the former and five grains (.33 gm.) of the latter are to be given daily, its effect being carefully watched. If no effect follows, the dose should be doubled, and further increased if necessary. As improvement takes place, smaller doses should be given at longer intervals, until finally from ten to fifteen minims (0.66 to 1 gm.) or ten to fifteen grains (.66 to 1 gm.) of the solid extract are given once a week or less often. During the first week the patient should be watched, with a view to guarding against heart failure, prohibiting all physical exertion on his part, this being an apparent effect of the medicine in excessive doses.

The myxedema being removed, it is necessary, of course, to continue the treatment in this second stage by such doses as will maintain the cure, for it is to be understood that, as the thyroid is still functionless, the omission of the treatment is followed, sooner or later, by its return. The quantity required varies in different cases, but it is found to range between five and fifteen minims (0.33 to 1 c. c.), the more precise dose being determined by trial. A single daily dose is preferred by Murray to a smaller dose more frequently repeated. A fall of temperature below normal, a slight return of swelling or of other symptoms, indicate that too small a dose is being given, while acceleration of the pulse indicates that the dose should be reduced. In a climate not subject to great variations the same dose may be given the year round. In hot weather a smaller dose suffices than in cold, and a dose that has been found sufficient during the summer may not be enough in the winter.

The treatment of cretinism is also by the thyroid extract. Relatively larger doses of thyroid extract can be given to children than to adults. The liability to syncope during treatment is less marked than in myxedematous adults, but it is advisable not to allow any unusual exercise during the first part of the treatment. In the absence of the extract, the sheep's raw thyroid may be administered, giving one-eighth to one-quarter of a lobe twice a week.

Thyroid grafting is also employed for the treatment of cretinism, with the same results and same shortcomings, and is carried out in the same way. It is especially with a view to more permanent results that the successful application of this method is desirable, and symptoms have been kept in abeyance for some time by it. Sooner or later, however, they return, and the operation must be repeated or the extract administered. If grafting, which is usually done into the peritoneal cavity, is practiced, it should be preceded by a course of thyroid extract, and the symptoms of myxedema removed as far as possible before the operation is done, usually for two or three months. The details of operative treatment are left to the surgeon.

The results of treatment in cretinism are as marvelous as in myxedema. They include not only the removal of the hideous deformity and the restoration of intellect, but also an increase in height, which, though not amounting to a restoration of the normal height, is still appreciable. The earlier treatment is commenced, the more prompt and marked is its effect.

Of the treatment previous to the introduction of that by thyroid extract, that by jaborandi and pilocarpin should be mentioned, because the partial benefit derived from them is explainable by supposing that they produced increased activity in small portions of residual glandular tissue. Should thyroid extract be unattainable, these drugs may still be used.

NEOPLASMS OF THE THYROID.

The thyroid is subject to a variety of morbid growths, among which may be mentioned:

1. *Adenoma*, which occurs as an encapsulated growth, varying considerably in size. There may be nodules in both lobes. Metastases of growths resembling thyroid tissue are reported to have been found in the lungs and bones of the body.

2. *Primary medullary cancer*, as a rare growth with a tendency to invade the trachea and esophagus, developed from the epithelial cells of the follicles. *Secondary cancer* has also been reported.

3. *Tuberculosis*, always supposed to be a possible but rare disease, has been found by Chiari in seven out of 100 postmortems on persons who had had tuberculosis. Bruns refers to six cases of tuberculous goitre.

4. *Syphilis*, including gummy growths.

5. *Hydatid disease*.

6. *Actinomycosis*.

Abscess of the thyroid is an occasional event.

The **treatment** of these abnormalities is surgical, except in the case of tuberculosis and syphilis, which demand the usual antitubercular and anti-syphilitic remedies.

DISEASES OF THE SUPRARENAL CAPSULES.

ADDISON'S DISEASE.

Definition.—A term applied to any disease of the suprarenal capsule.

Morbid Anatomy.—This includes (1) tuberculosis with fibrocaseous and calcareous degeneration; (2) cystic degeneration; (3) fatty degeneration; (4) simple atrophy; (5) chronic interstitial inflammation which may lead to atrophy; (6) malignant disease, including carcinoma and sarcoma; (7) hemorrhagic extravasations; (8) embolism.

Symptoms.—Some of these morbid states appear to be totally without symptoms, the conditions having first come to light at autopsy. Other symptoms may be produced by any of them, and there is none distinctive for any one state. They include:

Pigmentation or *bronzing* of the skin. This was first described by Addison as associated with disease of the suprarenal capsules, an association which, since the publication of his paper in 1855, has been called Addison's disease. The clinical concept thus named is especially a disease of the lower classes, Dr. Greenhow having found nine-tenths of cases among laboring people. It is also a disease of adults, being rare under thirty-five years. The lesion most frequently thus associated is the fibrocaseous tubercular one. But, as stated, the pigmentation may accompany any one of the above-named lesions, if prolonged, or may be absent in the presence of any one. As to the *coloration* itself, which is usually the first symptom to attract attention, it varies from a light yellow to a deep brown, and even almost black. It is deeper on the more exposed parts of the body, where the normal pigmentation is greater, and therefore is commonly first seen on the face and hands. In rare instances only is it general. It is associated at times with patches of absent pigmentation—leukoderma. It is noticeable also at times on the mucous membrane of the mouth, conjunctiva, and vagina, and very rarely even upon serous membranes in patches.

Great pains have been taken to explain this peculiar "bronzing," ascribed by Addison himself to the loss of function of the adrenals. Two chief theories have been suggested:

1. By experimental evidence it has been sought to show with some reason that these glands furnish some sort of internal secretion essential to normal metabolism. To explain those cases in which the adrenals are diseased and yet there is no pigmentation, it is suggested that accessory adrenals may be present, though none has been demonstrated, so far as I know; while the presence of pigmentation in association with healthy adrenals is ascribed to disease of the adjacent semilunar ganglia interfering in some way with the blood-vessels or lymphatics of the glands. Such a theory, that a secretion furnished in health by the suprarenal capsule is necessary to normal metabolism, is analogous to that which ascribes myxedema to the loss of function of the thyroid gland, and has acquired some additional support from the knowledge recently added upon this subject.

2. According to the second theory, the pigmentation is ascribed to disease of the abdominal sympathetic system itself, commonly associated with disease of the adrenals, but also at times caused by other chronic disorders which invade the solar plexus and ganglia. In one of my own cases in which all the symptoms, including pigmentation, were conspicuous, and

which came to autopsy, there was found, in addition to the advanced tuberculosis of the suprarenal capsules, also an enlarged semilunar ganglion. The latter view would make it a disease of the nervous system, and the pigmentation a trophic phenomenon.

As stated, there are no other symptoms which are distinctive of any one of the lesions of the suprarenal capsule described, but among those which are more or less constantly associated are *anemia*, *extreme debility* and *general languor*, *irritability of the stomach*, and quite often *diarrhea*. The irritability of the stomach is manifested by anorexia, nausea, and vomiting, and may be a very early symptom. The heart's action is feeble, the pulse correspondingly small and rapid, and there is also often a tendency to fainting. There is *dyspnea*. At other times there is *headache*. *Mental hebetude* goes *pari passu* with bodily weakness, while the other symptoms commonly associated with the latter condition are also present—namely, dizziness and ringing in the ears. Ultimately, the *asthenia* becomes so profound that the patient cannot rise, but keeps his bed, growing weaker and weaker, until he dies of sheer exhaustion. Sometimes there are *convulsions*, possibly due to brain anemia.

The *urine* is usually normal, although occasionally there is polyuria, and sometimes the urinary pigments have been found increased.

Diagnosis.—It is probable that pigmentation alone, at least unless it be very decided and general, is never sufficient to justify a diagnosis of suprarenal disease, since other abdominal affections are known to produce a similar condition. Among these are tuberculosis of the peritoneum, cancer, and lymphoma; pregnancy, uterine and even hepatic disease. The popular notion that every discoloration of the skin is due to some *derangement of the liver* (liver-spot) has scanty foundation. In the hardening of the liver sometimes associated with *diabetes*, pigmentation has been noticed. All these facts go to show that the nervous system must have some powerful influence, supporting the second theory. The same testimony is afforded by the pigmentation which attends *exophthalmic goitre*. *Protracted filthiness* and vagabondism also produce discoloration of the body which is not distinguishable *per se* from that of Addison's disease. Deep general pigmentation has been found associated with *melanotic cancer*. Finally, pigmentation is sometimes the result of the prolonged administration of arsenic. It is well, therefore, to seek carefully for signs and symptoms other than pigmentation before a diagnosis is made. In the case of my own referred to, there were pulmonary tuberculosis and tuberculous disease of the spine, with pigmentation and asthenia, on which was based the diagnosis of Addison's disease, confirmed by autopsy.

Prognosis.—In a well-determined case of Addison's disease, as might be inferred from the nature of the causes, recovery is impossible, though the course of the disease is commonly prolonged and improvement may take place. In a few cases only is the course rapid. From eighteen months to several years usually cover the duration.

Treatment.—This is principally symptomatic. We aim to restore the condition of the blood, and, of course, above all, iron is indicated. It may be associated with that other tonic so constantly used with iron especially—arsenic. An excellent preparation of arsenic in the solution of the chlorid, which is as good as Fowler's solution and mixes well with the chlorid of iron. The doses are the same as those of Fowler's solution—from three to five minims (0.18 to 3 c. c.); or the iron and arsenic may be given in pill

form as the carbonate of iron and arsenious acid, and to this strychnin may be conveniently added. If very asthenic, the patient should be kept in bed and fed on alcohol, with nutritious, easily-assimilable food, of which peptonized milk and broths, beef-juice, cod-liver oil, and glycerin are the type. The diarrhea should be treated as other diarrheas, with bismuth and other remedies. For the nausea the usual gastric sedatives, including ice, carbonic acid water, champagne, milk and lime-water in small doses, koumiss, whey, and the like are suitable.

With the knowledge which has grown out of the treatment of myxedema with thyroid extract, no treatment of the combination of symptoms known as Addison's disease would be complete without the administration of some similar preparation of the adrenal. George Oliver has had prepared an extract in the shape of the tincture; a powder and a glycerin extract are made; and the glands are eaten fresh or dried. The equivalent of two a day is recommended. Of the powder, three to five grains (0.2 to 0.3 gm.) are given three or four times a day. While no conclusive evidence of its efficiency has been obtained, the results of experience favor further trial of the preparation.

SECTION VII.

DISEASES OF THE URINARY ORGANS.

GENERAL SYMPTOMATOLOGY.

Three important symptoms more or less characteristic of diseases of the urinary organs, and especially of disease of the kidneys, may, for the sake of brevity, be considered at the outset of our studies of these affections. They include *albuminuria*, *renal dropsy*, and *uremia*.

ALBUMINURIA.

Definition.—By albuminuria is meant a condition of the urine in which it contains some one of the forms of albumin of which at present we need consider only serum albumin and globulin. The sources of the albumins in urine are various, and may be conveniently divided into *extrarenal* and *renal*.

EXTRARENAL ALBUMINURIA.—The pelvis of the kidney, the ureters, the bladder, the urethra, and in the female the vagina and uterus in addition, are the most important sources of extrarenal albuminuria. In all of them it is almost invariably the serum of *pus* formed during catarrhal inflammation which furnishes the albumin. The presence of pus-corpuscles, therefore, in sufficient number in the urine commonly explains the source of such albumin, which is, moreover, usually small in quantity—never more than about one-tenth the volume of urine tested, even with the most copious sediment of pus. It must not be overlooked, however, that the two sources, kidney disease itself and the mucous surfaces referred to, may coexist, in which event careful microscopic examination will sooner or later discover tube-casts, while the quantity of albumin will be larger than can be accounted for by the presence of pus alone.

Menstrual or lochial blood need only be referred to as sources of albumin in the urine hardly likely to be overlooked by any physician; while hemorrhage from any one of the mucous surfaces referred to, as well as from the kidney itself, would be a source of albuminuria. It is usually comparatively easy to determine whether a hemorrhage has its source in the kidney or in the mucous membranes previously mentioned. In the former coagula are rarely present, for the blood, entering the ureter slowly, becomes intimately mixed with the urine. It imparts to it, too, when acid in reaction, a *smoky hue* which is very characteristic. The coloring-matter of the corpuscles is commonly dissolved out by the urine which is thus tinged, and on standing, the stroma of the corpuscles sinks to the bottom as a brownish sediment. The microscope reveals these corpuscles shrunken, almost colorless, and often crenated. I have said that the smoky hue is present only in acid urine. When the latter becomes alkaline, either by spontaneous or artificial change in reaction, it assumes a brighter red hue, the degree of which depends upon the quantity of blood. The same cause, acidity, produces the smoky hue of blood

which is vomited, and therefore mixed with gastric juice. When blood comes from the pelvis of the kidney or the ureter in any quantity, coagula which are molds of the ureter are sometimes found, the descent of which is often attended with severe pain.

Another source of albuminous urine, though not likely to cause error, should be mentioned—viz., the so-called chylous urine, or chyluria, in which in consequence of some as yet imperfectly understood communication between the lymphatic system and the urinary tracts, chyle enters the urine and imparts its physical and chemical characters thereto. These are the presence of albumin, a milk-white appearance due to the presence of fat in a molecular state.

The kidney itself may be the seat of suppuration, and contribute through the pus thus added to an albuminuria.

RENAL ALBUMINURIA.

The Immediate Cause of Renal Albuminuria.—Delayed circulation of the blood through the glomeruli is doubtless of itself sufficient to cause albumin, an otherwise non-osmotic substance, to pass through the walls of the capillary blood-vessels into the urine, though it is more than probable that an altered state of the renal epithelium also contributes to a facility of transit. The necessary obstruction is produced by any cause which sufficiently resists the movement of the blood through the kidneys, whether it resides in the organ itself or in the venous system beyond it, whence the albuminuria which so often attends extreme valvular disease of the heart. The comparative smallness of such albuminuria as contrasted with that in parenchymatous nephritis, in which the renal cells are an early seat of change, is strong evidence in favor of some active participation of epithelial change in causing albuminuria. In chronic albuminuria another important influence operating to facilitate the transudation of albumin is a hydremic state of the blood, which is in turn a consequence of albuminuria.

Renal albuminuria also occurs as a secondary symptom in diseases other than renal. First may be mentioned the albuminuria of fever, such as that of typhoid fever, smallpox, etc. The albuminuria of diphtheria and scarlatina, due to an intercurrent parenchymatous nephritis, is, of course, not intended. The febrile albuminuria alluded to is not usually large, and disappears with the decline of the disease. It is in great measure the result of irritation of the kidney by the infectious agent; possibly also, in part, the result of diminished cardiac force with which the blood is driven through the kidneys and of the resulting turgor.

Other conditions in which albuminuria thus occurs are anemia, leukemia, diarrhœa, cholera, lead colic, also certain conditions of the brain and spinal cord, including hemorrhages into the brain, meningitis, epilepsy, tetanus, and others. In all of these there is probably diminished arterial pressure directly or indirectly through the nervous system.

The significance of renal albuminuria has altered greatly as our knowledge of this subject has increased. While large albuminurias of renal origin can scarcely be due to anything else but renal disease, and the degree of albuminuria is within limits a measure of the seriousness of the disease, yet the important fact remains that there may be true albuminuria, usually moderate, in which there is no disease of the kidney whatever; there may also rarely be Bright's dis-

ease in which there is no albuminuria. The significance of albuminuria is always increased by its association with tube-casts, yet there may be both albumin and casts in urine where there is no Bright's disease, while again, there may be Bright's disease without albumin or casts. I myself incline to the belief that such cases are infrequent, and yet this possibility must be acknowledged. In illustration of what has been said I may refer to:

PHYSIOLOGICAL OR FUNCTIONAL ALBUMINURIA.—The presence of a physiological or functional albuminuria at the present day is generally conceded. By it is meant an albuminuria unassociated with other symptoms. There are no tube-casts or feeling of ill-health. Such albuminurias are often discovered accidentally, especially by examiners for life-insurance. Much care should be exercised in concluding upon the nature of an albuminuria suspected to be functional. In the first place, it should be small, not exceeding one-tenth the bulk of urine tested, and through it is not necessary that it should be absent on rising, yet it is a strong point in favor of the functional nature if it is absent at this time and present only after some exertion has been made or on taking food. No tube-casts should be in the urine, the urea should be in sufficient quantity, there should be no retinal change, no hypertrophy of the left ventricle, no high tension to the pulse, nor even a suggestion of dropsy. Further, this condition should be watched over a considerable length of time before the conclusion is arrived at that we have to do with a harmless functional albuminuria.

Other proteid matters are sometimes found in the urine, such as globulin, mucin, peptone, and hemialbumose, but except in the case of globulin, their clinical significance is not sufficiently determined to justify their further consideration in a text-book. A certain amount of *globulin* is always associated with albumin. In an ordinary serum albuminuria the ratio commonly maintained is 10 to 18 of serum albumin to 1 of globulin, the ratio in the blood being 1 of serum albumin to 1 1-2 to 3 of globulin. A like ratio holds for these constituents in pus.

This ratio in albuminuria is at times exceeded especially in the case of the amyloid kidney, where I regard the presence of globulin in large amount as of diagnostic value.

TESTS FOR ALBUMIN AND GLOBULIN.

TO TEST FOR ALBUMIN.—The test which is at the same time the most delicate and reliable is the heat-and-acid test. It is best applied in the following manner:

The Heat-and-Acid Test.—A suitable quantity of urine, filtered if not clear, is poured into a test-tube, say to a depth of five cm. (2 inches), and boiled over a Bunsen flame or spirit-lamp. Then nitric acid is added, drop by drop, until from ten to fifteen drops are added to this quantity of urine. Any precipitate produced in the act of boiling which is dissolved by the acid is phosphates. After the total quantity of acid has been added the tube is placed aside for half an hour, and if at the end of this time no further precipitate appears, the specimen may, for clinical purposes, be declared free from albumin. It is very important that the acid should not be added first, as is sometimes directed, for it often happens that when a considerable amount of albumin is present, acid albumin is formed which is not precipitable by heat, and thus such quantities of albumin may elude detection. The test of heat and acid applied in the manner described is really more delicate than the con-

tact method with nitric acid, recognizing, as it does, smaller quantities of albumin.

The Contact Method with Nitric Acid, or Heller's Test.—On the other hand, the contact method with nitric acid is free from the error possibly occasioned by acid albumin to which the heat-and-acid test is subject. The contact method, also known as Heller's test, is best done by placing a sufficient quantity of nitric acid in the bottom of a test-tube and overlaying it gently with urine. If albumin is present, a sharp white line will promptly form above the acid. A dark, reddish-brown color-line which forms in concentrated urines at this point will not, of course, be confounded with albumin. Furthermore, in concentrated urines a layer of acid urates, dirty white, is sometimes found at the junction between the two fluids. It behaves very differently, however, from the sharp white line of albumin, since it soon begins to rise above the surface, while the albumin remains at its primary position. Further, this less definite layer is promptly dissipated on the application of a moderate heat. When the heat-and-acid method and the contact method are jointly used in the way described, it is impossible for such an amount of albumin as is of clinical significance to elude detection. It is true that picric acid solution, Tanret's iodo-mercuric solution, and one or two others are slightly more delicate than the heat and acid, but they are subject to a now generally acknowledged source of error, the precipitation of mucin and of the vegetable alkaloids of which quinin is the type, which always appear in the urine when administered in full doses.

The Picric Acid Test.—As confirmatory test, however, the picric acid solution is very useful, and if its application is negative, we may feel assured that there is no albumin present, while a delicate response is doubtful, for the reason named. The picric acid test is also best applied in the contact method, the urine being placed in the tube first and overlaid with the saturated picric solution, because the picric acid is commonly lighter than the urine to be tested. When they are of the same specific gravity, it is not easy to maintain a separation at the line of contact, but a careful examination of the fused portions will recognize a diminished transparency due to either mucin or albumin. A saturated solution of picric acid should always be kept on hand for the control purposes named.

TO TEST FOR GLOBULIN.—Globulin may be separated by Poehl's method as follows :

Render the urine slightly alkaline by ammonium hydrate, and after several hours filter, to separate the phosphates. Then add saturated neutral solution of ammonium sulphate in the proportion of one volume to one volume of the filtrate. If a precipitate forms, it is globulin.

RENAL DROPSY.

Renal dropsy does not differ essentially from cardiac dropsy, though it is less directly traceable to venous obstruction and consequent transudation. It very frequently appears first in the face and upper extremities, and this fact alone goes to show that something else than obstruction to the circulation enters into its causation. In addition, it is well known that there may be advanced renal disease without dropsy when one would naturally expect obstruction. Venous obstruction must, however, be considered as one of the con-

tributing factors, especially when in the lower extremities. Aside from this we must have recourse to theory to explain it. A hydremic state of the blood very probably favors the transudation in certain cases, this being occasioned by the deficient water secretion so often present. At first thought this would seem an explanation scarcely sufficient to explain the edema which appears so early in many cases of acute Bright's disease, but this objection is more apparent than real, for one need pause but for a moment to realize how quickly blood may become hydremic with an almost total anuria, while the habitual quantity of water continues to be ingested daily. Moreover, diminished urinary secretion often exists for some time before attention is called to it. I believe that sufficient stress has not been heretofore laid on this factor.

As the disease advances, the conditions favoring the hydremic state continue and grow so that in advanced stages this element doubtless contributes largely. It is more than likely also that in such stages alterations of some kind in the vascular and lymphatic walls contribute to facilitate the transudation, while the diminished elasticity of surrounding tissues may also constitute a factor. Where edema does not occur, its absence can only be explained by the presence of continued secretion of water by the kidneys or by supplemental secretion by some other organs, as the skin and bowels.

The degree of dropsy varies greatly in different cases and different forms of Bright's disease, being in some cases trifling and in others enormous, including, ultimately, invasion of serous cavities like those of the pleura, peritoneum, and even pericardium.

UREMIA.

The third symptom common to renal disease, and, indeed, peculiar to it, is uremia. It may be defined in general terms as a condition due to retention within the blood of excrementitious substances which it is the function of the kidney to excrete and which it does excrete in health. When we come to separate these substances, we are, however, completely at a loss, for no clinical or experimental studies have as yet given us the required information. Pre-eminently the experimental introduction of urea into the blood has repeatedly failed to excite symptoms of uremia, though the animals on which these experiments were made were presumably sound. Ligation of the renal veins has been equally futile in producing them. C. A. Herter has shown that the toxicity of the blood-serum is increased in uremic states, while extirpation of the kidney or a part of it increases the accumulation in the blood of urea and nitrogenous substances of the creatin class. It is probable also that the alloxuric bases, xanthin, hypoxanthin, which are virulently toxic, contribute to the sum of toxins responsible for uremia.

In consequence of such failure, clinicians—and pre-eminently Traube—have sought to explain certain of the more active nervous symptoms, such as the coma and convulsions, by supposing a localized edema of the brain or its membranes.

Symptoms.—It is not unlikely that *gastro-intestinal symptoms* including the loss of appetite, nausea, vomiting, and headache which sometimes usher in an attack of nephritis may be the result of retained excrementitious matter. At all events, these same symptoms may be the initial ones of a uremia, coming on suddenly when the cause is unsuspected. Vomiting thus caused may persist, and the patient perish in consequence. *Headache* is often occipital, extending down the neck. To it is superadded *dizziness*.

An early symptom is *drowsiness*, which may be sudden or gradual in its onset and may be slight or decided. From the latter degree the transition is easy to the next symptom, that of *coma*, from which the patient may or may not be temporarily aroused. Alternating with the latter may be epileptoid *convulsions*, which are the most alarming and dangerous symptom of Bright's disease. This is not always the succession of these symptoms. Convulsions may succeed drowsiness, but as often precede and they may occur without warning. Indeed, there may be no suspicion of Bright's disease whatever until a convulsion suddenly occurs. Drowsiness, in like manner, may be the first symptom of the renal disease to attract attention, others being overlooked or possibly even absent. The convulsions exhibit every grade of movement, from the slightest twitching to the most violent epileptiform spasm.

Suppression of urine, an almost constant symptom, is frequently the initial one which should at once excite suspicion. Accompanying it is often a breath of urinous odor, and when vomiting accompanies scanty or suppressed urine, the vomited matters sometimes have the same odor, the elements of urine being thus supplementarily eliminated.

Impairment of vision or actual blindness—amaurosis—suddenly occurring is another symptom of acute uremia which sometimes supervenes upon others, or it may itself usher in the complication. This blindness, it must be remembered, is altogether different from that which is the result of organic retinal changes, which are rare in acute nephritis, but common in some of the chronic forms. It may be due to retinal hemorrhage, but is often unassociated with demonstrable retinal change. Uremic amaurosis often disappears as suddenly as it sets in. Uremic *deafness* is also possible, but is a rare event.

Itching of the skin is another symptom sometimes present in uremia. It is probably due to the irritant action of urea upon the nerves of the skin as it is being supplementarily eliminated by that organ. That such increased elimination takes place is attested by that rare but still unquestioned occurrence, in which the entire integument is covered with a frost-like coating, which has been found upon analysis to be made up of crystals of pure urea.

Another symptom of uremia which belongs rather to the uremia of chronic renal disease is shortness of breath—*uremic asthma*, it is called. This is an asthma which differs from bronchial asthma in the absence of spasmodic contraction of the bronchi, and its uremic origin, I think, is extremely doubtful. I believe it is more frequently what I have described as cardiac asthma, due to heart failure, the result of dilatation succeeding some cases of hypertrophy. It may happen that true spasmodic asthma is produced by uremia, but it must be exceedingly rare. The attacks are likely to occur suddenly at night. To it alone should the name uremic asthma be given. Paroxysms of dyspnea are also caused by edema of the lung, which is not infrequent in acute nephritis. It is recognized by the presence of fine, moist râles. Of course, it is not impossible for nephritis to occur in an asthmatic, whose attacks would then occur as before, independent of the uremic cause, or they might be increased in frequency or rendered more unmanageable by the latter.

Cheyne-Stokes breathing is also a symptom of uremia and may last for a long time. It may occur quite independent of coma. It is more than likely that other disturbances of breathing, even some which closely resemble dyspnea, may be due to disturbances of the respiratory center.

The question of *temperature* in uremia has not been satisfactorily deter-

mined. My own experience points to the absence of any elevation, with at times a tendency to subnormal temperature. I am aware that studies have been published which go to show that an abnormally high temperature is characteristic, and this may exceptionally be the case. But in true, uncomplicated uremia I believe in the majority of cases the temperature will not much exceed the normal. It is true that toward the very end there is commonly a rise, but this attends dissolution in so many diseases that it cannot be considered characteristic.

The *pulse* is often slow in uremia before the appearance of severe symptoms: sometimes as infrequent as from forty to fifty, but with severe symptoms it becomes frequent.

Acute mania and *delusional insanity* (*Folie Britique*) may also be symptoms; rarely melancholia and paralysis, including hemiplegia and even monoplegia. These may occur independently of a convulsion or succeed it, in which event there may or may not be any coarse lesion found at necropsy. True uremic palsies are of undoubted occurrence. I have met hemiplegias which could not be distinguished from those of apoplectic origin until their total disappearance cleared up the matter.

TUBE-CASTS.

Tube-casts or "cylinders," as they are sometimes called, are molds of the uriniferous tubules. Their origin is not always the same. They may be produced by admission into the latter, by reason of capillary rupture or otherwise, of a coagulable constituent of the blood which there solidifies, and in this act entangles whatever it may have surrounded in its liquid state; subsequently it may contract and slip out of the tubule into the pelvis of the kidney, whence it is carried to the bladder and voided with the urine. Casts rarely exceed 1-25 inch (1 mm.) in length.

Two other possible modes of formation of casts must be mentioned, according to one of which the cast represents disintegrated and fused cells which may be the epithelial lining of the tubules, red corpuscles, or leukocytes; and according to another, of a secretion from these same cells as originally suggested by Rovido. That casts are sometimes formed according to the first, at least, of these two methods is not unlikely, while there is reason also to believe that the so-called "cylindroids" or mucus-casts originate in the second way.

That casts are sometimes found in urine free from albumin is undoubtedly true. That persons in whom such casts occur are entirely healthy cannot be as unqualifiedly asserted.

The mechanism of the formation of the different varieties of casts, on the supposition of an albuminoid exudation from the blood, is very simple. Thus, suppose a tubule to be filled with detached and loosely attached epithelium at the time the coagulable material is poured into it. These elements are entangled, and, as the casts contract, are carried out in the shape of an "*epithelial*" cast (Fig. 68). If the tubule should happen to have contained blood, the cast entangling it is called a "*blood cast*" (Fig. 70); if white corpuscles or leukocytes, a "*pus cast*" (Fig. 69). Casts containing even a few blood-corpuscles are also called blood casts. The basic substance of blood casts is most probably the fibrin of the blood. If the epithelium be firmly attached to the basement membrane of the tube and remain behind

when the cast passes out, or if the tube be entirely bereft of epithelium, then is the cast a "hyaline" (Fig. 71) or structureless cast. In the former instance the cast is of *smaller* diameter, and in the latter of *larger*, the diameter in the latter being that of the former plus twice the thickness of an

Fig. 69.—Pus Cast.

Fig. 70.—Blood Casts—(after Whittaker).

epithelial cell. Figure 72 *a*, from Rindfleisch, explains this sufficiently. From causes like these, as well as a subsequent contraction of the cast itself, the diameter of casts may vary considerably, ranging commonly from 1-2500 to 1-500 inch (0.01 to 0.05 mm.). A cast is seldom completely hyaline, gen-

Fig. 71.—Hyaline Casts. X 210.

Fig. 72.—Hyaline and Granular Casts, Illustrating the Formation of the Former at *a*.—(Rindfleisch).

erally containing a few granules and one or two glistening oil drops, but it is still called *hyaline*. Completely hyaline casts do, however, occur. A variety of hyaline cast, more solid in appearance and resembling molten wax, is a "waxy cast" (Fig. 74). Some hyaline casts are so delicate as to be overlooked unless the light from the mirror illuminating the field of view be

modified by shading with the hand or by manipulation of the mirror itself. If a cast contains granular matter, which is generally the granular débris of the degenerated epithelial lining of the tubule or blood-corpuscles, it is called a "granular" cast, and *highly granular* (Fig. 73, *a*), *moderately* or *pale granular* (Fig. 72, *c*), *slightly* or *delicately granular* (Fig. 72, *b*), according to the amount of granular matter present. When the material of granular casts is derived from broken-down blood corpuscles, the casts appear yellow or yellowish-red. Finally, if a cast is loaded with oil drops, either free or contained in epithelial cells, it is called an "*oil cast* or *fatty cast*" (Fig. 75).

Casts of smaller diameter are sometimes found within those of larger, the material of the latter having been poured out around that of the former after it has undergone some contraction. This occurs usually with waxy or hyaline casts. In consequence of the mode of formation previously referred to, hyaline and waxy casts vary considerably in diameter, some being as nar-

Fig. 74.—Waxy Casts. $\times 150$.

row as 1-1000 inch (0.025 mm.) and even narrower, while others are as much as 1-500 inch (0.05 mm.) wide. There is no doubt that some of these are formed in the straight or collecting tubes near their openings on the papillæ. To these a limited number of epithelial cells is sometimes attached.

In addition to the epithelial casts previously described, there are found in urine under the same circumstances molds of the uriniferous tubules made up of simple aggregations of the *epithelial cells themselves*—simple exfoliations of the cellular contents of the tubule, which, having increased by proliferation, form a compact cellular mass. In addition to this are sometimes found epithelial casts in which the cells are seated on the outside or around the fibrinous mold.

Mucus-casts, Cylindroids.—Casts are occasionally found which are apparently pure *mucus-molds* of the uriniferous tubules (Fig. 76). Unless covered by accidental elements, as granular urates or phosphates of lime, they are smooth, hyaline, or gently fibrillated molds, especially characterized

by their great length, in the course of which they divide and subdivide, diminishing in diameter as the division proceeds, showing positively that they come from the kidney. Yet there is no albumin, or merely as much as could be accounted for by the presence of pus which sometimes attends them. For they are particularly apt to occur where there is irritation of the bladder, which is apparently extended through the ureters of the kidney. Under these circumstances they are frequently met. They are not infrequently voided in

Fig. 75.—Oil-Casts and Fatty Epithelium. $\times 200$.

Fig. 76.—Cylindroid or Mucus-Casts. $\times 200$.

cases where the urine has a very high specific gravity, 1030 or higher, containing an excess of urea and urates.

These casts are not identical with the bands of mucin which are found in urine of highly acid reaction. The mucin bands are probably precipitated by the acids, are often beset with granular urates, and might on this account be mistaken for casts. At the same time the mucus-cast is probably nothing but pure mucus or mucin.

DISEASES OF THE KIDNEY.

DERANGEMENTS OF CIRCULATION.

ACTIVE CONGESTION.

Etiology.—Active congestion occurs as the result of poisoning by cantharides or arsenic, overdoses of turpentine, copaiba, cubeb, and carbolic acid. It is identical with the first stage of acute nephritis, however caused. The kidney in acute fever has usually been considered as actively congested, but recent experiments by Walter Mendelsohn go to show that the kidney in fever is really anemic, small, pale, and bloodless, so that the kidney is really comparable to the anemic kidney of cholera, in which, too, there are albuminuria and nutritional changes of a degenerative kind analogous to the cloudy swelling affecting the renal cells in acute fever, but more advanced in degree.

Morbid Anatomy.—The kidney of active congestion is slightly

enlarged, swollen, and, after removal of the capsule, brown or mottled. On section, the cortex is wider and darker than in health, the blood-vessels are overfull, the Malpighian bodies are distended, and the cells are the seat of cloudy swelling. The medulla is less markedly red and sharply defined from the cortex.

Symptoms.—There are none except a scanty urine of high specific gravity and high color, sometimes small albuminuria, with a few hyaline and pale granular casts.

PASSIVE CONGESTION OR CYANOTIC INDURATION.

Etiology and Pathogeny.—While any agency which obstructs the movement of the blood through the kidney may cause passive congestion, the causes encountered in actual practice are mostly limited to valvular disease of the heart and chronic pulmonary disease involving extensive areas of the lung, such as emphysema, interstitial pneumonia, and pleurisy, with extensive effusion or marked adhesions. Tubercular phthisis is a less common cause, because of the impaired nutrition and small quantity of blood. Pressure on the renal veins by tumors, the pregnant uterus, or ascitic fluid acts similarly.

In any event the mechanism of its production is the same. The blood is crowded into the venous side of the vascular system. In mitral insufficiency the blood is regurgitated from the left ventricle into the corresponding auricle, and thence into the lungs; the latter organs become engorged, and again resist the entrance of blood from the right side of the heart, whence it is backed into the right auricle and valveless vena cava. The smaller veins of the extremities at first resist the encroachment by means of their valves, but the veins of the abdominal viscera, including the liver and the kidneys, are without valves, and are first, therefore, to receive the brunt of the stagnation, and they become engorged with blood. In pulmonary or pleural disease the obstruction begins in the lungs instead of in the heart, but the mechanism is the same. Pressure by tumor on the renal vein is even more direct.

Morbid Anatomy.—The kidney of cyanotic induration or passive congestion is hard, firm, and bluish-red as to its external surface. In the earlier stages it is enlarged simply from the presence of the large amount of blood detained in its vessels. The stellate veins are unusually distinct. The capsule strips off easily, and on section the enlargement is found to involve the cortex, but the veins of both cortex and medulla are engorged, that of the straight veins causing the medulla to appear darker in hue than the cortex. The Malpighian bodies, on the other hand, are not always engorged. The cut surface of the kidney is moist and succulent, but the microscope reveals no further changes either in the cortex or the medulla, the epithelium being unchanged.

After some duration the kidney is slightly if at all larger than the normal organ, though rarely smaller. The other superficial characters of hardness, smoothness, and bluish-red color, however, remain. Sometimes there appears a slight tendency to lobulation. At this stage the capsule does not strip off quite so easily as usual, but may drag small portions of the parenchyma with it. There may then be seen some shallow depressions. On section, the vessels are less turgid, and the relations of the cortex and medulla are not much altered. There may be a slight overgrowth of interstitial tissue and a small-celled infiltration between the tubules. Malpighian bodies are

sometimes shriveled, and the epithelium of the tubules is granular and slightly fatty.

Symptoms.—These are primarily those of the diseases of which it is the consequence, of which I will emphasize only *anasarca*, because of its importance. To such is superadded *scanty urine of high specific gravity*, containing usually a small amount of *albumin* and a few *small hyaline casts*.

The dropsy first involves the lower extremities, in the area drained by the inferior vena cava. There also occur, however, effusions into the pleural sac and peritoneum, and the hands and arms may be involved.

The *urine* is scanty and of high specific gravity, often 1030 to 1035, and even higher. It is turbid with urates, depositing a copious sediment of them and of uric acid. The albumin is usually small in quantity, but may become larger if the obstruction to the movement of the blood is great. The casts are small, transparent, or faintly granular, and not numerous—indeed, often absent. Blood is rarely present, while its presence may be considered evidence of a superadded nephritis. The solids are secreted in normal amount. In fact, such kidneys can apparently be restored to their normal function at any time by proper treatment. *Uremia is exceedingly rare*. Very rarely does it happen that an interstitial nephritis is induced.

Diagnosis.—Passive congestion exists to a certain degree in all cases of valvular heart disease without compensation, but higher degrees may be suspected when the urine becomes scanty and albuminous, and when all the symptoms of the cardiac affection become aggravated. When the physician sees the patient after the symptoms of passive congestion have become marked, it is often a nice question to decide which of the two conditions is primary, the cardiac or the renal condition; but this subject will be further considered in treating of the relations between kidney disease and heart disease.

Prognosis.—With the addition of the renal complication, the inconveniences and annoyances of the cardiac disease become greatly aggravated, while the difficulties in the way of successful treatment are greater. Yet the results which sometimes follow appropriate and energetic treatment and the substitution of favorable for unfavorable hygienic surroundings, such as succeed the admission of a neglected outcast to the wards of a hospital, are often astonishing. Under these circumstances it is not unusual for the dropsy to decline, the albumin and casts to disappear, and the patient to be restored to comparative comfort, without, however, any change in the original lesion, which, upon the slightest provocation, may re-excite all the symptoms.

Treatment.—As intimated under prognosis, the substitution of favorable for unfavorable hygienic surroundings, if the former exist, is the primary requisite. Shelter, warmth, rest, and good food are indispensable. After this digitalis is the sheet-anchor, for evident reasons. We have here to deal with a dilated, weak, failing heart, unable to drive the blood forward. Its power must be increased, and we have a remedy capable of doing this in digitalis. Sufficient doses must, however, be given, whether of the tincture, powder, or infusion. A half ounce (15 c. c.) of the infusion may be given every four hours to an adult; of the tincture, not less than ten minims (0.65 c. c.), or twenty drops, to be reduced when diuresis sets in. Under such doses, if the cardiac disease is not too advanced, the quantity of urine may increase, become clear, its albumin and casts diminish, and with these also the dropsy, dyspnea, and restless, sleepless nights. All that has been said under the treatment of cardiac valvular disease of substitutes for digitalis is applicable here, and the reader is referred to that section.

Due attention must also be paid to the bowels, for the sake of securing prompt action of the diuretics, as well as the elimination which their free action accomplishes. The hydragogue cathartics, such as elaterium and the salines, are often excellent adjuvants.

ACUTE PARENCHYMATOUS NEPHRITIS.

SYNONYMS.—*Acute Nephritis; Acute Diffuse Nephritis; Acute Desquamative Nephritis; Acute Tubal Nephritis; Acute Bright's Disease; Acute Catarrhal Nephritis; Croupous Nephritis; Albuminous Nephritis; Hemorrhagic Nephritis; Acute Albuminuria; Acute Renal Dropsy.*

Definition.—Acute parenchymatous nephritis is an acute inflammation of the kidney, the tubular, vascular, and interstitial tissues being simultaneously involved in different degrees in different cases. In the majority of cases, perhaps, the parenchyma, or secreting structure, is first and most invaded, whence the term parenchymatous nephritis.

Etiology.—Most cases of acute parenchymatous nephritis are caused by the poison of scarlet fever or diphtheria, and occur, therefore, in children. A certain number originate in exposure to cold, especially cold and dampness, while the body is warm and perspiring. The latter cause is particularly potent if the person be fatigued or exhausted. When acute nephritis supervenes on scarlet fever, it is usually not until the end of the second week, often when convalescence is well established. It may occur as early as the tenth day, seldom, if ever, later than the thirty-first.

Other grave infectious diseases, as smallpox, acute endocarditis, and acute articular rheumatism, typhus and typhoid fevers, pneumonia, and malaria are also occasional causes. Measles, erysipelas, pyemia, jaundice, and diabetes have been known to cause it. Skin diseases, as well as extensive burns of the skin, are acknowledged causes: the former rarely, but the latter almost always if the burns be sufficiently extensive. Simple follicular tonsillitis is also a not infrequent cause. I have known an abscess in the thigh, succeeding the lodgment of a splinter in the toe, to be followed by typical acute nephritis. Pregnancy is the cause of a good many cases of acute parenchymatous nephritis, to which, in turn, most cases of puerperal convulsions are due.

Most cases of acute nephritis due to other causes than scarlatina, diphtheria, cold, and pregnancy are mild in degree; and even in cases due to pregnancy, if the patient is once safely delivered, recovery is usually rapid. In looking for the evidence of nephritis in acute infectious diseases, it must not be forgotten that intense febrile movement may cause albuminuria, independently of any structural change in the kidney due to the toxic agent. When thus caused, the albuminuria is always small.

Certain specific poisons of vegetable and mineral origin are capable of producing acute nephritis. Among the best known of these substances are cantharides, turpentine, oil of mustard, wormseed oil, and phosphorus; in a less degree, the mineral acids, arsenic, nitrate of silver, lead, and mercury. Very large quantities of alcohol, when swallowed, have caused acute nephritis.

The microbic origin of nephritis has also been invoked. Apart from analogy, which, with our present knowledge of bacterial agency, renders

such cause highly probable, pathogenic organisms have been found in the urine of cases, pure cultures from which, by Mannaberg, produced intense nephritis when injected into the blood of animals. Oertel claimed, fifteen years ago, that in renal diseases following diphtheria he found "great numbers of micrococci and exuberant proliferations of the same," both in the renal tubes and Malpighian bodies; Heller, that he had repeatedly found the blood-vessels and their branches in acutely inflamed and swollen kidneys from cases of pyemia greatly dilated and plugged with masses which, under low powers, presented a peculiar grayish-yellow appearance, and with high powers were found to consist of extremely minute, highly refracting granular particles. These particles he considered spherical bacteria, and the resulting masses bacteria emboli. It is, therefore, now commonly conceded that the bacteria responsible for the acute infectious diseases are also the agents which produce the complimentary nephritides in all of them.

As may be inferred from the etiology, acute nephritis is often a disease of early age, although when due to cold or any one of the causes named except scarlatina, it is as much more likely to affect adults as these latter are more frequently subjected to such causes. It is rare after forty, almost unknown after fifty. More males are attacked than females in adult life, evidently because they are more frequently exposed to the causes. But even in childhood there is a slight preponderance of cases in boys affected, which can hardly be thus accounted for.

Morbid Anatomy.—This varies with the stage of the disease, as well as its severity. In the first place, as ordinarily caused, the disease is symmetrical, both organs being alike involved. In the fully developed stage the kidneys are more or less enlarged, in the latter stages always so, sometimes to more than twice their normal volume, and they may weigh from eight to twelve ounces (240 to 360 gm.), those of children reaching the former, and those of adults the latter.

The capsule strips off easily, without dragging any of the parenchyma with it. Bereft of its capsule, the kidney itself is softer, inelastic, and doughy. Its surface is smooth and exhibits a peculiar mottled appearance, which is due to the fact that the little circlets of veins which form the boundary of the lobules are distinctly injected, while the area surrounded by each circlet is paler than in health, and in the more advanced stages even yellowish-white in color. This "irregular mixture of congestion and anemia," as Sir George Johnson early called it, is further contributed to by the injection of other veins indistinct in health. Spots of hemorrhagic extravasation may also be found scattered over the surface.

On section, it is evident that the enlargement is due to change in the cortex and the interpyramidal convoluted portion. The cut surface is smeared over with a dark-red or chocolate-hued blood, but on scraping or washing it away, the vessels are found injected like those of the surface, and between them the same paleness or yellowish-white hue is seen. The Malpighian bodies are enlarged and distinct, dark red, sometimes pale. Punctiform hemorrhages may also be present, as on the surface of the organ. The pyramids are dark red.

Minute Changes.—These are confined almost solely to the labyrinthine structure. They by no means always correspond in degree with what would be expected from the symptoms, being often entirely inadequate to explain them. The changes are *tubal*, *glomerular*, and *interstitial*.

1. *Tubal Changes.*—These vary a great deal with the stage of the disease. The earliest change assumed by the cells is cloudy swelling, a result of increased nutritive activity. In this state the cells are swollen and “cloudy” from a deposition of albuminous granules, which may obscure the nucleus. Although kidneys removed after death from cases of acute parenchymatous nephritis have, as a rule, advanced far beyond this stage, yet it is often possible to find points at which cloudy swelling exists alongside of more advanced stages, while alongside of these, again, may be tubes in which the epithelium is normal. As a result of the cloudy swelling, the cells are larger, and the tubes are therefore distended, broader than in health, but a stage later they are still more distended with granular cells, granular débris, and often red-blood discs and leukocytes. Under a low power, the tubules appear as black, more or less opaque lines. A closer examination of the *cells* at this stage, as obtained by scraping, shows them to be granular in various degrees. In some the nucleus is still visible, in others demonstrable by the aid of staining fluids only, and in others still entirely obscured. Occasionally a few fat drops may be present. In other situations the cells are so closely packed in the tubules that they cannot be differentiated, being apparently fused in one continuous, dark, granular mass. It is to these tubules, distended with granular cells and their débris, dark by transmitted light, but white by reflected, that the pale or white color seen between the injected blood-vessels is due. Casts of the uriniferous tubes are also found *in situ*, usually blood casts or small hyaline casts. Minute extravasations of blood, visible to the naked eye, have been referred to. They occupy the tubules, and in the “hemorrhagic” form the interstitial tissue.

2. *Glomerular Changes.*—In all cases in which the nephritis is due to a toxic substance which enters the blood the glomerule suffers first. The capillaries of the *tuft* are distended with blood, which bursts through into the Malpighian capsule, distending it with red blood-corpuscles and leukocytes. In a more advanced stage, the glomeruli may be paler, in consequence of the proliferation of the cells lining the capsule and covering the glomerule (glomerulo-nephritis).

These glomerular changes are present in almost all cases. They include swelling and desquamation of the capsular epithelium, and an accumulation of cells in the interior of the capillaries, probably due to a proliferation of their endothelial lining or an accumulation of white blood-cells, or thickening and hyaline degeneration of the capillary walls. These are especially frequent in nephritis after scarlet fever or diphtheria.

3. *Interstitial Changes.*—In mild cases there is no interstitial change, no formation or deposit of new material between the tubes. In others there is a serous transudate, with a few leukocytes in most cases, and red blood-discs. In severer cases there is a large outwandering of cells, and a small-celled infiltrate settles itself between the convoluted tubes and around the capsules. In cases of extreme severity, a diffuse nephritis involving both tubes and intertubular tissue may be present from the outset. In such event, the latter is uniformly infiltrated or pervaded more intensely in certain places by leukocytes.

The epithelial lining of the straight tubes of the pyramids is unchanged, but the tubes themselves often contain cellular and granular material which has descended from the convoluted tubes.

Serous infiltration and effusion are present in various tissues when the

patient is dropsical at the time of death. Among other tissues sometimes thus infiltrated are the membranes of the brain, constituting what is known as edema of the brain. The mucous membrane of the pelvis of the kidney may be injected, but is otherwise unchanged.

Symptoms.—The mode of onset of acute nephritis is not uniform, but among the symptoms earliest noticed is slight *swelling* or *puffiness in the face*, below the eyes, associated with more or less *falling off in urinary secretion*. This *edema* rapidly extends to the upper extremities and trunk, and thence, if the disease does not abate, into the lower extremities and abdominal walls. In the male, the scrotum and prepuce are favorite seats of swelling. The great serous sacs are the last to fill with fluid in acute nephritis, although in bad cases ascites not infrequently occurs, while there may also be transudation into the pleural and pericardial cavities. The degree assumed by the general anasarca is sometimes enormous, resulting in the extremest distortion. The eyes may be actually closed by the swelling, and movement of the lower limbs rendered almost impossible. Dropsy does not always follow the order here named. Much depends upon the position of the patient. Thus, if he be upon his feet, the latter may be the first to swell, or if he be lying in the recumbent position, the back may be the seat of the first swelling. While dropsy is a very frequent symptom in acute nephritis, it is not, however, always present. It is more particularly in the nephritis after scarlet fever and exposure to cold that it is a decided and almost invariable symptom. After the other infectious diseases it is frequently absent.

Not infrequently the disease is ushered in by *nausea* and *vomiting* and very rarely by uremic symptoms (see p. 685).

Changes in the Urine.—Simultaneously with, and sometimes earlier than, the dropsical symptoms are *diminution in the quantity and alteration in the quality of the urine*. The former may amount to actual suppression. The urine is darker than natural, and often smoke-hued from the effect of the natural acid reaction on a small quantity of blood. Should the urine become alkaline, the color becomes a brighter red. The hue is more positively red if the quantity of blood is large, which is not often the case; but here again the peculiar tint returns if the blood is allowed to subside. The blood may disappear, to return again.

The *specific gravity* of the urine at first is high—1025 to 1030—mainly due to the diminished quantity, while the solids remain nearly normal. Later, if the symptoms abate, the specific gravity diminishes with the increase in the quantity; or, if the disease lasts for any length of time or passes over into the chronic form, a similar reduction in weight occurs; this may result in a specific gravity as low as 1010.

The chief alteration is the *presence of albumin*. This is generally copious, the urine often solidifying on the application of heat and acid, while it constantly contains more than half its bulk. This albumin is derived in part from the extravasated blood, and in part is a result of the inflammatory action. If estimated by weight, it will equal 0.5 to 1 per cent., and, in rare instances only, 1.5 per cent.

Next in importance is a reduction in the twenty-four hours' secretion of *urea*, which is invariable until convalescence sets in. The percentage remains as high or higher than in health, but the twenty-four hours' quantity is diminished. There is a good deal of range within the limits of health in the quantity of urea eliminated in twenty-four hours—from twenty to

forty gm. (300 to 600 grains) in adults, and it varies with the amount of proteid food ingested. More frequently the amount is reduced to one-fourth or one-half the normal. The phosphates and chlorids are also reduced.

As to *sediment*, the urine of all cases of acute parenchymatous nephritis deposits a sediment which, in the early stages at least, is copious and brownish or reddish-brown in hue; later, it may diminish in amount and assume a lighter color. *Microscopical examination* reveals this deposit to be made up mainly of casts of the uriniferous tubules, free cells from these same tubules, blood-corpuscles, red and colorless, and very constantly crystals of uric acid, together with granular urates. The casts include the varieties known as epithelial casts, blood casts, hyaline casts, waxy, and dark granular casts. Pus casts and numerous leukocytes are also sometimes present. The hyaline casts are probably pure fibrin. The epithelial casts consist of the same material, to which epithelial cells of the tubules are attached, and blood casts have blood-corpuscles caught in the coagulated exudate. The epithelium thus attached, as well as that which is found free in the urine, is variously altered. Some of the cells are merely the seat of cloudy swelling, others are decidedly granular, while others again are converted into compound granule cells or granular fatty cells by complete fatty degeneration. These arise as the disease advances. Casts containing a few oil drops may also be present, but much oil is not found until the case has continued for some time—in fact, become chronic.

Along with the diminished quantity of urine is often met a disposition to *frequent micturition*, the efforts at which are only partially successful, resulting in the emission of from a few drops to a tablespoonful. This frequent desire to pass water is a purely reflex symptom, the bladder being free from disease. It sometimes precedes, in point of time, all other symptoms. It is by no means constant.

Fever is not a marked symptom in acute nephritis; indeed, it is generally absent, unless as a part of the disease causing it. To a less degree the same is true of *pain*. It is mostly absent, and when present amounts only to a dull ache, as a rule. *Chilliness* and *rigors* sometimes introduce the disease. *Nausea* and *vomiting* are not infrequent in the beginning. Sometimes these symptoms usher in the disease. The *pulse* is quite characteristically altered. While not materially changed in rate, it exhibits, especially in sphygmogram, a decided increase in tension, as shown by the broader apex and diminished dicrotic element.

Uremia.—At almost any time in the course of an acute nephritis the patient is liable to *uremia*, while the *train of nervous symptoms* usually known as *uremic*, and ascribed to the accumulation of excrementitious substances in the blood, is not confined to this form of Bright's disease, and is by no means invariably present. Its causes and phenomena, so far as known, were considered under general symptomatology, page 688. When present, however, it adds a phase of extreme gravity.

The duration of acute nephritis is variable—from a few days to several months, while the acute form may become chronic. The former class of cases are fatal, for none which recover do so in a few days. The most rapid usually require a month. As to the cases of longer duration, the possibility of recovery at any time cannot be denied, but nothing is better determined than that the longer the duration the more difficult the cure. Of course, such cases are no longer acute.

Complications.—These are not numerous in acute, as contrasted with chronic Bright's disease, and some which are described as complications are not really such, but local symptoms. Thus, *edema of the lungs* occurs as a part of the general tendency to dropsy, and may be a grave symptom, resulting in death by suffocation. It is not the result of an intercurrent bronchitis. *Pneumonia*, on the other hand, is an occasional true complication. *Inflammation of the serous membranes* is more truly a complication, but not every case in which there is effusion into a serous cavity is of such a nature. Such effusions are local dropsies. Inflammation of serous membranes is rather more prone to occur, while the exudate may assume a purulent character, thus also increasing the gravity of the case. Pleurisy is the most frequent form of this inflammation, pericarditis next, and peritonitis next. The tubercular origin of the graver forms of pleurisy occurring in Bright's disease has been suggested.

Hypertrophy of the left ventricle is not a frequent complication of acute nephritis. It is a well-recognized one of chronic Bright's disease. Time is an essential condition to its production. It is not, therefore, until the kidney disease has existed for some time that it can ordinarily occur. It occasionally happens, however, that the hypertrophy occurs earlier. Thus, Dickinson reports a case recognized at eight weeks, and von Leube one at ten days succeeding the first symptom. The infallible sign of hypertrophy is sharp accentuation of the aortic second sound, with or without demonstrable enlargement of the normal area of dullness.

Allusion has been made to the *gastric symptoms* which very commonly attend acute nephritis, especially after scarlet fever. Samuel Fenwick* and Wilson Fox† have shown that these may be associated with organic changes in the structure of the stomach. Dr. Fenwick characterizes these as gastritis, as evidenced by increased vascularity of the mucous membrane, distention of the tubes by a confused mass of cells and granular matter, and occasional thickening of the basement membrane. To these, Dr. Fox has added thickening of the intertubular tissue.

Notwithstanding the frequency of convulsions in acute nephritis, structural *alterations* in the *brain* are almost unknown. Apoplectic effusions are rare, probably because of the comparative structural integrity of the blood-vessels of the brain in the young, in whom the disease mainly occurs. In like manner, the blindness which not infrequently occurs as a symptom of uremia is unattended by retinal changes, nor does that condition known as albuminuric retinitis occur in acute parenchymatous nephritis, except with the extremest rarity.

Diagnosis.—The diagnosis of acute parenchymatous nephritis is ordinarily quite easy. The previous history, the usually easily recognizable cause, the suddenness of the attack, the scanty and bloody urine with its high specific gravity, the copious albuminuria, the blood and epithelial and dark granular casts, the blood-corpuscles, free epithelium, and granular cells in the urine—these are a combination of symptoms which admit of only one interpretation. At a later stage, the absence of one or more of these symptoms may somewhat increase the difficulty, but it is scarcely possible to err if those which remain are duly considered. It must be remembered, also, that an acute condition, such as this described, may supervene upon any one of the chronic forms of *Bright's disease* to be described, and this may give rise to

* Samuel Fenwick, "The Morbid States of the Stomach and Duodenum," 1863, p. 177.

† Wilson Fox, "Medico-Chirurg Transac.," vol. xli. p. 361.

some difficulty of diagnosis, but if there be hypertrophy of the left ventricle, it is likely that there was chronic disease before; in the latter case, too, there is apt to have been anemia existing for some time, previous edema, headache, and other symptoms of chronic Bright's disease.

Febrile albuminuria is quite often mistaken for acute nephritis by those who have had little experience, though the distinction is easy. In pure febrile albuminuria, the quantity of albumin is very small, and while there may rarely be a few hyaline casts, there are no blood discs and no epithelial casts. The absence of dropsy is of no significance, for in the acute nephritis of the infectious diseases, except scarlet fever and diphtheria, there is seldom dropsy. There may also be febrile albuminuria in scarlet fever which is quite different from the nephritis occasioned by this disease. It occurs early, and in this stage the other features of febrile albuminuria obtain, while the scarlatinal nephritis does not come on, as already stated, until after the end of the second week.

While the glomerular changes referred to are more usual in scarlatinal nephritis, there is no certain way of recognizing such condition, and the term glomerulo-nephritis, which is applied to the nephritis associated with these changes, is scarcely justified from the clinical standpoint, because there are no symptoms by which it can be recognized.

The diagnosis of *uremia*, commonly easy, is sometimes difficult. This is especially the case when, instead of the usual complex list of symptoms detailed on page 689, there are but one or two. By no means every nervous manifestation coincident with Bright's disease is uremic, and I am inclined to believe that some are ascribed to it which should not be. On the other hand, localized convulsions and hemiplegias, commonly ascribed to some anatomical lesion in the brain, are often uremic in origin. Given, however, a case of sudden convulsions or coma, or even muscular twitching, if it is associated with scanty urine and diminished urea excretion, it may be ascribed to uremia, provided there is no cause which will explain it more satisfactorily. Uremia has been mistaken for *opium* and *alcohol intoxication*, and it must be admitted that the coma in all three is very much alike. But one need only be forewarned to prevent such error. In opium-poisoning the pupils are contracted, in alcoholism they are dilated, in uremia they vary.

Prognosis.—Grave as this disease is justly considered, recoveries from it are numerous and the prognosis is generally favorable. Even without treatment, cases may recover, and more recoveries follow a judicious treatment. The prognosis should, however, always be guarded, as insidious causes may produce death when it is least expected. Among the most important of these is uremia.

Bartels says that death from uremia in acute nephritis has never occurred in his experience, except when the disease has resulted from scarlatina or diphtheria; but Dickinson narrates a fatal case resulting from exposure, in which death was preceded by coma and other symptoms of evident uremic origin, and I am certain I have seen similar cases.

Pulmonary edema is a cause of sudden death, the patient drowning, as it were, in his own secretions. Its onset is characterized by shortness of breath, frothy expectoration, and abundant small râles. Purulent exudation into the serous cavities may also precipitate death, very rarely.

The symptoms of gravest import are, therefore, those of uremia, manifested in any one or all the various ways, the presence of any of the complications alluded to, and especially suppression of urine. Cases should not,

however, be despaired of, even when there is complete suppression of urine. Always, however, this is the gravest of symptoms, and death generally ensues within a couple of days after it sets in. The possibility of sudden death should always be borne in mind, and mentioned to the relatives of the patient, although the number of cases in which this occurs is not very great. Of course, the longer the duration of the case the less the likelihood of recovery.

Treatment.—Many cases of acute nephritis recover under the conditions of *rest, quietude, and warmth*, and it is further certain that, whatever other means of treatment are used, these three conditions are absolutely necessary to recovery. A patient with acute Bright's disease, therefore, whatever its mode of origin, should be put to bed, kept quiet, and covered warmly.

The *diet* of patients with acute Bright's disease should be of the simplest and easiest of digestion, and should contain a minimum of proteids. The irritability of the stomach in this disease has been alluded to, and it is important that food should be adapted to it. Milk may be considered the typical food, not merely because of its easy assimilation and nutritious character, but because there is abundant testimony to prove that albuminuria diminishes under its use, while the amount of nitrogen contributed to the blood is less than by animal flesh. The combination of lime-water, and still better of carbonated water or Vichy, with milk, is an eminently suitable one. While solid animal food is not to be recommended, weak animal broths may be permitted, to break up the monotony of a pure milk diet. *Beef-teas and extracts should be prohibited as harmful.* Rice and farinaceous preparations generally are suitable adjuvants to the milk diet.

We should seldom, however, be satisfied with this treatment alone. The selection of other measures will depend somewhat upon the severity of the case. If the urine be suppressed, *dry cups*, or, in severe cases, cut cups to the loins may divert the blood and relieve the stagnation which always exists in the acutely inflamed kidney. Cups should be followed by a *warm poultice* to the same region, which, indeed, should be used under any circumstances, whether the cupping is necessary or not. Dry cups should not be allowed to remain on one spot longer than to secure a bright redness, after which they must be withdrawn or moved to another spot in the vicinity. By allowing them to remain too long, the blood is stagnated in the capillaries, its onward movement prevented, and there is, therefore, no derivation of blood from the involved organ.

The foregoing measures have for their object the direct relief of the congestion of the kidney. This is further accomplished by *purgation*, which supplements the action of the kidney. But a purgative is early employed not more for this purpose than to promote the action of other remedies. Absorption is slow when the blood-vessels are congested and there is a sluggish current. The cathartic relieves this turgor, and after its effect prompt absorption and action of other remedies may be looked for. The purgative most suitable is a saline. A simple dose of bitartate of potassium, simple magnesia for children, citrate of magnesium, or Epsom salts for adults will be sufficient. The indication is to get a watery stool as soon as possible. In view of the fact that the stomach is often sensitive, it is desirable to use an aperient which is not nauseous or irritating, and to this end some one of the delicate effervescing preparations so common in modern pharmacy may be used.

Next, or simultaneously, the action of the skin should be promoted. This is done by maintaining warmth and avoiding cold, as already insisted upon. But we are not confined to these protecting measures. The skin may be made to do the work of the kidney itself, and thus one of the most alarming dangers of Bright's disease, uremic intoxication, averted, while at the same time the congestion of the kidney is also relieved. The class of remedies which produces this action are diaphoretics (the warmth described is one of these), and of the simple remedies, none is better than the ordinary sweet spirit of niter, especially if it be combined with neutral mixture and small doses of ipecacuanha. If more active measures are required, some one of the preparations of jaborandi may be used, the dose varying with the effect it is desired to obtain. If moderate diaphoresis only is desired, doses of from ten to fifteen minims (0.65 to 1 gm.) of the fluid extract may be given to adults every two hours, and increased, if necessary, until the effect is brought about. To children, from five to ten minims (0.3 to 0.6 c. c.) may be given in the same manner, or pilocarpin may be given in doses of from 1-24 to 1-12 grain (0.0027 to 0.0054 gm.). The further use of this important remedy will be again referred to in treating uremia.

Another method of accomplishing the same end is by *warm baths*, or, better still, by the warm pack, in which the patient is wrapped in a wet sheet and then enveloped in a sufficient number of blankets. Perspiration is thus copiously induced, and when thus caused is agreeable and never attended by the faintness which sometimes follows the use of the hot-air bath. In an ordinary severe case of acute Bright's disease, a single pack of this kind will often remove all urgent symptoms and happily inaugurate the convalescence. It may, however, be repeated daily, if necessary.

Diuretics are, perhaps, the first means thought of by most practitioners in the treatment of Bright's disease, and they are indicated where there are dropsy and scanty urine. They should, however, be deferred until the measures just described have been employed. Digitalis is the diuretic most to be relied upon. It is necessary, however, to have a reliable preparation, and unless one is sure of the quality of the tincture, it is best to use a freshly prepared infusion. I have already explained, on page 595, why I believe more efficient results are obtained from the infusion than from the tincture.

Digitalis should, therefore, be given in sufficient doses—1-2 to one fluid dram (2 to 4 c. c.) of the infusion to children, and two fluid drams to half a fluid ounce (8 to 16 c. c.) to adults—repeated every three hours, until an appreciable effect is produced on the rate of the pulse, when it should be diminished. Not until then can we look for a diuretic action. I prefer at first to give it alone. Later it may be combined with acetate, citrate, and bitartrate of potassium. The diuretic action of these salts probably depends upon the impetus they give to osmosis of fluids holding them in solution, thus filling the blood-vessels, which, in their turn, give out water to flush the kidney. To adults, twenty grains (1.3 gm.) of either may be given every two or three hours, freely diluted, because water itself is an excellent diuretic; from five to ten grains (0.32 to 0.648 gm.) to children, as often. An important object, too, is to maintain an alkaline urine, which tends to dissolve exudates. For this purpose, the alkaline-mineral waters are also useful, or what is commonly known as cream-of-tartar tea may be drunk instead of water. A teaspoonful of potassium bitartrate is put into a pint of boiling water, and taken cold as drink is wanted.

Another admirable diuretic combination, including all of these elements, is Trousseau's diuretic wine, which consists of :

℞ Junip. contus.	3 x.	40 gm.
Pulv. digitalis,	3 ij	8 gm.
Pulv. scillæ,	3 j	4 gm.
Vin. xerici,	Oj	½ liter
Macerate for four days and add			
Potas. acetatis,	3 iij	12 gm.
Express and filter.			
Sig.—Tablespoonful three times a day for an adult.			

Infusion of digitalis may also be used in the shape of fomentations. Cloths wrung out in hot infusion of digitalis and laid over the abdomen of the patient have been known to produce diuresis when all other measures have failed.

Theobromin is also a diuretic which should not be forgotten in the treatment of renal dropsy, although it is better adapted to cardiac dropsy. The same is true of caffein. For the method of administration of both of these see treatment of cardiac dropsy, page 599.

Treatment of Acute Uremia.—The alarming and dangerous character of the symptoms of this condition demand a separate consideration of the measures required in their treatment. The treatment which has just been described is such as would be called for by an ordinary case of acute nephritis of a decided character. The tendency of it will be to prevent the retention of those effete matters, whatever their precise nature, which constitute the cause of uremia. But all efforts in this direction sometimes fail, and we are called upon to contend with convulsions or coma, or, more frequently, both in alternation. How shall they be met? The indication has already been explained. Elimination is demanded. The kidneys are not acting, and the secretion of urine is suppressed. There remain, therefore, but the bowels and skin to operate upon. But the patient is unconscious and cannot swallow voluntarily. Such remedies must, therefore, be used as do not require his co-operation. These are *croton oil* and *elaterium*. Of the former, two drops, slightly diluted with plain oil or glycerin, may be carried into the back part of the throat, or, in case of extreme necessity, undiluted, may be introduced into the mouth, whence it is quickly absorbed. Its operation may be facilitated by a rectal injection. Of *elaterium*, a quarter of a grain (0.0165 gm.) in solution may be administered by the mouth.

In like manner, the skin may be made to substitute the action of the kidney. The *vapor or hot-air-bath or hot pack* should at once be availed of. The vapor may be conveyed by a pipe two or three inches in diameter, carried from a vessel containing water, under which a spirit-lamp is placed, under the bed-clothing, the patient being well covered with a mackintosh and blanket, excepting the head. An ordinary rain-spout may be used. Hot air may be similarly conveyed, but does not act so quickly. Its action may be favored by moistening the skin. The hot pack is also very efficient and perhaps less enervating.

Jaborandi or its active principle, *pilocarpin*, may be used, the latter preferably, because available hypodermically. One-third grain (0.02 gm.) of the muriate may be thus administered, and if perspiration does not set in in a half hour, it may be repeated. Its action is also greatly facilitated by warmth applied to the patient. A freshly prepared infusion may be injected into the rectum with almost equally prompt results. Four ounces (120 c. c.) of hot water should be poured on a dram (4 gm.) of *jaborandi* leaves,

and, when sufficiently cool, strained and injected. The doses here mentioned are intended for adults. When less urgency is required, a fluid dram (4 c. c.) may be inspissated and made into a suppository. Should edema of the lungs occur, it may be overcome by the hypodermic injection of atropin, 1-60 grain (0.001 gm.).

If the convulsions continue, *blood-letting* may be practiced, or it may be done at once if the patient is not very feeble. No one doubts the efficiency of bleeding in puerperal convulsions, and if puerperal convulsions are uremic, as they are with few exceptions, then bleeding should be of service in the uremic convulsions of acute Bright's disease.

The *hydrate of chloral* should not be forgotten; indeed, it is one of the most valuable remedies for the convulsion and should be one of the first measures tried. In the case of an adult, a dram (4 gm.) in solution may be injected into the rectum; fifteen to thirty grains (1 to 2 gm.) for a child. Its use is sometimes followed by the promptest favorable results. *Chloroform* may also be used to control the convulsion while the eliminating measures are acting.

The *use of opium* requires mention. The caution which has always been suggested in its use I believe to be, in the main, a wholesome one, and I should prefer to produce hypnotic, sedative, and antispasmodic effects by chloral and the bromids whenever it is possible. At the same time there can be no doubt that opium is less harmful in acute nephritis than in chronic, and especially chronically contracted kidney, and when other measures fail to control convulsions, it may be used cautiously. It was in the convulsions of acute nephritis that the late Professor Loomis, of New York City, recommended it, although its wider use has grown out of this suggestion. His practice was to treat cases of uremic convulsions in acute nephritis with hypodermic injections of large doses of morphia—1-2 grain (0.033 gm.) or more.

The same measures which have been detailed, excepting the general blood-letting and chloral, may also be employed in the treatment of suppression of urine or of obstinate dropsy without uremic symptoms, with such modifications as circumstances may suggest, due regard being paid to the strength of the patient. They will be further referred to when discussing the treatment of the chronic forms of Bright's disease.

Sooner or later, also, in the treatment of acute parenchymatous nephritis supporting measures are rendered necessary to repair the losses which the blood suffers by the albuminuria, and to some extent also by the depleting measures of treatment. These effects should indeed be anticipated by proper diet, tonics, quinin, especially iron, wine, malt liquors, whisky, or brandy, as indicated. These measures will also be more particularly alluded to in the treatment of chronic Bright's disease.

Treatment of Complications.—Complications should be treated by remedies called for by such conditions independent of the renal cause. Effusions into the pleural cavities and abdomen are often best relieved by paracentesis or aspiration; pneumonia and bronchitis by counterirritation.

CHRONIC PARENCHYMATOUS NEPHRITIS.

SYNONYMS.—*Chronic Diffuse Nephritis; Chronic Tubal Nephritis; Chronic Catarrhal Nephritis; Large White Kidney.*

Definition.—A chronic diffuse hyperplastic process in the kidney, involving the epithelium, glomeruli, and interstitial tissue.

Etiology.—This cannot always be traced. While it is frequently a continuation of acute nephritis, more frequently it originates *de novo*. To cases in the former category scarlatina and pregnancy contribute the greater number. To the second class belong insidious cases, the cause of which is often not traceable. Habitual exposure to cold and dampness, such as residence in damp, cold houses, may cause some. Tubercular disease of the lungs is an undoubted cause. Great stress is laid by German writers upon malarial poisoning as a cause. In this country it is not a frequent cause. One or two pretty well-founded cases, with others of more doubtful authenticity, include my experience with this cause. S. C. Busey, I. E. Atkinson, and William Sydney Thayer have, however, also assigned this as a cause in special papers devoted to the subject. It may be the case in more southern parts of the United States, where malarial poisoning is more intense than in the Middle States. Alcohol is a cause, and the nephritis of confirmed drunkards and the employees of breweries may be thus accounted for, though it cannot be denied that the exposure to which some of the former class are subjected may be responsible. Males, and of these young adults, are the more frequent subjects. Sepsis in prolonged surgical affections may produce chronic nephritis.

Morbid Anatomy.—There are two distinct stages in the morbid anatomy of chronic parenchymatous nephritis if the disease is of sufficient duration—viz., the stage of enlargement, represented by the *large white kidney*, and that of contraction, or the *fatty and contracting kidney*. A special variety is *chronic hemorrhagic nephritis*.

1. *Stage of Enlargement.*—There are few more striking objects in morbid anatomy than a typical example of the *large white kidney*. The kidney is large smooth, white, or slightly tinged with yellow; weighs generally from seven to ten ounces (217 to 310 gm.), but is often much heavier. It is usually doughy, and sometimes elastic in consistence. The capsule, which may be thinner than in health, strips off easily, but occasionally drags a little of the parenchyma with it. When the smooth white surface thus uncovered is examined, the little capillary circlets bounding the lobules in the normal organ are in some places indistinct, in others conspicuous; the same is true of the stellate veins of Verheyen. Numerous yellow specks are seen scattered over the surface. Hemorrhagic extravasations are also occasionally present, but very much more rarely than in the acute form. Alongside of these the greater translucency of more nearly normal areas results also in a characteristic mottled hue. *On section*, it is evident that the enlargement resides altogether in the *cortex*, which is also anemic, its intense white contrasting strongly with the pink hue of the cones, which, though paler than in health, are much less so than the cortex. Closer examination of the cut cortex reveals the same yellow specks as found on the external surface. They contribute, with similar less decided alterations, to form a series of dull white striæ which

alternate with somewhat broader, translucent striæ radiating toward the surface; the former correspond to the area of the convoluted tubules and Malpighian bodies,—the labyrinth,—the latter to that of the medullary rays.

The pelvis of the kidney in chronic parenchymatous nephritis is the seat of catarrhal swelling and a slight degree of hyperemia.

Minute Change.—Microscopic examination of thin sections shows the involvement of both *tubes, blood-vessels, and intertubular substance*. Of the former, many are found choked with granular cells and the granular débris of cells, causing them to appear, under the microscope, as black, opaque lines by transmitted light, very similar, indeed, to the tubes in acute nephritis. In other situations the tubules are filled with fat globules and fatty cells. In places the lumen of the tubes is preserved, in others not. Other cells are the seat of hyaline change. Others still are nearly normal. The parts presenting a yellow tinge are those in which the fatty elements have replaced the normal, and this is the composition of the yellow specks already alluded to as visible to the naked eye. They represent a coil of tubules filled with oil drops or fatty cells.* Certain tubules contain casts, usually of the waxy kind. Sometimes, indeed, they are very numerous. Rarely, hemorrhagic extravasations are also found in the tubules.

The *capillaries* of the cortex are completely or nearly empty of blood, which has been expressed from them by the distended tubules. To this and to the fatty cells is due the extreme whiteness of these kidneys, whence the name by which they are known. Many of the glomeruli are enlarged, their capsules thickened, their vessel-walls thickened and hyaline, their capillary and glomerular epithelium proliferated and degenerated.

The *pyramids* in chronic parenchymatous nephritis are more changed than in the acute form, but the changes in them are quite secondary. They are sometimes a little paler, owing partly to a granular and fatty alteration in the cellular lining of the straight tubules, and partly to the presence of cells pushed down from the convoluted tubules above them. On the other hand, they may be congested and darker in color. The straight tubes of the cones as well as the looped tubes of Henle often contain waxy casts.

In chronic parenchymatous nephritis the *interstitial tissue* is always altered, and, it may be said, as a rule in proportion to the duration of the disease. It has already been said that sooner or later interstitial overgrowth always presents itself, although it is difficult to say when this overgrowth begins in any given case. Langhans reports a case in which death occurred five weeks after the appearance of the first symptoms, directly traceable to a thorough wetting, in which the stroma was *markedly thickened*. And in a case of Dickinson's already alluded to, intertubular cellular formation, "though approximating as much to pus as to fiber," was found within six weeks of the onset. Again, cases of much longer duration may be entirely without it. Interstitial *fibrosis* may, however, be considered as a superaddition of chronicity, and whenever a case is distinctly chronic, it may be inferred, with tolerable certainty, that it is present. In this overgrowth the quantity of the connective tissue between the tubules varies extremely, being sometimes so slight as to be discoverable only on microscopic examination of thin sections; at other times it is appreciable to the naked eye. Minute examination shows the thickened trabeculæ to consist of numerous round and oval

* No satisfactory explanation has yet been offered of the great differences in the degree of fatty degeneration in the different kidneys of chronic parenchymatous nephritis or in different parts of the same kidney. Dickinson says the cells have a greater tendency to be fatty when cold is the cause.

nuclei, between which may be a homogeneous or more or less distinctly fibrillated intercellular substance.

2. *The Stage of Atrophy—The Fatty and Contracting Kidney or Small White Kidney.*—The interstitial new formation previously referred to possesses the properties usual to new connective tissue. Produced primarily to replace destroyed tubular structure, it shrinks and gradually contracts the previously enlarged organ, while obliterating in turn a certain amount of the same structure. The extent of contraction varies greatly, increasing with the duration of the process. The kidney may continue as large and even larger than the normal organ, though smaller than the large white kidney, and its surface is uneven, lobulated, rough, and granular. Its capsule does not strip off easily, as from the large, smooth organ, but drags with it considerable of the tubular structure. The capsule removed, however, the surface of the kidney exhibits between the constrictions the same pallid, speckled appearance, distinct stellate veins, etc., already described; and on section the cortex exhibits the same anemic appearance, but may be narrowed. Microscopically, sections exhibit the same alternation of groups of normal and choked tubules already described, alongside of other places in which the tubules, together with the Malpighian bodies at their extremities, are obliterated. Between them is found a large amount of interstitial tissue, and the Malpighian bodies are surrounded by concentric layers of the same. Even minute cysts, the result of obstruction of tubules by the constricting tissue, are found. The secondary origin of this form of kidney is not conceded by everyone. An independent primary origin is claimed for it.

3. A special form of this stage is *chronic hemorrhagic nephritis*. In this form brown hemorrhagic foci are scattered throughout the cortex between and into the tubes. The organ is still larger than normal, and presents in other respects the histology of this stage.

It not infrequently happens that along with the changes constituting chronic parenchymatous nephritis are found also those of *lardaceous disease*. Thus, in a large white kidney the Malpighian bodies will often strike the mahogany-red reaction with iodine characteristic of this condition, although the alteration may not be recognizable by the naked eye. Occasionally the change may even affect the afferent and efferent vessels.

Symptoms.—There are few distinctive symptoms of chronic parenchymatous nephritis. When not a sequel of acute nephritis it often begins insidiously, and, after a variable period of indescribable ill health, including, however, often *digestive derangements*, an *anemic, waxy appearance* develops, with *puffiness of the face* and *swelling of the feet*. Ultimately, the *anasarca* may become general, involving the face, hands, feet, legs, thighs, and trunk. The serous sacs also frequently contain fluid, almost always in severe cases. The swelling may be confined to the extremities or to the face, and may even be limited to more unusual situations, as the scrotum. Indeed, dropsy is often entirely wanting, but as a rule it is manifest sooner or later, and no symptom gives the patient so much inconvenience. In advanced degrees his legs and thighs are twice their normal dimensions. They are so heavy he cannot lift them, while they are often excoriated and moist with exuding serum, and smarting with irritation. Very frequently, as the result of spontaneous rupture of the skin, the discharge of serum is profuse, saturating the bed-clothing and even dropping upon the floor; occasionally, also, with relief to the patient.

Another very constant symptom is *anemia*, producing a peculiar translu-

cent waxy appearance, quite characteristic and often alone sufficient to suggest the disease. But there may be very slight degrees of it which are not at all peculiar. Again, the *debility* of those suffering from advanced degrees of this condition is very striking. If able to walk at all, they soon get out of breath—are soon exhausted. *Dyspnea*, especially on exertion, is therefore a frequent symptom, and sometimes is extreme. Locomotion is often impossible in consequence of the extreme swelling, even if the strength otherwise permit it.

The Urine.—The urine is diminished to about 10 to 40 ounces (300 to 1200 c. c.), although somewhat variable in quantity. It is often turbid, reddish-yellow, specific gravity normal or below, highly albuminous, and deposits often bulky, cloudy sediment. At other times the sediment is scanty. The quantity of urine also increases as the patient improves or as the stage of contraction is entered upon, so that it may even exceed the normal. The *albumin*, while also large, varies as to its percentage amount with the quantity of urine passed—from 0.5 to 2 per cent., or from one-half to three-fourths of the volume of the urine tested. The amount of albumin lost in the urine is sometimes very large. It has even occurred that the percentage proportion of albumin in the urine has exceeded that in the serum of the blood from the same patient. The quantity of albumin has very little effect upon the specific gravity. Indeed, the lighter urines are generally those which have the larger amount of albumin, because highly albuminous urines often contain little area.

The *sediment* is made up of variously granular casts, among which the dark granular are conspicuous by their numbers and size, and especially their width. There are also found oil-casts and casts containing entire and fragmentary epithelial cells, which are likewise granular and oily. Finally, yellow waxy casts are found. Casts vary in number, being sometimes scanty, but as a rule they increase with the development of the disease and grow less as it mends. Occasionally they are entirely absent for a time, even in this form of Bright's disease, sometimes as the result of treatment, when such absence may be considered a favorable sign. Sometimes, on the other hand, the tubules are choked with them, and they do not descend into the urine. Compound granule (granular fatty) cells and other forms of fatty renal cells are often numerous. Leukocytes are also often very numerous, while red corpuscles may be present and in the hemorrhagic form are very numerous.

The normal constituents of the urine are *generally diminished* in quantity. The most important of these is *urea*. To the reduced amount of solids, and particularly of urea, the reduced specific gravity is due.

Notwithstanding the small proportion of urea which is excreted in this affection, *uremia is infrequent in chronic parenchymatous as compared with acute nephritis* and contracted kidney. It is more frequent after the stage of contraction is reached.

The Stage of Contraction.—Are there any symptoms by which we can recognize the stage of secondary contraction, which takes place sooner or later, provided the patient lives? The most reliable evidence that this has occurred is the presence of hypertrophy of the left ventricle and accentuation of the aortic second sound, although the possibility of an earlier hypertrophy cannot be denied. The increased vascular tension, mentioned as presenting itself even in acute nephritis, continues in the chronic variety to stimulate the heart to more forcible contraction, which must sooner or later result in hyper-

trophy. As already stated, time is required to reach this stage, and by the time hypertrophy is developed, contraction of the kidney is likely to have occurred. Long duration of the disease also affords presumptive evidence that contraction has taken place. If a case of undoubted parenchymatous nephritis continues under observation for a year or more, the process of contraction is likely to have commenced.

The *dropsy* diminishes and may disappear as the stage of contraction is entered upon. So, also, the *urine* changes in its properties. The quantity, previously small, is increased, while the specific gravity falls below normal—1010 to 1015; the quantity of albumin is also much smaller than during the stage of inflammation. In these respects—absence of dropsy, larger amount of urine, and smaller amount of albumin—it resembles the true contracted kidney of interstitial nephritis, with which, indeed, it may be confounded in the absence of a previous history. But the casts continue to be quite numerous, and exhibit much the same character that they do in the stage of enlargement, although they too may be few; and if we have not a knowledge of previous history, the diagnosis between contraction secondary to previous enlargement and primary contraction the result of interstitial nephritis may be impossible. Uremia is more common in the stage of contraction than that of enlargement.

In the hemorrhagic form the urine almost constantly contains blood. The quantity varies somewhat and is diminished while the patient is in bed, but reappears the moment he arises.

The *duration* of chronic parenchymatous nephritis is variable. Many cases terminate unfavorably within a year after they have been established, but I have one case now under observation in the stage of contraction which I have known to exist for sixteen years at least. Others, especially mild forms, last a long time, causing comparatively little inconvenience.

Complications.—The complications of chronic parenchymatous nephritis are the same as those of acute. Edema of the lungs, bronchitis, pneumonia, and inflammation of serous membranes are all liable to occur. Hypertrophy of the left ventricle is more common than in acute nephritis, for the reasons already referred to, but still very much less so than in interstitial nephritis. Derangements of digestion are very frequent, probably due to a more advanced stage of the structural changes described under acute nephritis. The acute blindness, unattended by retinal changes, described as occurring in the uremia of acute nephritis, rarely occurs here, while retinal changes are rather more frequent, but still uncommon compared with interstitial nephritis, under which they will be described.

Diagnosis.—Many cases are very easy of diagnosis. The extreme pallor of the patient, the diminished urine of medium specific gravity, the usually large amounts of albumin, the numerous dark granular, oil, and waxy casts of large diameter, free fatty cells, and fatty granular cells, especially if we are able to trace a history of long duration, all point to the disease; and if there is an antecedent history of scarlatina or exposure to cold, pregnancy, or long exposure, probability becomes certainty.

The symptoms of *amyloid* or *lardaceous kidney* very closely resemble those of the large white kidney, and it has been mentioned that the same causes are capable of developing both. It is often impossible to say which form of disease is present. It has usually been considered that if there is enlargement of the liver and spleen, or persistent diarrhea, and the cause is one which may produce lardaceous disease, it is certain that the latter condi-

tion exists; but observation has shown that the first two, at least, may be present, together with all the causes and other symptoms which are regarded as favoring lardaceous disease, and yet the disease be parenchymatous nephritis;* while the usual causes of lardaceous disease may operate to produce it in the liver, leaving the kidney intact. As a rule, there is not so much dropsy in lardaceous disease, casts are more scanty, and generally hyaline, granular, and waxy; hypertrophy of the heart and uremia and albuminuric retinitis do not occur. Often, too, the two forms of disease coexist, either as the result of the same cause, or the amyloid disease may be the result of long-continued parenchymatous nephritis.

The stage of contraction is more difficult of recognition unless we have had the case for some time under observation and are able to trace its continuation with the stage of inflammation. The resemblance to the *contracted kidney* of interstitial nephritis may otherwise be very close. But here, again, the albuminuria is likely to be larger, and the casts more numerous, and to include the numerous varieties mentioned instead of the scanty, small hyaline casts which attend interstitial nephritis. In the latter the quantity of urine exceeds the normal, while in the former, although the quantity is larger than in the stage of enlargement, it is still less copious than in true interstitial nephritis.

Prognosis.—This is unfavorable so far as recovery is concerned. Well-marked cases terminate usually within two years, and sometimes within a few months. Many cases, however, may be very much prolonged by treatment, and if prolonged to the stage of contraction, the patient may be tolerably comfortable for some time—seems, indeed, to have another lease upon life. But sooner or later the dropsy returns, the heart fails, and the patient dies of exhaustion, or some one of the complications or uremia intervenes to carry him off. Of the former, edema of the lungs or of the glottis and pneumonia are particularly dangerous. In the stage of enlargement, uremia, while it is of rarer occurrence, is also less apt to end fatally than in the stage of contraction.

On the other hand, it is to be remembered that there are many mild cases of chronic parenchymatous nephritis with correspondingly mild symptoms wherein the progress of the disease is slow and may extend over many years.

Treatment.—While it occasionally happens that spontaneous recoveries from acute nephritis occur, this is not the case with the chronic form. Here the expectant plan of treatment does not suffice. The patient with chronic parenchymatous nephritis, if left alone, grows steadily worse, and although measures of treatment may not frequently result in recovery, they often, if judicious, cause marked improvement and long avert the fatal end. There is always an intermediate stage between that of acute nephritis and the condition of the large white kidney, from which recovery often takes place, which calls for a modification of the treatment described for the acute, or some additions to it.

The chief indications in the treatment of chronic parenchymatous nephritis are two:

1. To improve the quality of the blood, which may have become anemic and contaminated with urea and allied effete matter.
2. To deplete the blood of accumulated excrementitious matter, and to

* See an article by Dr. Paul Furbringer, "Zur Diagnose der amyloiden Entartung der Nieren," *Virchow's Archiv*, Bd. lxxi., 1877, S. 400.

combat the symptoms and complications which form a source of great inconvenience and danger to the patient.

I. The first of these indications is chiefly fulfilled by the use of iron, quinin, and strychnin, nourishing food of a suitable kind, a proper hygiene. Iron is regarded by many as almost a specific in chronic parenchymatous nephritis, and is prescribed constantly in the most reckless and thoughtless manner. *Large doses of iron should not be given.* They are useless, lock up the secretions, cause headache, and increase the danger of uremia. The well-known Basham's mixture is a great favorite. It is really a solution of acetate of iron, and, being made by adding to tincture of the chlorid of iron acetic acid and solution of the acetate of ammonia, has the advantage of at least tending to diuresis, while it is also a roborant.* But the tincture of the chlorid of iron alone is an efficient preparation which is always accessible, and when combined with the sweet spirit of niter and freely diluted, is perhaps as efficient as Basham's mixture. Only a few drops should be given. To either one the quinin and strychnin may be added, if desired, while to the iron the infusion or tincture of quassia makes a compatible addition.

With regard to *diet*, while it is true that a sufficient amount of food of good quality is desired, those articles should be selected which contain a minimum of nitrogen. Experience has shown that when the appetite is good and large quantities of meat are eaten, uremic convulsions have been more frequent, whereas when the appetite has been bad and little food taken, uremic convulsions in chronic nephritis are very rare. While, therefore, it is not necessary to omit all such food, it is desirable to limit it to moderation, and, while drawing upon the vegetable kingdom for food, to make up the deficiency in meats by the free use of milk. The good results of the milk treatment in cases of chronic nephritis are now generally acknowledged and are evidenced in the diminution of albuminuria, decline in dropsy, increase in the quantity of urine passed, and general amelioration of symptoms. Of the different methods of employing milk, the pure milk diet has been most satisfactory. From 2 1-2 to 3 1-2 quarts (2.5 to 3.5 liters) a day meet the requirements of an adult male, and less is often sufficient. The milk should not be skimmed, but diluted, for by retaining the cream the casein or proteid constituent is maintained in smaller proportion. Rich milk is not desirable—indeed, it is better taken diluted with Vichy water or carbonated water and at stated intervals, say from six to eight ounces every two hours. It is not, of course, always necessary to confine the patient to a pure milk diet, but it should at all times constitute a large part of the food.

Next to diet, rest is a most useful measure to ameliorate the symptoms of chronic nephritis, and an albuminuria reduced to a minimum while the patient is up may often be further reduced by putting him to bed. The beneficial effect of rest upon edema due to any cause is too well recognized to require other than an allusion. The advantages of rest in bed are, however, sometimes more than counterbalanced by the disadvantage to the patient of confinement and want of fresh air and outdoor life. These, of course, must be weighed, and that one adopted which serves the patient best.

Under hygienic measures is included suitable clothing. That next the body should be of wool, for it must be remembered that, on the one hand,

* The more usual formula for Basham's mixture is as follows: R Tinct. ferr. chlorid., ℥ ʒ ij (7.4 c. c.); Acid. acet. destillat., ℥ ʒ ij (7.4 c. c.); Liq. ammon. acetatis, ℥ ʒ iij (90 c. c.); Curaçoe or syrups simpl., Aq.æ, aa q. s. ad ℥ ʒ vj (180 c. c.). M. et Sig. Teaspoonful or dessertspoonful twice a day, in half a tumbler of water. If the mixture becomes turbid, it is probably because some of the acetic acid has evaporated, when a few more drops may be added to clear it up.

the skin is a powerful adjuvant to the kidney in its eliminating operations, and, on the other hand, any interference with or suppression of the action of the skin must throw more work on the kidney. Cold is the agent which produces such suppression, and warmth the means by which the action of the skin is encouraged, and no texture prevents the former or secures the latter more effectually than wool. For the same reason, while the maximum amount of fresh air is desirable, cold and dampness should be avoided or sufficiently guarded against.

2. The second indication is to deurate the blood of accumulated impurities, as well as to combat the symptoms and complications which cause inconvenience or jeopardize life. These symptoms are those of dropsy, effusions into the serous cavities, and congestions. The patients suffering from them are usually confined to the house, or go out of it at so great inconvenience as to make it intolerable to do so. Of dropsy, there is abundant evidence to the naked eye; but of the necessity of depuration there is, unfortunately, no direct means of estimation except by a volumetric analysis of urine, which has been rendered very much easier of late by ready methods for determining urea. The results of such analysis to be of value must be taken in connection with the kind of food ingested. Fortunately, the means which are best calculated to relieve the one are most likely to relieve the other. These measures are, in addition to diuretics, such as promote a more decided action of the skin than any yet mentioned and certain purgatives.

With regard to diuretics, nothing need be added to what has already been said under acute nephritis (p. 704). But as to measures which promote a decided action of the skin, I desire to add the warm bath, the Turkish bath, warm-pack bath, and the hot-air or vapor bath already alluded to. Any of these may be used as convenience or the patient's choice may determine, while the frequency with which they should be used depends on the urgency of the case.

The "warm" or "cold pack" is a very pleasant form of bath. The patient is wrapped up in a wet sheet, either warm or cold, and further enveloped in a sufficient number of blankets. A very comfortable sweat generally ensues, which is continued for an hour. In the use of the warm bath the patient is immersed at a temperature of about 104° F. (40° C.), and kept there for from half an hour to an hour. He is then removed and wrapped in blankets. It has been said under the treatment of acute parenchymatous nephritis that these effects are more conveniently and as efficiently brought about by the use of jaborandi and its derivative, pilocarpin. The directions for their use, given in connection with acute nephritis, need not be repeated. They may be used about as often as the baths, usually on alternate days, occasionally daily, with advantage.

The judicious use of aperients is an efficient means of depurating the blood and reducing dropsy. The selection must depend on the urgency of the case, as sufficient has been said in connection with acute nephritis. But in many cases of chronic nephritis a stage is finally reached at which all treatment of the kind described fails to relieve the dropsy, which becomes eventually the sorest burden of the malady. The body becomes greatly increased in weight, the integument of the extremities is stretched almost to bursting, and sometimes it does rupture, followed by leakage, which, although in one way inconvenient, is in many senses a great relief to the patient by diminishing the tension referred to. Acting upon this, physicians have long been in the habit of puncturing the swollen parts to produce the required leakage. It is

a common practice to make a number of minute punctures with a needle or sharp-pointed bistoury, but free incisions may be made on the inner or outer side of the ankle of each leg. Free drainage is thus secured, often with great relief; or Southey's tubes may be used at convenient places. They are introduced by means of a little trocar and after this is withdrawn fine india-rubber tubing is attached to the little cannula and carried to a suitable vessel outside the bed. Some remarkable recoveries have followed incisions. Great care should be taken to keep the tubes clean, as they are liable to become dirty and clogged.

The treatment of the complications is in no way different from that of the same conditions under other circumstances. The point to be impressed is the importance of being constantly on the lookout for them. Effusions into serous cavities are probably the most important. Edema of the glottis requires especial allusion, as a complication most alarming and threatening to life. Inhalations of steam may be tried, but prompt punctures or incisions are the only certain means of relieving the patient and saving his life.

I know of no measures directly curative in acute or chronic nephritis,—that is, remedies which by their direct action remove the morbid state,—and I believe none exist unless it be the operation to be next described. All that can be done is to place the patient in a condition most favorable for nature's kindly offices, which are always exerting themselves toward cure. This is accomplished by the measures recommended, which also eliminate the mechanical and poisonous products which interfere with recovery.

Operative Treatment.—Decapsulation of the kidney as a cure for chronic nephritis was proposed by Dr. George M. Edebohls, the suggestion growing out of some results of operation for floating kidney in persons who happened to have coincident chronic parenchymatous nephritis. His results were published in the "Medical News," April 22, 1899. His first thought was that the cure of Bright's disease was due to correction of the displacement of the kidney, and it was not until three secondary operations upon kidneys which had been anchored some time previously demonstrated to him the essential conditions underlying the cure of chronic Bright's disease by operation, viz., decapsulation or decortication. Edebohls reported in the "New York Medical Record," December 21, 1901, eighteen cases, all of whom recovered. Two died of other causes, one after an operation for ruptured tubal pregnancy exactly one year after the kidney operation, and the second after hysterectomy eight years after Edebohls's operation on the right kidney. Dr. Edebohls informed me November 8, 1902, that he had operated up to date on forty-five cases of both sexes, and the results continue encouraging. In twenty-seven cases he operated on both kidneys at one sitting. The operation consists in stripping off the capsule and cutting it away entirely, close to its junction with the pelvis of the kidney.

The success of the operation is seemingly due, as Edebohls suggests, to arterial hyperemization of the kidney, whereby an increased and adequate blood supply is furnished the organ which permits an absorption of interstitial and intertubular inflammatory products, thus relieving the tubules and glomeruli from the pressure previously interfering with function.

My experience with this operation has been limited to one case, but that a very severe one of chronic diffuse nephritis succeeding upon scarlet fever. The patient was a little girl aged ten. The case had lasted over four years and there was general anasarca as well as ascites. At the time of operation she was so weak that my colleague, Dr. Frazier, feared to operate on both

kidneys at the same time. One only was therefore decorticated. The result may be truly called marvelous. The secretion of urine which under the most favorable circumstances before operation did not exceed 30 ounces rose rapidly, and on the fourth day after operation over 100 ounces were secreted, and in ten days she was free from dropsy and ascites and a month later seemed perfectly well. There continued, however, to be a large albuminuria and there were numerous casts. On March 14, 1903, the second kidney was operated upon. She did well, but as there was no dropsy there did not succeed the large increase in the secretion of urine. In a few days, however, the quantity of albumin diminished decidedly and she is seemingly well.

CHRONIC INTERSTITIAL NEPHRITIS.

SYNONYMS.—*Contracted Kidney; Chronically Contracted Kidney; Renal Cirrhosis; Cirrhotic Kidney; Granular Degeneration; Granular Kidney; Red Granular Kidney; Gouty Kidney; Renal Sclerosis.*

Definition.—Chronic interstitial nephritis is a chronic process resulting ultimately in a shrunken kidney, in which there has been extensive destruction of the tubular substance and overgrowth of interstitial connective tissue.

Etiology.—Of the recognized forms of Bright's disease, interstitial nephritis shares with chronic parenchymatous nephritis a large number of instances in which the cause is undiscoverable. There are, however, some well-determined causes. Among the most tangible of these is gout. *Gout* is associated with so many cases of contracted kidney that the term *gouty kidney* has become a well-recognized synonym for the product of interstitial nephritis. There are probably no cases of gout which have continued for any length of time which are not accompanied by interstitial nephritis. Uric acid and allied substances in the blood are probably the exciting cause. Another well-recognized cause is *lead* in lead-poisoning, the absorbed lead acting like the poison of gout. Hence painters, glaziers, workers in lead in any form, are frequent victims. Dr. Dickinson considers it safe to assert that of painters at least one-half eventually die of granular degeneration of the kidneys. This is certainly not the case in this country. It is true that *alcohol* has always been assigned an important rôle in the production of chronic interstitial nephritis. It is probably true, especially if associated with a habit of overeating proteid foods. The latter habit alone I believe to be a frequent cause of chronically contracted kidney. It is almost incredible how much some persons eat,—persons, too, who are inactive in mind and body. Such persons must overwork the kidney and gradually bring on a condition of chronic nephritis, which does not, however, usually appear until after middle life. On the other hand, I believe alcohol alone is responsible for more cases of chronic parenchymatous nephritis. The late Dr. Henry F. Formad, who, as coroner's physician for many years in Philadelphia, made an enormous number of autopsies on drunkards, always held this view, and claimed that the kidney was peculiar enough in shape to be called the "pig-back" kidney.

Long-continued *cystitis*, especially following gonorrhœa, is a cause in a few instances, the inflammation traveling up the ureter to the pelvis of the kidney and thence to the intertubular tissue. The more usual result of such extension is suppurative nephritis.

Among the causes the operation of which cannot be so directly proved

are *anxiety* or *business care* and *worry*. Dr. Clifford Allbutt, quoted by Dr. Robert T. Edes,* goes so far as to attribute "twenty-four out of thirty-two cases in private practice to some long-continued anxiety or great grief." This also is contrary to my experience. It is true that this disease very often exists for a long time undiscovered in business men who have lived under a state of constant mental tension. The effect of this cause is augmented if its subjects combine too liberal eating and drinking with the hard work and anxiety.

Hereditary influence is occasionally a cause of contracted kidney. A remarkable instance of this has occurred in my own practice. I was consulted by a man, aged thirty, who had granular kidneys. His father and mother both died of Bright's disease, aged fifty-six and sixty-three years, respectively. The mother had convulsions. A brother died of Bright's disease, without convulsions, at the age of thirty-seven. Two children of this brother had Bright's disease when four and seven years of age, respectively. A second brother died at the age of twenty-nine with convulsions. A third and fourth brother, aged twenty-three and thirty-two years, respectively, have had Bright's disease for six years. A sister, aged thirty-six, has had Bright's disease for five years. A brother, aged twenty-six, and a sister, aged thirty-four, have as yet exhibited no signs of Bright's disease. A maternal cousin died of undoubted Bright's disease, and other members of the family belonging to previous generations died with symptoms which suggest Bright's disease. The patient, himself, has undoubted granular kidney, discovered in August, 1880. An examination of his urine in 1876 revealed no evidences of the disease. There is no gout in the family. Dr. Dickinson also relates the history of a family in which a hereditary albuminuria existed independent of gout.

Prolonged *passive congestion*, due to valvular heart disease, may become a cause of granular kidney. The same may be said of *stone in the kidney* causing numerous attacks of nephritic colic. I have known typical chronic interstitial nephritis ensue on such attacks of nephritic colic.

Pregnancy, so frequently a cause of acute parenchymatous nephritis, is rarely, if ever, a cause of interstitial nephritis or chronic parenchymatous nephritis. It is true contracted kidney is sometimes found in autopsies of women dying of puerperal nephritis, but I believe it more frequently precedes than follows the pregnancy.

Interstitial nephritis is commonly a *disease of middle age*, the majority of persons in whom it is discovered being past forty. A few cases occur under thirty. The youngest patient whom I have ever had was twenty-six. Still younger cases are reported.

It must be remembered that there is a tendency to overgrowth in the interstitial tissue of the kidney, as of other organs, in old age. Hence the term, *senile atrophy of the kidney*. It is not safe, therefore, to call every instance of atrophied kidney met in the postmortem room a case of interstitial nephritis. The clinical history, or some one of the well-marked symptoms of the disease, as albuminuria or uremic symptoms, should have preceded to sustain the diagnosis.

As to *sex*, nearly twice as many males have the disease as females, because of the more frequent exposure of the former to the causes of the affection.

* Robert T. Edes, "Some of the Symptoms of Bright's Disease," "Boston Med. and Surg. Jour.," vol. ciii, No. 2, July 8, 1880.

Morbid Anatomy.—In interstitial nephritis, both kidneys are involved, but there is often a marked difference in the extent of the disease in each.

Macroscopically, the organs are evidently smaller than in health, often less than half as large. I have seen them less than five centimeters (2 inches) in length. Next to this reduction in size, the most striking feature of the contracted kidney is its uneven or granular surface, which is, however, not always recognizable until after the capsule is removed. Very characteristic also is the presence of cysts with more or less clear watery or gelatinous contents, often visible through the capsule. These are not invariably, but quite frequently, present. The capsule, itself thickened, strips off with difficulty, dragging portions of the secreting structure with it. Owing to the resistance which the blood meets in its passage through the kidney, a larger portion of it passes out of the organ by way of the capsule; hence the blood-vessels of the latter are dilated, as are also the lymph-spaces.

Bereft of its capsule, the kidney is hard, granular, tough, and usually darker than in health, whence one of its names, the "red granular kidney." This color is in strong contrast to the white or slightly yellow tinge of the fatty and contracting kidney, and although it is not always marked, and sometimes even substituted by a paleness, it is still easily distinguished from that of the contracting kidney of parenchymatous nephritis. The granules on the surface of the contracted kidney are distinct round and oval elevations of the surface, ranging in size from that of a pin's head to that of a pea, or from 1-25 to 1-5 inch (1 to 5 mm.). Those of smaller size are most numerous, and at first correspond with the lobules, the bases of which are visible on the surface of the normal organ. The larger ones result from the coalescence of two or more of the smaller. The granules themselves are of a lighter color than the depressed circlets between them, which are tinted with vascularity and have a purplish or faint red hue. The cysts already referred to are now more distinct (after removal of the capsule), and vary greatly in size. While equaling in minuteness the smallest of the granules, some of them are as large as a walnut. The larger are apt to be ruptured on stripping off the capsule.

On section, it is at once evident that the reduction in size of the kidney is largely due to a narrowing of the cortex, although the medulla is also contracted. The former may not be more than from 1-8 to 1-6 inch (3 or 4 mm.) in width, and exhibit every degree between this and the normal. The Malpighian bodies are smaller, less numerous, and can scarcely be detected by the naked eye, while the small arteries are more prominent from the thickening of their walls. Increased density and firmness of the organ are apparent. In a gouty subject, linear chalk-marks of sodium urate may be present, more particularly in the pyramids of straight tubules, and are contained within, as well as between, the latter. The little cysts referred to as seen on the surface may also be scattered throughout the section from cortex to papillæ, but they are more numerous in the former. They are not always present. The pelvis of the kidney may be unaltered. It is sometimes enlarged, and the calices are elongated from retraction of the pyramids. On the other hand, if the kidney is very much reduced in size, the capsule may be pursed up and proportionately smaller.

Minute Structure.—Minute examination of thin sections through the cortex clearly reveals the condition to be an excess of connective tissue, with destruction of the tubules and blood-vessels. The process is best

studied if the sections include the capsular edge, as the disease progresses from without inward. In such sections may be seen extensive tracts of connective tissue separating the tubules, which, in healthy kidneys, are closely in contact without appreciable intertubular substance. The *tubules* themselves appear in places quite normal; in others they are represented by fragmentary portions in which the cells are still unchanged; in others, again, the cells exhibit a granular degeneration; some tubes are evidently dilated; others still are completely shriveled, while it is evident from the larger areas of connective tissue that many have completely disappeared. In a few tubules waxy casts are present. The Malpighian bodies are surrounded by concentric layers of nucleated connective tissue. Many of them are shriveled and atrophied, and an attempt to inject them with colored injecting fluids fails either partially or completely. Some thus altered lie detached from the tubules, with which they should be continuous. The granules on the surface of the kidneys are resolvable by the microscope into tubules, some of which are in a tolerably perfect state, some decidedly dilated.

The *cysts* originate partly in dilatations of obstructed segments of the uriniferous tubules and partly in dilated Malpighian capsules. Proof of the latter mode of origin is found in the fact that compressed capillary tufts are sometimes found lying up against one side of the wall of the cyst. The same overgrowth of connective tissue may be seen in the pyramids, but it appears later, extends more slowly, and never reaches the degree found in the cortex.

The *blood-vessel* of the contracted kidney is the seat of important changes. In the first place, it shares with the tubules the compressing effect of the contracting new formation. As the result of this, a part of the capillary system is destroyed, and in the part thus destroyed are many capillary coils in the Malpighian bodies. Hence, as many afferent arterioles send their blood directly into the second capillary network, which is also cut down by the pressure. The vessels which remain are often sclerotic, dilated, and twisted, and in consequence of the destruction of numerous Malpighian bodies send much of their blood out through the capsule of the kidney. The intima is thickened, and the media and adventitia are invaded by hyperplastic connective tissue, but always to a less degree. Even arterioles whose walls have thus been thickened become involved in the atrophic processes affecting the glandular tissue of the organ, and ultimately disappear.

Associated with these changes are a *general arteriosclerosis* and *hypertrophy of the left ventricle* of the heart, sometimes also of the right. The final effect of these alterations is to produce a brittleness in the arteriole walls, which disposes them to rupture on very slight increase of intravascular pressure. Hence the frequent fatal termination of cases of interstitial nephritis by apoplexy, also the frequent nasal and retinal hemorrhages which characterize the disease.

The *retinal changes*.—*retinitis albuminurica*,—symptoms of which form so important a part of the symptomatology of chronic interstitial nephritis, are various and vary with the stage of each case. Many cases are first diagnosed by the ophthalmic surgeon. The changes include serous swelling of the disc and surrounding retina, hemorrhagic extravasations, dirty white splotches, representing fatty degeneration, and dilatation of the veins and capillaries, with fatty degeneration and sometimes hyaline thickening of their walls.

Symptoms.—The great obscurity as to the origin of a large majority

of cases of contracted kidney is only equaled by that of the insidiousness of their approach. The beginning of the disease is certainly not characterized by any distinctive symptoms; and its progress is often unmarked by any, until those of uremia mark the beginning of the end. To the observing physician some obscure symptom may suggest an examination of the urine; or the peculiar tense and bounding pulse of hypertrophy of the left ventricle, or the more tangible symptom of a slight swelling of the feet or ankles, recognizable only at night or through the unexpected tightness of a boot, may lead to the same examination.

Changes in the Urine.—Attention being called to the *urine*, it will be found to present characters which are more or less distinctive and lead easily to a diagnosis. When freshly passed, it is acid in reaction, copious, often exceeding the normal amount, and never scanty, except in the last stages of the disease. The quantity is often sixty (1800 c. c.), and may reach ninety ounces (2700 c. c.). The patient very commonly must rise at night, probably not more than once or twice, to pass his water. There may be corresponding thirst. Consequently, the urine is light in color and of low specific gravity,—1005 to 1015,—and contains a trifling or moderate flocculent sediment. It is generally albuminous, but the albumin is small in amount and may be temporarily absent, or it may be absent before a meal and present after it. Later, however, the albumin becomes constant. It seldom exceeds one-tenth the bulk of fluid tested, and is very constantly a great deal less, showing a delicate line of white by Heller's nitric acid test. Tube-casts are present, but not usually numerous. They are almost solely hyaline and pale granular. Some of the hyaline casts are delicately so, requiring delicate illumination for their detection; others are distinct and sharply cut; others still contain two or three glistening oil drops. Casts may at times be absent and again reappear, as is the case with albumin. Toward the termination of cases of interstitial nephritis the urine diminishes in quantity, the specific gravity increases, and the casts become much more numerous, and include among them highly granular or dark granular and occasionally even blood casts in addition to those mentioned, and there are sometimes a few blood discs earlier. The *urea* is also diminished, sooner or later, and in this manner the lower specific gravity is contributed to. This fall becomes marked toward the close, accounting for the uremic symptoms which often first announce the disease. It may be as low as fifteen grains (1 gm.), and may range anywhere between this and the normal twenty-four hours' quantity, which may be put down at from 308 to 617 grains (20 to 40 gm.) in an adult, being largely influenced by the kind of food ingested. All the remaining normal constituents may be said, in general terms, to be diminished.

As to the other symptoms, a feeling of *unaccountable weakness* or of being tired is very often present, but it is a symptom which occurs in many conditions, and should only be considered as suggestive. *Slight edema* about the feet and ankles is often present, being so slight as to escape detection, or it is discovered accidentally. When present it is significant, but it is often entirely wanting.

Hypertrophy of the left ventricle of the heart without valvular disease is so constant as to be alone suggestive of the disease. No case of interstitial nephritis has existed for any length of time without this condition supervening, and as few cases are discovered until they have existed for some time, few are found without hypertrophy. In more than one-half of cases, at least, there is evident hypertrophy. It is recognized at first not so much

by the resulting enlarged percussion area as by the sharp accentuation of the aortic second sound. Corresponding to this, the *pulse* is hard and resisting, indicating high tension and thickening. These two symptoms have, therefore, great diagnostic value. *Sclerosis* is distinguished from tension by obliterating the blood-current by pressure and feeling the artery beyond this point. The sclerosed vessel continues tangible; that of simple high tension disappears. A symptom of this stage is often an uncomfortable *pulsation* felt in the head and even in other parts of the body.

The causes of these changes in the vascular system will be considered when treating of the relation of heart disease and kidney disease.

As the disease becomes more advanced there are added *cardiac symptoms*, including dyspnea, palpitation, and reduplication of the first sound. The last is probably due to a want of synchronism in the systole of the two ventricles. There is usually no murmur, because there is no valvular disease. The latter may be present. The patient may have had valvular disease prior to the renal malady, or the latter itself, by its long continuance, may have produced endocarditis and atheroma with an aortic systolic murmur, or there may be a mitral murmur due to relative insufficiency. Valvular disease is, however, unusual. The hypertrophy of the heart is conservative, and all goes well as long as the power of the heart lasts. When the latter begins to fail and dilatation appears, the blood pressure diminishes, and with it begins a train of symptoms, among which diminished secretion of urine and dropsy are the most conspicuous, along with gallop rhythm, dyspnea, palpitation, and dizziness. These symptoms may again be averted for a time by hypertrophy of the right ventricle, which is a symptom of disturbed compensation. Among derangements of breathing must be included Cheyne-Stokes breathing, commonly toward the end of the disease.

Dimness of vision due to retinitis albuminurica, already described on page 719 is a characteristic symptom. It is often the first recognized, and hence the diagnosis is frequently first made by the ophthalmologist. It is a serious symptom, generally considered a sign of advanced disease, as, indeed, it usually is. Some assign two years as the limit of life after its recognition, but this is too unfavorable a prognosis. The atheroma of the blood-vessels is the cause of another symptom which frequently determines the mode of death—rupture of a blood-vessel in the brain: in a word, *apoplexy*. This accident is more usual late in life, but Dickinson reports a case in which cerebral hemorrhage occurred in a girl of twelve. The proportion of cases of recognized interstitial nephritis in which this happens is not large, but many cases of apoplexy are directly traceable at autopsy to unsuspected renal cirrhosis. Dickinson believes that of fatal cases of apoplexy, one-half are preceded by this form of disease. Hemorrhages in other situations are referable to this same altered state of the blood-vessels, as, for example, into the retina, from the nose, and even into the stomach. Hence, *sudden blindness*, in addition to the dimness of vision due to retinitis albuminurica, is a symptom which occasionally presents itself. Amaurosis and amblyopia also occur, and may disappear, but dimness of vision due to retinitis albuminurica is a permanent symptom, though I have seen it improve under treatment. Auditory disturbances also occur, such as ringing in the ears, with dizziness and more or less deafness.

The termination by *uremia* occurs more frequently in this than in any other form of Bright's disease. Bartels says that nearly all the patients he

has seen die in the extreme stage of atrophied kidneys sank under the symptom of chronic uremia. He is probably correct, and it is frequently the first intimation of the existence of any derangement, manifesting itself in any one or more of the forms already described under acute nephritis. Headache, drowsiness, convulsions, stupor, delirium, maniacal excitement, renal asthma, restlessness, nausea, vomiting—any one of these symptoms may usher in the dreadful train which is so likely to be fatal. E. C. Seguin especially has called attention to occipital headache as a symptom of uremia.* Von Leube considers that even the intermittent headaches which occur in this disease, and which very closely resemble migraine, are probably due to uremia. Temperature follows the same rule in uremia as in other forms of nephritis. The *convulsion* is commonly associated with a rise of temperature. *Dyspeptic symptoms*, with obstinate vomiting, particularly in the morning on rising, are apt to usher in a chronic uremia. *Diarrhea* is less common, but also sometimes occurs toward the close, when it may be very difficult to control.

The duration of this form of renal disease is indefinite. Always a chronic process, it may last for years undiscovered, and when discovered before it is too far advanced, the knowledge of its presence will suggest measures of precaution and treatment which may so prolong life that it need only be determined by its natural limit or some other disease. Yet complete recovery from well-established interstitial nephritis is probably unknown.

Complications.—These include bronchitis, pericarditis, pleurisy, pneumonia, and, more rarely, endocarditis, peritonitis, intertubular gastritis, and even inflammation and ulceration of the bowels. But all inflammatory complications, except bronchitis, pleurisy, and pericarditis, are less frequent than in acute nephritis. Bronchitis is said to be the most frequent complication, while pericarditis is the most dangerous, being almost invariably fatal. The former occurs in about 33 per cent. of the cases, and the latter in 25 per cent., according to W. Howship Dickinson, and 7 per cent. according to Sir T. Grainger Stewart. My own experience accords more nearly with the latter. Pleurisy and pneumonia are also of tolerably frequent occurrence, Dr. Stewart finding the former in 15 per cent. of his cases and pneumonia in 7 per cent. Acute endocarditis and peritonitis occur, but very seldom.

Diagnosis.—The diagnosis of an interstitial nephritis is usually easy, if in any way an examination of the urine is suggested. The increased quantity, the low specific gravity, small albuminuria, delicate hyaline, pale granular casts, and hypertrophy of the left ventricle, even in the absence of other symptoms, are sufficiently distinctive. The conditions which should suggest such an examination are a feeling of constant weariness, slight swelling of the feet, drowsiness, frequent headaches, confused intellect, dyspeptic symptoms, obstinate nausea, delirium, coma, and convulsions. High arterial tension should always suggest examination of the urine.

The special condition from which it is most difficult to distinguish it is the milder form of *chronic diffuse* or *parenchymatous nephritis*, especially if the latter has reached the contracting stage. In fact, the symptoms are often identical, and unless the history helps us, it may be impossible to decide. The evidences of decided fatty change, such as the oil cast or free fatty renal cell in the urine, settle the question in favor of chronic diffuse nephritis.

* "Archives of Medicine," vol. iv., No. 1, New York, August, 1890.

Diabetes insipidus is comparable to contracted kidney in the increased quantity of urine of low specific gravity, but there is no albumin, casts are absent, and the quantity of urine is much greater.

Prognosis.—The prognosis is unfavorable as to recovery, but favorable as to prolongation of life if the diagnosis be made sufficiently early. Cases with casts and small albuminuria may continue under observation for ten or more years. If not made previous to the setting in of uremic symptoms, little may be expected. But even at this stage, energetic treatment may still avail to avert the immediate danger and prolong the patient's life. The possible sudden occurrence of convulsions and coma, and of death therefrom, should always be remembered and impressed upon the relatives of the patient. These constitute unfavorable symptoms, to which, toward the end, Cheyne-Stokes breathing may be added.

Treatment.—From what has been said under prognosis, it is evident that the most hopeful result to be expected from treatment is the protection of the patient from the consequences of his malady, rather than the restoration of the kidney to its normal condition. Our power in the former respect depends largely upon the stage at which the disease is discovered. If detected at a period in which the urine is abundant, the albuminuria small, the casts few, and there is no edema, the indications are:

1. To maintain the integrity of the blood, by preventing the accumulation of urea and allied compounds.
2. To treat, as they arise, the accidents and complications which are often so dangerous to the patient.

The first of these is best accomplished by dietetic and hygienic measures, aided by the use of a few remedies. First, as to *food*, all that was said under chronic parenchymatous nephritis is applicable to interstitial nephritis, because the appetite is still good, and a suitable selection can be exercised. As the urea has its chief source in the azotized elements of food, it is plain that the larger the quantity of such food consumed, the larger is the accumulation of urea to be eliminated by the kidneys. Now, while it is not possible nor, perhaps, desirable to exclude all nitrogenous food, it may be largely reduced. This is accomplished by the substitution of all or a part of animal flesh by milk, while drawing the elements of a mixed food from the vegetable kingdom. The so-called vegetarians have proved conclusively that it is possible to live and maintain good health upon milk and an otherwise exclusively vegetable diet, and, while this diet may not be compatible with the highest mental and physical development of which man is capable,* which is not at all proved, the resulting life is perfect enough for all its objects, and will doubtless be acceptable to those who prefer to live. On such a system I have known the patient with contracted kidney to maintain apparently perfect health for many years.

With regard to habitual beverages, the use of strong alcoholic drinks is harmful, and brandy, whisky, champagne, sherries and ports should be prohibited. The light wines, and especially the red wines and lighter alcoholic drinks, as lager beer, porter, etc., may be used in moderation. I have already referred to the very great value of the alkaline mineral waters, such as those of Vichy, Vals, and Kissingen; to these a little claret may be added at dinner.

What has been said of clothing, fresh air, and exercise in connection

* See Carpenter's "Physiology," seventh English edition, 1869, p. 77.

with chronic parenchymatous nephritis is even more applicable to interstitial nephritis. Warmth of the body, maintained by woolen garments next the skin to encourage its action, and the avoidance of damp and cold, which check it, are peremptory. The wetting of the body by rain, or of the feet alone, has frequently been the exciting cause of a fatal uremic attack. India-rubber overshoes should be worn in damp weather.

In this connection, sea-bathing requires mention. It is well known that sea-bathing sometimes induces albuminuria in normally constituted persons, or, at least, in individuals at other times free from albuminuria. This is probably due to a temporary congestion of the kidney, from introversion of the blood kept up by the duration of the bath. Still more mischievous, therefore, must be the effect of prolonged sea-bathing upon one whose kidneys are already damaged and incompetent to perform their office. Sea-bathing, therefore, or any form of cold bathing, should be interdicted to the patient with contracted kidney or, indeed, with any form of chronic nephritis. Sea-bathing is especially mentioned because it is considered healthful, and persons remain in the water so long at a time. On the other hand, a daily warm bath at bedtime, and especially an occasional Turkish bath, is advantageous.

For the same reason residence in a warm, equable climate is often of signal service in interstitial nephritis; and cases are reported in which the albumin has disappeared and symptomatic recovery taken place during such residence.

Prolonged bodily or mental fatigue should also be avoided by these patients, as they have been known to be the exciting cause of uremia and death; especially are they so when associated with free eating and drinking. The patient should live a life as easy and as free from any of these causes which have been considered as his circumstances will permit.

As to drugs, they are of limited utility. The moderate use of *tonics*, including quinin, strychnin, and iron, is useful to combat the tendency to anemia and weakness, which sooner or later follows. In this form of Bright's disease, even more than in chronic parenchymatous nephritis, is the indiscriminate use of iron to be guarded against. Iron in contracted kidney, as often used, is a harmful drug. It locks up secretions, causes headache, and increases the danger of uremia. Only when there is evident anemia should it be used, and then only in very small doses. I hold that so long as iron blackens the stools or constipates the bowels, the doses are too large, and they should be reduced until the effect on the stools is very slight or not noticeable. Elimination is favored by stimulating the secretion of the skin, and this is best accomplished by an occasional warm bath, or, especially, a Turkish bath, with thorough friction and protection from cold by woolen underclothing. The Turkish bath is an admirable remedial measure, especially before the disease is too far advanced.

Diuretics are not indicated in the earlier stages, because the secretion of urine is already free. The bowels should be kept regular by the use of the natural aperient waters, the Hunyadi, Friedrichshalle, and Rakoczy, or an occasional blue pill, or a dose of magnesium sulphate. Of course, later in the disease, when the heart begins to fail and the urine is scanty, both diuretics and purgatives are indicated. The same principles are to govern us in using them as have already been laid down under acute nephritis. Very high arterial tension sometimes demands treatment. A certain amount is a result of the conservative train of symptoms, beginning

with hypertrophy of the left ventricle, and is necessary; but when a resulting throbbing is unpleasantly appreciable, especially if there is throbbing headache with flashes of light at each pulsation, tension should be lowered. The remedy which excels all others is nitroglycerin, which should be given in doses of 1-100 grain (0.00066 gm.) and upward every three hours or oftener. The best preparation is the one per cent. alcoholic solution, of which one drop represents 1-100 grain (0.00066 gm.), the granules being more convenient, but less reliable. The dose should be rapidly increased until the physiological effect is obtained, and then reduced to what is found best to effect its purpose. Either the susceptibility of different persons varies greatly or the drug varies greatly in quality. I have repeatedly given it every two hours for days together in doses of 1-100 grain (0.00066 gm.). It may be associated with digitalis, with which it co-operates by relaxing the arteriolar spasm which digitalis produces, and which interferes with its happiest effects.

The second indication mentioned, the *treatment of the complications and accidents* incident to the condition, resolves itself into the treatment of the bronchitis, the pericarditis, the pleurisy, pneumonia, endocarditis, gastric and intestinal disorders, which have been named as occurring, and especially of the most serious calamity of all, uremia. The treatment of the complications is that of the same conditions under other circumstances. Paracentesis is a measure which is often of signal service in effusions into the chest, and occasionally of the pericardium.

Dyspeptic symptoms are best treated with pepsin and acids, and such other remedies as may be symptomatically required. *Opium* should be cautiously employed, if at all, not only in the gastro-intestinal disturbances, but under all circumstances, as it undoubtedly increases the dangers of uremia. This has been abundantly proved. It need not be discarded altogether, for there is sometimes no substitute for it in certain bowel affections and conditions of severe pain, but it should be given in smaller doses than usual and its effects watched. In like manner, hypnotic, sedative, and antispasmodic effects, when desired, should be produced by sulphonal, trional, chloral, and bromids, if possible.

Finally, as to the treatment of uremia, the measures described in the treatment of uremia in acute nephritis are to be used. Apoplexy, which is not an infrequent termination of the disease, in consequence of the atheromatous state of the blood-vessel walls, is recognized by the paralysis, general or partial,—most frequently hemiplegia,—which accompanies the unconsciousness. Remedies are here generally futile, but such may be used as are indicated for apoplexy. The upright position, bleeding, counter-irritation, and, if the patient survives the immediate accident, iodid of potassium, with a view to promoting absorption of the extravasated clot, may be used. Hemorrhages in other situations, as from the nose or alimentary canal, are treated by the same measures as when they occur under other circumstances. The close resemblance at times of the symptoms of uremia to those of apoplexy should be remembered.

As to special treatment, or treatment directed to the removal of the interstitial overgrowth in the kidney, there is none. Theoretically, the iodid of potassium ought to be of service. Unfortunately, the peculiar requirements of its administration—viz., the length of time during which the patient must take the remedy before any results may be expected, and the consequent difficulty in accumulating a sufficient number of cases—are

such that it is almost impossible to determine whether it can be of any service or not. Owing to these difficulties, it is doubtful whether its exact possibilities have as yet been determined. There can be no disadvantage in administering it, if the dose is so small as not to derange the stomach. Very rarely can more than a few grains daily be given. I believe I can say, however, of the bichlorid of mercury, that I have seen its long-continued use in doses of, at first, 1-24 grain (0.0027 gm.), and later 1-50 grain (0.0013 gm.), kept up a long time, followed by improvement. I have also seen improvement in the impaired vision of albuminuric retinitis follow its use. Certainly, in the event of a clear syphilitic origin, the iodid of potassium should be used. I have also used the biniodid of mercury with apparent happy results, in doses of 1-24 gr. (0.0027 gm.) to 1-16 gr. (0.0040 gm.) a day.

LARDACEOUS DISEASE OF THE KIDNEY.

SYNONYMS.—*Amyloid Disease; Albuminoid Disease; Waxy Kidney; Depurative Disease.*

Definition.—A morbid state of the kidney in which its structural elements are more or less infiltrated with a substance of albuminous composition and of bacony luster, best recognized by the deep mahogany-red color it strikes when treated with a solution of iodin.

Etiology.—The most frequent cause of lardaceous disease is profuse and long-continued suppuration, such as occurs in chronic bone disease, whether tubercular, syphilitic, or traumatic in origin; or such discharge as constitutes the expectoration in cases of chronic phthisis and chronic bronchitis with bronchiectasis. Syphilis itself, independently of the tertiary conditions which it produces, is a frequent cause of lardaceous disease. Cachectic states of any kind, chronic dysentery, ulceration of the bowels, and chronic albuminuria are possible causes.

Either sex is equally subject to lardaceous disease, but as men are more frequently exposed to its causes, it is in them rather more common. Very young children are rarely affected, for evident reasons, but in young persons from eleven to thirty it is most frequent. After thirty it grows gradually rarer. Tubercular hip disease in children, especially, is a cause.

Morbid Anatomy.—The incipient stages seldom present alterations recognizable by the naked eye, unaided by reagents. But if, after section of the kidney, the cortex be treated by a solution of iodin and iodid of potassium,* numerous mahogany-red points make their appearance; or if by a solution of violet anilin, as many red or pink points. These are the Malpighian bodies, whose capillary tufts are the first to be affected by the change. The kidney, in this early stage, is normal in size or very slightly enlarged. Its capsule strips off readily, leaving an organ which exhibits no changes, or a paleness or translucency which readily escapes notice, but may be recognized at the edges of a thin section. Very often, too, they are completely overshadowed by other alterations, for amyloid kidney is

* *The Iodin Test Solutions.*—The best test solution for macroscopic purposes is one made by dissolving 2½ grains (0.15 gm.) of iodin by the aid of five grains (0.32 gm.) of iodid of potassium in one fluid ounce (30 c. c.) of water. The solution contains about one-half of one per cent. of iodin. For microscopic preparations a solution weaker than the foregoing, or a one-quarter of one per cent. of iodin dissolved by twice the quantity of iodid of potassium, is more suitable, and sometimes a solution containing as much iodin as water alone will take up answers best.

most frequently a superadded event in the course of chronic diffuse nephritis, while the same event may happen in interstitial nephritis. The large white kidney of chronic parenchymatous nephritis is especially apt to exhibit a slight degree of lardaceous change, which may altogether escape notice unless iodine is used. Hence, *iodine should be tried upon all kidneys removed at autopsy.*

In a more advanced stage of uncomplicated lardaceous change the kidneys are both enlarged, usually symmetrically, but the extreme degrees of enlargement are commonly associated with fatty degeneration of the epithelium. Such organs were a pair weighing twenty-three ounces (715 gm.) which came under Dr. Dickinson's* notice. Dr. Johnson † refers to a case in which the two kidneys weighed twenty-eight ounces (870 gm.). Rindfleisch ‡ has seen a single instance of that very rare condition, complete lardaceous infiltration,—that is, in which the basement membrane of the uriniferous tubes, as well as the capillaries, was infiltrated,—in which the kidney was enlarged to nearly twice its normal size. In the uncomplicated forms of lardaceous disease the capsule is not adherent, but if interstitial changes coexist to any extent, it is adherent. It leaves the surface of the kidney pale and anemic; occasionally, the stellate veins are conspicuous. The characteristic translucency may even be recognized in the organ in bulk, but in sections it is more striking. When the change is present in high degree, the edges of a thin section are almost as translucent as a similar section of bacon. On laying open the kidney the cortex is seen to be enlarged; it is pale, anemic, waxy, firm, and resisting. The pyramids are normal in hue and area. The iodine solution added to such a kidney produces its peculiar coloration not merely in the Malpighian capillaries, but also in the afferent and efferent vessels and the vasa recta of the pyramids. In a still later stage, that of atrophy, the kidney becomes contracted, diminished in size, rough, and even distorted in shape. The capsule is adherent, and on section the cortex is found narrowed, sometimes as much so as in the contracted kidney of interstitial nephritis.

Microscopic Changes.—To microscopic examination in the first stage, in which the naked eye often fails to detect anything abnormal without the aid of iodine, the Malpighian bodies exhibit a lustrous or waxy appearance. They are also enlarged and the capillary walls thickened. At this stage there is no visible alteration in the tubules or in their epithelium. In the second stage larger vessels are involved, the vasa afferentia and efferentia in the cortex, and also the vasa recta of the cones; also the second capillary network of the cortex, and an exudation occurs into the tubules of a glistening material which forms casts. This is undoubtedly at times the amyloid material, for such casts sometimes strike the mahogany reaction. At other times they have the composition of ordinary hyaline casts. It is to be remembered, too, that similar waxy casts are found in the tubules in other forms of chronic and even acute renal disease.

The arteriole walls are thickened by an involvement of both interna and media. This thickening is attended by an extraordinary distinctness of the muscular fiber-cells of the circular coat. Later, the basement membrane and epithelial lining may also be invaded, the cells being swollen, translucent, and apparently fused. It is also quite usual for the epithelium of the cells to be

* Dickinson, *op. cit.*, p. 249.

† Johnson *op. cit.*, p. 104.

‡ Rindfleisch, "Path. Histology," "New Syd. Soc. Trans.," 1873, vol. ii. p. 167.

fatty, and the capillary walls to contain aggregations of fat globules, while the urine in the later stage contains oil casts and fatty cells.

In what has been called the third or contracting stage of lardaceous kidney, but which may be the ordinary contracted kidney on which the amyloid change has been ingrafted, minute examination reveals, in addition to the appearances described, the hypernucleated intertubal overgrowth. Cysts are occasionally present for the same reason that they are found in the granular contracted kidney, and the surface assumes also a certain degree of granulation.

Symptoms.—An individual who has had syphilis, or who has plithisis, bone-necrosis, or other affection causing an exhaustive drain, may acquire this form of kidney disease without appreciable addition to his symptoms. There may be a growing frequency in micturition, but this symptom may be totally absent. Accidentally, it may be, a somewhat copious albuminuria is discovered. At first the urine may be quite clear, and no casts are met, or they are exceedingly scanty and hyaline or faintly granular. Later, a slight edema of the feet may appear while the patient is up and about, but it disappears during the night while he is in bed. The albuminuria is now copious, but still varies, and casts may be more numerous, or may still be scanty and continue hyaline or faintly granular. The urine is now decidedly increased in quantity—fifty-three to eighty ounces (1600 to 2500 c. c.); its specific gravity is low—1005 to 1015. More rarely the urine is scanty. A cachectic anemic condition develops. There is sometimes a peculiar fetor of the breath, but it is doubtful whether this is characteristic of this more than of other forms of chronic kidney disease. Still later all these symptoms increase; the dropsy is persistent, the urine loaded with albumin, and, in addition to the ordinary delicate hyaline casts, it may contain the glistening waxy casts.

Senator announced some years ago that *serum globulin* is increased in the urine of amyloid kidney. Some winters ago I was enabled to make some observations which make me confident that he is right and that it is quite a valuable diagnostic sign. Fatty casts and free fatty epithelium from the tubules of the kidney may be superadded, as well as free oil drops. Epithelial casts are rare, as is blood. Edema of the lungs may also occur as a serious complication. Toward the close of the disease, the urine, which had been increased, becomes diminished in quantity, but is seldom suppressed. Of the chemical constituents, it may be said of all that they are, as a rule, slightly diminished, but not sufficiently to influence the course of the disease. It is in consequence of this that uremia is almost unknown in lardaceous disease, the urea and extractives being eliminated in sufficient amount to avert this evil. Nor do we find hypertrophy of the left ventricle or high arterial tension.

But lardaceous disease of the kidney almost never occurs alone. It is always accompanied by similar changes in the liver, spleen, and often of the intestinal canal. Hence, evidences of alterations in these organs are more or less marked. Thus, the percussion areas of the liver and spleen are almost always enlarged, and the blood-vessels of the stomach and intestines are often involved. In the former event obstinate vomiting, and in the latter equally obstinate diarrhea, results. The latter is far more frequent than the former.

As to *duration*, the disease generally runs a very chronic course, which is limited only by the malady of which it is a complication. As such it is always of shorter duration than interstitial nephritis, and may be shorter than chronic parenchymatous nephritis, although the latter affection and lardaceous

disease more closely resemble each other in respect to duration. When obstinate diarrhea and vomiting supervene, the end is usually not remote.

Diagnosis.—There are some instances in which lardaceous disease is easily recognized. If a patient has had syphilis with secondary and tertiary symptoms, or has long been a victim to phthisis, and he is discovered to be edematous and to have a large albuminuria, with waxy hyaline and fatty casts and an enlarged liver and spleen and obstinate diarrhea, there can be little doubt but that lardaceous disease is present. But when neither of these two general diseases is present, or the phthisis has not existed a very long time, or there is not decided evidence of enlarged liver and spleen, we cannot be certain. While it is never safe to diagnose lardaceous disease without the presence of enlarged liver and spleen, the presence of these enlarged organs along with large albuminuria, and the other symptoms which attend it, do not necessarily imply amyloid kidney. The symptoms and course of the disease, particularly in its latter stages, are so like those of *chronic parenchymatous nephritis* that it is often impossible to distinguish the two. Further, there is every reason to believe that chronic nephritis is sometimes caused by the same dyscrasic conditions as produce the lardaceous disease. In such cases, therefore, a diagnosis is impossible. Finally, the two conditions may exist jointly.

The only other form of renal disease which it is at all possible to confound with lardaceous disease is *interstitial nephritis*. But in this we have the almost total absence of dropsy, small albuminuria, and scanty sediment, in which granular and hyaline casts are found. While the quantity of urine is increased in both these forms of chronic Bright's disease, the quantity is larger in interstitial nephritis. Hypertrophy of the left ventricle, an almost invariable symptom in contracted kidney, is very rare in lardaceous disease, while enlargement of the spleen and liver is common and does not occur in interstitial nephritis. Contracted kidney may also be associated with lardaceous disease.

Prognosis.—In the matter of prognosis much depends upon the presence or absence of the original disease causing the lardaceous change in the kidneys. If the former cannot be cured, the effect of the latter can only be to hurry on the unfavorable termination, although it is subject to the abatements as well as exacerbations of that affection. If the original disease is curable and the patient young, there are no limits to the possible improvement, although it is scarcely likely that the diseased structures are ever restored to their normal state. But as it is unlikely that all the renal vessels are involved in the change, and the organ itself, especially before its complete development is attained, is one capable of assuming an extraordinary degree of supplemental function, it is not impossible that there may be a complete restoration. If the patient is past middle life, even if it should happen that the original disease has disappeared, the probabilities of recovery are small, while a decided degree of improvement is not impossible. If the stage of alteration of the blood-vessels of the stomach and intestines, as attested by obstinate vomiting and diarrhea, is reached, the disease is necessarily rapidly fatal.

Treatment.—Of the lardaceous disease it may be said with greater emphasis than in any other form of renal disease, "an ounce of prevention is worth a pound of cure." A due appreciation by surgeons and syphilographers of the causes of lardaceous disease would prevent the occurrence of many cases, the timely amputation of a limb long the seat of suppuration and the thorough treatment of syphilis being all that is necessary to accomplish this. To this end also frequent examinations of urine should be made by the

surgeon in charge of cases of the kind so often referred to, and the slightest indication of albuminuria should be the signal for prompt interference, if such be possible, while the possibility of the occurrence of this renal complication should always be before the surgeon's mind. Especially watchful should surgeons be who are in charge of children with hip-disease.

In syphilis the faithful and persistent use of remedies for a sufficient time after all the symptoms of the primary and secondary affections have disappeared is essential. To this end the "continuous," rather than the "intermittent," treatment of syphilis by small doses of mercurials long continued is the plan most likely to secure the eradication of the disease, and this should be kept up for at least six months after the disappearance of all syphilitic symptoms. (By small doses are meant doses of from 1-50 to 1-25 grain (0.0013 to 0.0026 gm.) of the bichlorid.)

If the causing disease continues to exist, the treatment of the amyloid disease is the treatment of the former—if it is syphilis, iodid of potassium and mercurials; if phthisis, cod-liver oil, iron, creasote and creasotal, quinin, an abundance of nourishing food, in which milk and cream should be conspicuous, alcohol, and restorative measures generally, together with fresh air and suitable exercise. Supposing the original disease to have disappeared, the measures of treatment indicated are precisely those of chronic parenchymatous nephritis, for the details of which the reader is referred to the section on that disease.

SUPPURATIVE INTERSTITIAL NEPHRITIS AND PYELONEPHRITIS.

SYNONYMS.—*Septic and Pyemic Nephritis; Interstitial Suppurative Nephritis; Surgical Kidney.*

Definition.—Suppurative nephritis, due to invasion of the kidney or its pelvis by pathogenic bacteria, either by way of the circulation or the urinary tract.

Most frequently this form of nephritis starts in the pelvis of the kidney as a pyelitis, and thence extends into the interstitial tissue of the organ. Such a condition is pre-eminently a *pyelonephritis*. It may also happen that the nephritis starts in the interstitial tissue of the substance of the organ as the result of infectious embolism or traumatism or obstruction of the tubules by concretions. In either event both the kidney and its pelvis are sooner or later involved, and it is scarcely possible to separate the two conditions in diagnosis, and I do not, therefore, separate the two diseases.

Etiology.—The most frequent medium of invasion by *bacteria* is *retained decomposed urine*. Retention may be due to stricture of the urethra or even phimosis, to stone in the bladder or ureter or pelvis of the kidney. Perhaps there are always bacteria ready to avail themselves of sufficiently favorable conditions, but a favorite route of introduction is by unclean catheters. In many of these cases inflammation of the bladder is an intermediate state. Calculous concretions in the substance of the kidney also furnish conditions favorable for the action of bacteria of suppuration.

Infectious emboli cause a small number of cases of suppurative nephritis. The emboli are usually derived from the valves of the heart in cases of ulcerative endocarditis, but they may also arise in putrid wounds, stumps, or other

seats of putrid inflammation. The abscesses found in the kidney in common with other organs in pyemia are thus produced. *Tubercle bacilli* are also causes, entering by either of the routes named, producing tubercular pyelonephritis. Among the organisms found in the urine and held responsible are, besides the tubercle bacillus, the *bacterium coli commune*, the *proteus Hauser*, the streptococcus and staphylococcus. *Parturition* is a most infrequent medium of introduction of pathogenic bacteria, while the infectious fevers are recognized causes.

Traumatic agencies such as blows, kicks, or penetrating wounds in the neighborhood of the kidney, or falls from a distance and striking upon the sharp edge of a fence or similar object, may also cause suppurative nephritis.

Suppurative nephritis may occur at any age subject to the operation of the cause. The youngest patient I ever had was two years old.

Morbid Anatomy.—The appearances vary necessarily with the stage of the disease and also somewhat with the cause. In an earlier stage, if the inflammation pass from below upward, as is most frequently the case, the mucous membrane of the pelvis is first affected, being swollen and dirty gray in color, sometimes visibly congested. Later, the pelvis and calices may be dilated and the papillæ flattened. The distention may go on at the expense of the kidney until the whole organ is converted into a *pus-sac* bounded by a varying remnant of renal tissue. Such sac may be a constant source of pus, or if complete obstruction occurs, the pus may become inspissated and *cheesy*. The ureter is also often dilated, sometimes resembling, in consequence of such extreme dilatation, the intestine.

In tuberculosis extending *via* the urinary tract the *apices* of the cones are also invaded, it may be from the mucous membrane by continuity, or by direct lodgment of the bacillus. Successive portions of the kidney substance break down, and the ultimate product will be the same—a sac filled with liquid pus or *cheesy, putty-like substance*.

In other instances, especially when the kidney is invaded by way of the vascular or lymphatic system, as in *pyemic abscess*, foci of suppuration a millimeter and upward in diameter are scattered in the cortex and separated by sound renal tissue. They are surrounded by an intensely red border, are often visible through the cortex, and may be ruptured by dragging of the capsule. On section at an early stage, linear streaks of pus may be found in the medulla.

At a later stage these little collections of pus unite to form larger ones, these again to form others still larger, destroying the tubular structure of the kidney as they encroach upon it, and it is at this stage that cases of pyelonephritis not infrequently terminate unfavorably and the specimens come under observation. At first each of the abscesses thus formed is confined to the region of a single pyramid, and it not infrequently happens that a kidney is partitioned off into spaces corresponding with these. Before this occurs, however, the abscess bursts through the papilla and calyx into the pelvis of the kidney. Thus, in an opposite direction from that first described, the kidney may again be converted into a purulent sac, but these cases generally terminate fatally long before this stage is attained.

When the *abscess is embolic* in origin, its seat is at first occupied by an area of intense hyperemia, resulting in *hemorrhagic extravasation*, which takes place also into the tubules, causing bloody urine. To this succeeds suppuration. The size and number of the abscesses depend upon that of the plug obstructing the blood-vessels, which is usually one of the interlobular

arteries or a vas afferens. The embolic abscesses may also be multiple, in consequence of the breaking of the embolus into a number of minute fragments. When the cause is *traumatic*, the process is not so easily defined. Circumscribed abscesses may occur, or the kidney may be converted into a soft, pulpy mass, a mixture of pus, blood, and broken-down renal substance.

Symptoms.—The symptoms of this condition are not numerous and, apart from the characters of the urine, are not very distinctive. In milder degrees of pelvic inflammation before the kidney is invaded there may be none. *Pain* and *tenderness* are the most constant, but considerable inroads may be made upon the structure of the kidney before pain results. On the other hand, it is often very severe, while the *tenderness* over the region of the kidney is pronounced. This tenderness is the most distinctive and valuable symptom. Usually the severest pain is in the renal region, whence it radiates toward the front of the abdomen and groin, and may be accompanied by retraction of the testicle. When the condition is the result of impacted calculus, the seat of the impaction is the primary seat of pain. It may be between the umbilicus and the pubis when the stone is lodged down in the ureter. The pain is always intermittent to a degree, sometimes totally so, but generally it is more or less constant, increased paroxysmally. Various positions are assumed by the patient with a view to easing the pain, among which lying on the face is not infrequent.

A distinct *tumor* may sometimes be discovered in the region of the kidney by palpation and percussion. This implies an enlargement of the organ, due either to its conversion into a purulent sac, or an augmentation of its size owing to the distention of its pelvis with pus or calculi or both. Very frequently it is due to perinephric invasion.

Fever is also a remittent symptom. Possibly in a very few latent cases it may be altogether absent, but except in these there is always elevation of temperature, with corresponding frequency of the pulse. These latter at times become decided, and in advanced stages the fever is septic, being followed by profuse *sweats*. In acute cases, especially pyemic, the beginning of suppuration is often marked by a *chill* and *high fever* or succession of chills, but in other instances it is quite impossible to recognize the beginning of the suppurative stage.

The *characters of the urine*, as intimated, are more distinctive. Except in acute infectious cases, the urine almost invariably sooner or later contains pus, and unless it does contain pus, no certain diagnosis can be made. *Blood* is also a very constant constituent from cases of suppurative nephritis, but while such urine is scarcely ever examined by the microscope without discovering a few blood discs, the quantity is often not large enough to be recognizable to the naked eye. The quantity of *pus* varies greatly. While it may be so copious as to produce a heavy white opaque deposit one-sixth to one-fifth the bulk of urine, it may be represented by little more than a trace. This variation will occur at different times in the same case. Pus from the kidney and its pelvis is usually distinguished from that formed in the bladder by the absence of that glariness so characteristic of the latter, due to admixture with mucus and decomposition products. Pus from the pelvis of the kidney is rarely fetid, as compared with pus from the bladder.

The urine is usually *diminished in quantity*. Complete suppression is not uncommon toward the close of cases presenting extreme degrees of destruction. Notwithstanding such diminution, the color may be pale and the specific gravity low, owing to the small proportion of urea present, the

range of specific gravity in a single case being from 1003 to 1016. In reaction the urine is faintly acid, neutral, or alkaline, and though often prone to rapid decomposition, this is a much less characteristic feature than in cystitis. *It is always albuminous*, but the quantity of albumin is never very large, and varies generally *pari passu* with the quantity of pus and blood. When more albumin is present than is thus accounted for, it is likely that the parenchyma of the kidney has become involved. Such cases are, therefore, more serious. In such cases, too, *tube-casts*, ordinarily rarely found in suppurative nephritis, may appear.

It sometimes happens that there is a sudden increase in the quantity of pus in the urine, followed by a gradual diminution, or the urine, previously clear, may suddenly become loaded with pus. Such occurrences indicate the probable period of *rupture of an abscess* through a papilla and a pouring out of its contents into the pelvis of the kidney, or of the removal of a temporary obstruction to the descent of the pus. It may happen that a small portion of the substance of the kidney is thus discharged, when it may be recognized by microscopic examination, which will discover the tubules and glomeruli of the kidney. Occasionally, also, the abscess, instead of rupturing into the pelvis of the kidney, perforates into the perinephric tissue, burrowing in different directions and producing fistulous openings. Perforations may thus take place posteriorly in the lumbar region, or anteriorly at the groin, into the colon, and more rarely into the lungs and liver, and even into the peritoneal sac.

The *course* and *duration* of suppurative nephritis vary greatly. Traumatic cases are comparatively rapid, either toward recovery or death. Pyemic cases may run their course in forty-eight hours, and are invariably fatal. But cases due to other causes—viz., impacted calculus, tuberculosis, stone in the bladder, or cystitis—may be prolonged indefinitely, while some terminate without being discovered. Sooner or later the patient generally succumbs to exhaustion, but life may be sustained for years with paroxysms of the severest suffering and a surprising degree of destruction of the kidneys. The *greatest danger to those thus affected is intercurrent illness*, which is always more serious and more apt to terminate unfavorably. It is then that the kidneys, previously surprisingly sufficient in eliminating power, give way in this respect, the symptoms of uremia supervene, and the patient dies of this complication. It is well known that the operation for stone is much more likely to be followed by a fatal result when the patient happens to have a surgical kidney.

There are no *complications* peculiar to suppurative interstitial nephritis save those mentioned as causing it; or as resulting from unusual accidents, such as rupture and perforation into neighboring organs, or uremia.

Diagnosis.—The diagnosis of suppurative nephritis may be easy or difficult. It is easy when there is the history of a traumatic cause followed by hematuria, and later purulent urine, with tenderness and pain over the region of the kidney. On the other hand, while prolonged inflammation of the bladder, stone in the bladder, nephrolithiasis, or other causes of obstruction and decomposition of urine always afford good reason for suspecting that suppurative nephritis exists, it is not safe to assert its presence whenever these conditions exist. If, however, the urine contains pus constantly or intermittently, and in addition to this there is pain or tenderness in the renal region, suppurative nephritis may be averred with reasonable certainty. I know of no distinctive cellular elements from whose presence in the urine it may be

asserted that pus comes from the pelvis of the kidney or ureter, for though the little columnar or pear-shaped cells are referred to these sources, they also come from the urethra and bladder.

As to differential diagnosis, the only certain means of recognizing the *tubercular form* is by finding the *bacillus* in the purulent urine, at the present day greatly facilitated by the use of the centrifugal apparatus. Should the symptoms described occur in a case of tuberculosis of the lungs, the tubercular nature of the nephropylitis becomes quite probable.

Pyelonephritis is distinguished from *paranephritis* by the more circumscribed shape of the tumor, the absence of edematous infiltration of the lumbar region, and by the presence of purulent urine, unless it happens, as it rarely does, that the paranephric abscess breaks into the kidney and discharges by the ureter. Pain on flexing and rotating the thigh is characteristic of paranephric abscess, because of the involvement of the psoas muscle. Pyemic abscesses of the kidney may be suspected if a pyemic process is present, and a chill supervenes, followed by any or all of the renal symptoms described.

Prognosis.—Operation has done much to improve the prognosis of late years. Yet so far as recovery is concerned, it is still in most cases unfavorable. Traumatic cases may recover if the injury is not too extensive, while very grave injuries are usually rapidly fatal. Recovery, too, ensues on cases succeeding infectious fevers and pregnancy. Cases due to obstruction of the ureters cannot get well so long as the obstruction and irritation continue, and as their removal is often impossible, such cases gradually grow worse. On the other hand, their fatal termination may be delayed indefinitely. It is often a matter of astonishment, on viewing the postmortem appearance of cystic purulent kidneys, that the patient has lived so long with such extreme structural changes present, the barest remnant of secreting structure being sometimes found. It is impossible to say how far repair may take place if the cause can be removed. Conditions of this kind occur when a stone has been removed after having been long present either in the bladder itself or in the kidney or ureter. It is scarcely necessary to say that such persons are in imminent danger from the effect of cold, acute disease, or other cause which tends to suppress the action of kidneys already crippled in function.

Treatment.—As *operation* offers the best chance of cure in many cases, a surgeon should be called early. There is no curative treatment by medicine for suppurative nephritis without a *removal of the cause*, and as the latter is often impossible, it follows that medicinal measures are mainly palliative. One of the most frequent indications is the *relief of pain*, which is often so severe as to call for powerful anodyne measures—opium and its alkaloids being absolutely essential. Hypodermic injections of morphin in doses of from 1-8 to 1-3 grain (0.008 to 0.022 gm.), repeated, if necessary, are favorite and effectual methods of relieving the intense pain, which is often due, not so much to the inflammation, as to the impacted calculus or other cause of obstruction. Suppositories of from one-half to two grains (0.03 to 0.13 gm.) of the extract of opium may be substituted. Hot fomentations and simple counterirritants, such as mustard, are also valuable adjuvants.

The *catarrhal process* in the kidney, its pelvis, and the ureter, and also in the bladder, may be treated with varying success. Diluents are decidedly indicated, and for this purpose any one of the numerous negative mineral waters may be used. The alkaline mineral waters are contra-indicated, as they inspissate the pus and make it more difficult to pass. The only remedies

I have found of any use are the balsam and benzoic acid. Of the former, I prefer sandalwood oil, because it is better borne by the stomach than copaiba. Given in gelatin capsules, each containing ten minims (0.65 c. c.), of which one or two may be taken three times a day, a decidedly beneficial effect upon the catarrhal inflammation sometimes ensues, seen in the diminished amount of pus. Benzoic acid fulfills another indication, that of securing an acid reaction of the urine, which is very often either alkaline or so faintly acid that it rapidly becomes alkaline, and thus predisposes to decomposition. The benzoic acid is best given in the form of capsules. For an adult three or four five-grain (0.32 gm.) capsules daily are usually sufficient to keep the urine acid. Larger doses than these may be given, or benzoate of sodium may be used in ten-grain (0.6 gm.) doses. It may be given either alone or in conjunction with the sandalwood oil, the former being given before and the latter after a meal. To children smaller doses may be given. To them one may begin with one grain (0.006 gm.) three times a day and increase the dose. The various vegetable diuretics, as buchu, pareira brava, etc., are of little use in suppurative nephritis and pyelitis.

The constant and inevitable tendency in these cases to run down in general health, in consequence of the drain and wear and tear to which they are subject, demands *tonics*, such as quinin, iron, and strychnia, while milk and other nutritious articles of diet are always indicated. The dangers to which the patient is subject from exposure, cold, and dampness should be averted by suitable care and woolen clothing.

I desire to repeat that many of these cases are saved at the present day by a timely nephrotomy, by which the pus is discharged, the kidney drained, and calculi, if present, removed. I look back upon many cases that were allowed to perish whose lives would at least have been materially prolonged by operation.

ABSCESS OF THE KIDNEY.

Definition.—This term may be applied to a kidney which is more or less completely converted into a sac of pus.

Symptoms.—These are tenderness, swelling, and, in extreme cases, fluctuation, commonly associated with pyuria, which is in rare instances absent. It may be intermittent, and the tumor caused by the pus collection may also disappear. There is usually fever of the hectic or septic type.

Prognosis.—This varies with the cause, though often favorable, after operation.

Diagnosis.—This is usually early, by attention to the symptoms named.

Treatment.—This is surgical,—operative,—and is usually successful in affording great relief, if not curing the patient completely.

PARANEPHRITIS OR PERINEPHRIC ABSCESS.

Definition.—Paranephritis is an inflammation invading the connective tissue about the kidney, terminating almost always in suppuration.

Etiology.—A number of causes may be responsible for perinephric abscess. Thus there may be rupture of a nephric abscess through the capsule of the kidney; perforation of the bowel, most frequently seen in connection with appendicitis; extension of suppurative disease from the spine, as in caries of the vertebræ, or from a burrowing empyema; finally, blows and injuries may terminate in suppuration about the kidney.

Morbid Anatomy.—At autopsy the kidney is found surrounded by pus, which is usually posterior to it, rarely in front between the kidney and the peritoneum. The pus has often a fecal odor from contact with the large bowel. It may burrow in various directions, and even burst into the pleura and be discharged by the lungs; or it may work its way to the groin and appear at Poupart's ligament. In turn it may perforate the bowel or rupture into the peritoneum, bladder, or vagina. Occasionally the fatty bed of the kidney is found to be converted into a fibrous capsule fused more or less closely with that of the true kidney capsule.

Symptoms.—Most cases are secondary to disease in the neighborhood. *Pain and tenderness* in the region of the kidney are the most constant symptoms. In addition there is a peculiar *edematous* or *boggy condition* in the same locality, giving rise to pitting on pressure. The position assumed is often distinctive, the thigh being flexed to relax the psoas muscle, tension on which, especially in adduction, increases suffering. The patient, if able to walk, relies as much as possible on the opposite leg, on which he leans, assuming also a stooping posture with the spine fixed. The whole attitude and behavior of the patient remind one of hip-joint disease, while the pain may even be referred to the knee, as in this disease. These symptoms do not, however, appear at once, and the approach is often insidious. At other times suppuration is ushered in by chills, fever, and sweats. The plastic form of fibroid paranephritis is without distinctive symptoms. Various directions of burrowing and seats of perforation were mentioned in treating of the morbid anatomy.

Diagnosis.—The diagnosis from *nephric abscess*, with which it is most likely to be confounded, has been considered. The attitude of the patient in lying or standing is like that in *hip-disease*, but the history elicits that in its incipency the pain is much higher up in perinephric abscess, while examination shows that the swelling and tenderness are above the hip and not over the hip-joint itself. As most cases except those due to injury are secondary to disease in the neighborhood, it is not necessary to separate the two classes. Secondary forms are more sudden in their onset, though this is not always the case. Doubtful cases may be settled by the exploring needle.

Treatment.—This is by section and free drainage, for though spontaneous rupture sometimes takes place, it is apt to be preceded by destructive and dangerous burrowing, which should be anticipated by operation.

NEPHROLITHIASIS (STONE IN THE KIDNEY).

Definition.—Nephrolithiasis means "stone in the kidney," but the term is a general one, which covers the presence in the kidney, its pelvis, or ureter of concretions large enough to justify the term "stone," of smaller masses appropriately known as "gravel," and fine particles known as "sand."

Morbid Anatomy.—Except in the case of "sand," which includes particles made up either of pure uric acid or oxalate of lime, gravel and stone, as found in the kidney and its pelvis, always have an organic basis through which are distributed the mineral matters which go to make up their bulk, and which remains as a framework after the mineral matters are dissolved out. The matters thus precipitated, in some one of the shapes named, in the order of frequency are:

- (1) Uric acid and its compounds of sodium, ammonium, and potassium.

(2) Oxalate of lime. (3) The phosphates of calcium and of ammonium and magnesium.

Only in the case of uric acid stones of small size, and of oxalate of lime stones likewise moderate in size, do we have the bulk of the stone made of a single constituent. More frequently it is the case that uric acid or oxalate of lime stone forms the nucleus, and about this aggregate in concentric layers, the phosphates, which make up the great bulk of all large stones as well as some stones in their entirety. More rarely a uric acid nucleus is surrounded by oxalate of lime or the reverse. Not only may the sediments become the nuclei of large stones, but foreign matters, such as a clot of blood or a fragment of any kind of matter accidentally reaching the urinary passages, may also play a like rôle.

The steps for determining the more precise composition of stones will be found in appropriate manuals on the examination of urine, but the three principal varieties present certain physical characters by which they can with considerable certainty be determined. Thus, *uric acid stones* are usually smooth or lobulated, dark-red or reddish-brown in color, hard in consistency, and rarely acquire a size of a centimeter (0.4 inch) in diameter, while many of them are no larger than a lentil. They may be multiple. *Oxalate of lime stones* are very hard and uneven, so characteristically so that they have received the name mulberry calculi, from their resemblance to this fruit. Their hard-pointed projections produce exquisite pain in transit from the kidney through the ureter into the bladder. They attain about the same maximum size as uric acid stones, and are also often multiple. The *phosphatic stones* are white in color or grayish-white, quite soft, easily disintegrated, may often be crushed between the fingers, though at other times they are much harder. They attain the largest size, being often as large as a hen's egg. When stones lie in the ureter rather than in the pelvis of the kidney, they are apt to be more elongated, or sometimes spindle-shaped, and present at times a spiral marking which is characteristic. Others are molded to the shape of the pelvis of the kidney with a prolongation for each calyx, which may be further branched—the dendritic or coral calculi. Rarer forms of calculi are made up of cystin, xanthin, carbonate of lime, and urostealith.

Etiology.—The rationale of the precipitation of sediments which aggregate to form concretions is not always the same, and is perhaps not thoroughly understood. In the case of uric acid the deposit takes place either because the urine contains more than the normal quantity of uric acid, or because, for some reason, the amount of water secreted is abnormally scanty. In either event the uric acid is precipitated in the excretory tubes of the medullary substance or in the pelvis of the kidney, forming minute concretions made up of from five to ten whetstone-shaped crystals, whence they descend in the form of sand or gravel to the bladder. At times the sediments grow by successive additions in the pelvis of the kidney, forming thus true *renal* concretions, whose descent into the bladder, if at all possible, is accomplished with the greatest difficulty and pain. The method in which such concretions form in the calices of the kidney around a papilla is well shown in Figure 77.

Oxalate of lime calculi form similarly by the precipitation of crystals of this substance immediately after the urine is secreted.

Phosphatic concretions are rarely primary. In order that they may form, the proportion of phosphates must be largely increased, or the reactions

of the urine must be permanently alkaline. More frequently phosphates precipitate around nuclei of uric acid or oxalate of lime, or foreign bodies. The effect of these seems to be to cause an alkalinity in the urine immediately about them or, in cases of more general cystitis, in all the urine in the bladder. This alkalinity causes the precipitation of phosphates about the primary nucleus and formation of stone of various sizes. Rarely layers of phosphates and uric acid alternate.

Symptoms.—It sometimes happens that a stone is found *postmortem* in the substance of the kidney or in the pelvis which was not suspected, but it is hardly likely that even in these cases symptoms were not present. They were simply overlooked or ascribed to some other cause. The most constant symptom of nephrolithiasis is *pain in the region of the kidney* associated with

Fig. 77.—Hilus of Kidney with a Large and Small Renal Calculus, Showing How Precipitation and Aggregation Take Place—(from *Rindfleisch*).

more or less *tenderness*. Like the pain of stone in the bladder, it is *aggravated by motion*, especially rough motion, and there are certain positions of the body in which the patient is made more or less uncomfortable. Quite often the inflammation caused by the stone proceeds to suppuration, and the whole of the kidney, more or less, is substituted by a pus-sac. The pain is often suddenly aggravated when a large stone so lodges as to plug up the ureter and interfere with the descent of urine, or a small one descends through the ureter into the bladder. Under these circumstances come the attacks of so-called nephritic colic, characterized by pain which may equal in severity any to which man is subject. It has other distinctive features. It radiates downward into the groin and the neighborhood of the bladder and down the inside of the thighs and into the testicle, which is often retracted. Sometimes it extends upward toward the diaphragm, and it is not always easy to sepa-

rate the pain of nephritic colic from that of hepatic colic when the former is on the right side. It may happen that both kidneys are the seat of impacted stone, though this is a very rare event. There are often nausea and vomiting, a cold sweat appears, and the patient may collapse.

After the pain and colic the changes presented by the *urine* may be highly distinctive, aiding greatly the diagnosis; at other times the urine is absolutely negative. It very frequently contains blood, though the quantity is commonly small, and may be demonstrable only by the microscope. Especially is there blood in connection with fresh attacks of nephritic colic. Pus is almost always present in small or large amount. Cylindroids or mucus-casts may be found, true casts rarely. In some cases, too, uric acid crystals in the shape of red or brickdust-like particles either before or during an attack of nephritic colic point to the uric acid nature of the stone. The same is true of oxalate of lime crystals. In the case of the last two substances the urine is acid in reaction. Phosphatic stones may be suspected if the urine is alkaline in its reaction, as it is only possible for phosphatic sediments to form in the presence of an alkaline or neutral urine while uric acid crystals can only remain permanent in an acid urine. Oxalate of lime, the most insoluble of all crystals, occurs, however, in either acid or alkaline urine. In cases of gravel or sand, as contrasted with stone, there are no symptoms as a rule between attacks, as the stone must reach an appreciable size before it produces the constant or almost constant pain characteristic of it. In some cases there is complete suppression of urine, even when the kidney on the opposite side is normal, though more frequently when it is diseased, and death from uremia may occur in consequence.

Diagnosis.—It has been intimated that nephritic colic may be confounded with *biliary colic*. Usually the symptoms of each are sufficiently distinctive. The presence of jaundice in biliary colic is invariable and comes on very soon after the obstruction begins. The stools are without bile and grayish-white in color. Usually the pain is more toward the epigastric region as a center, and thence through the upper abdomen and perhaps through to the right shoulder-blade. The urine is also bile-stained, and responds to the tests for the coloring-matter of bile. Other substances, however, besides stone, may produce nephritic colic. Thus, *clots of blood* may obstruct the ureter and give rise to all the pain occasioned by an impacted stone, and in the absence of a history of stone and of hemorrhage there are no symptoms by which the two causes of colic can be separated. In the case of *hydatid cysts* of the kidney, fragments of these, too, may be discharged, and in suppurating kidney *inspissated pus* may occlude the ureter. I have in my possession some striking molds a centimeter in diameter and several centimeters long, composed of inspissated pus, which plugged up the ureter for a time and were subsequently discharged. Renal colic has been mistaken for *intestinal colic*, but such confusion is dissipated as the condition continues. Renal colic is also produced when the ureter is compressed by any cause as a *twist in the ureter* of a floating kidney, or by compression of a tumor. The symptoms of stone in the kidney sometimes closely resemble those of *stone in the bladder*, but the pain in the latter, though it may be felt, to the back, radiates towards both sides; in stone in the bladder the urine contains more mucus and is alkaline or becomes readily so, while in nephrolithiasis the pus is purer and the urine acid. In all cases pointing to the presence of stone in the bladder the sound should be promptly used.

The most invaluable aid to the diagnosis of stone in the kidney is the

X-ray examination, and in all cases of suspected stone this measure should be employed. Almost without exception a stone, if present, is disclosed, and many times stones have been found at operation after such examination has disclosed them which would have been given up at operation but for the certainty of its presence thus determined. Rarely it has happened that the X-ray has apparently disclosed a stone when none has been found at operation.

Prognosis.—The prognosis of stone in the kidney is very much more favorable now than it was fifteen years ago, in consequence of the safety with which operations can be performed. The kidney may be exposed, split open, and the parts reapposed and restored with perfect recovery, and whenever the diagnosis of stone in the kidney is made, an operation should be done. When many severe attacks occur without other conclusive evidence, an exploratory operation is sometimes justified for the sake of diagnosis. When the sand or gravel is so small as to pass the ureter, the suffering terminates with its passage into the bladder.

Treatment.—It is needless at the present day to say there are no medicines which, when administered, are capable of producing solution of a stone if it be of any size. In cases in which there is no such formation and we have simply to contend with gravel or sand, therapeutic measures to prevent its further formation, and even in some cases to promote solution, may be availed of.

It is, however, a matter of extreme importance before treatment is instituted to know exactly the kind of sediment that is to be dealt with, and to this end the urine should be carefully studied. Thus, uric acid is dissolved by alkalis, and the object of treatment should be to alkalize the urine as much as possible, with a view to keeping the uric acid in solution. On the other hand, to give alkalis to the patient with phosphatic stone or sediment is only adding "fuel to the flame." As to oxalates, they are equally insoluble in both acids and alkalis, but there is reason to believe that they are produced under the same conditions which produce uric acid sediments, and the treatment is therefore the same for either.

The required alkalinity of the urine for the *solution of uric acid* may be produced in any one of a number of ways. Perhaps the most desirable of all is the free use of alkaline mineral waters, represented by the foreign waters of Tarasp, Vals, Vichy, and Ems, and in this country approximated by Saratoga Vichy and Saratoga Geyser waters, which may be termed alkalo-saline waters. It is unfortunate that in this country we have no native sources of alkaline mineral waters, at least east of the Rocky Mountains, and the alkaline waters of the West are so strong that it would not be possible to use them without dilution, while very few physicians seem to have had any experience with them. In the absence of true alkaline waters the numerous negative mineral waters which are so strongly recommended by their owners may still serve a useful purpose as diluents and solvents. They are almost too numerous to mention, but the Bedford, Poland, Waukesha, Buffalo lithia, Geneva lithia, and Londonderry lithia waters are among the best known. In a few cases they alone may be sufficient if used freely enough. They may be rendered more active by combining alkaline salts, such as the citrate of potassium and the bicarbonate of potassium and lithia. The lithia waters for sale in this country contain uncertain, and at most very small, quantities of lithia. I think it much better, under the circumstances, to add a definite amount of lithium carbonate or citrate to a glass of water—say from five to ten grains (0.3 to 0.6 gm.). At least one quart

(2 liters) of any of the true alkaline waters should be used every twenty-four hours by an adult subject to uric acid sediments, and a corresponding or larger quantity of the more negative waters referred to. *Liquor potassii* of the United States Pharmacopœia is a very excellent means of counteracting acid tendencies. It may be given in doses of from fifteen minims to one-half dram (1 to 2 c. c.), and milk is a very suitable vehicle. Piperazin, a comparatively recently introduced solvent for uric acid, undoubtedly possesses this power outside of the body, and in a few cases it has also seemed to me of service when administered to patients with uric acid gravel. Some assert and others deny its efficacy. Its costliness is in the way of its general use in sufficient quantity to test its real value. All that has been said of treatment of the uric acid diathesis may be applied to that of the *oxalate of lime*.

Much also may be accomplished by *diet*. Persons with uric acid diathesis should limit the amount of nitrogenous food, using a minimum of meat and cultivating the use of milk and vegetables as a diet.

The *phosphatic tendency* is, unfortunately, not so easily combated, as our resources for the purpose of acidifying the urine are very limited. Only two drugs, benzoic acid and boric acid, have this reputation, and they possess it to a slight degree only, while large doses are not well borne by the stomach. From five to ten grains (0.3 to 0.6 gm.) of each may be given three, four, or five times a day, as borne by the stomach. Here, too, there is, of course, the same indication for the free use of diluent drinks, and in these cases the negative mineral waters are as good as any, while, perhaps, distilled water serves as the type of a solvent. When the composition of the stone is unknown, it is best to use this class of waters rather than alkaline waters, lest the stone happen to be phosphatic, in which event alkaline waters would cause further deposit. While the mineral acids cannot, of course, be given in such dose as to produce acidity of the urine, they are still useful in counteracting any tendency to high degrees of alkalinity.

In the matter of diet, too, the phosphatic diathesis requires an opposite treatment. Meats are here indicated, while milk and vegetables may form a less abundant part of the food because of their tendency to alkalize the urine.

In treating the uric acid diathesis with alkalis it is possible to carry the effect too far and cause deposit of phosphates where uric acid sediments were previously precipitated. It is important, therefore, to watch the urine carefully and to avoid such an administration of alkalis as will cause phosphatic sediments to make their appearance. It is well known that stones are found in the bladder, which exhibit alternate layers, now of uric acid and now of phosphates, although the latter substance almost invariably makes up the bulk of calculi which have attained any size. The rationale of this is perhaps as follows: as soon as the uric acid gravel or oxalate of lime gravel becomes large enough to act as an irritant, it increases the organic matter in the urine in the shape of pus and mucus. These matters, it is well known, favor an alkaline reaction, so that the little stone becomes surrounded, as it were, by a stratum of phosphate-precipitating urine, and the larger it grows, the more apt is this to be the case. When alternate layers exist, it may be inferred that the natural acidity reasserts itself and throws down the uric acid and urates, which in turn form a layer about the stone.

The extreme pain of attacks of nephritic colic must be combated by anodynes, and for this purpose rarely is anything except opium and its alkaloids sufficient, while the hypodermic mode of medication is far the best, both because of its prompt action and the less serious effect upon the stomach. It

is rarely the case that less than 1-4 grain (0.016 gm.) of morphin thus administered is sufficient, and very frequently this dose must be repeated very soon. It has happened to me that when the pain was less severe, I could control it with full doses of phenacetin and acetanilid, or by the aid of these substances render smaller doses of morphin sufficient. For this purpose not less than fifteen grains (1 gm.) should be given. Hot poultices are useful to a certain extent in relieving pain when applied to the lumbar region and to the groins, while hot baths are of great service in relaxing spasm and allaying pain due to it.

The escape of the stone from the ureter into the bladder is followed by unspeakable relief, and its discharge from the urethra usually follows sooner or later with little or no pain, although a stone of considerable size may lodge in the urethra and require extraction. When stones are not discharged, they are likely to become the nuclei of larger stones in the bladder, where, of course, the majority of stones acquire their growth.

Stones too large to pass *per vias naturales* should be cut out of the kidney. It must be remembered, however, that after apparent well-founded diagnosis it sometimes happens that no stone has been found on section. Yet, strange as it may seem, it frequently happens that the symptoms do not return after such negative operation. Such cases, on the other hand, may prove to be cases of tuberculosis of the kidney.

TUMORS OF THE KIDNEY.

Definition and Application.—The term “tumor of the kidney” is applied to almost any enlargement of the organ due to morbid growths. Yet there are morbid growths of the kidney which are not sufficiently large to produce appreciable change in its size. Thus, the *adenoma* does not usually exceed 4-10 inch (1 cm.) in diameter, though it may be two inches (5 cm.) or more. The same is true of the *angiomata* and *leukemic tumors*, of *fibroma* and *lipoma*, which sometimes form small white nodes in the fibrous tissue near the bases of the pyramids. *Lymph-adenoma* occurs in the kidney associated with similar disease of lymph glands, liver, and intestine. *Villous papilloma* sometimes grows in the pelvis of the kidney. *Syphilitic gummata* also belong to the group of moderate-sized tumors rarely producing symptoms.

Cysts, single and multilocular, acquire larger size, producing appreciable enlargement of the kidney. The malignant tumors, *sarcoma* and *carcinoma*, belong to this category, and with cysts are, clinically speaking, perhaps the chief occasion of the term “tumor of the kidney.” On the other hand, *renal abscess*, or pyonephrosis, does not usually earn for the kidney involved the name “tumor,” while hydronephrosis does.

Symptoms.—Certain local symptoms are produced indifferently by any one of the tumors large enough to become clinically appreciable. In the first place, *renal tumors* grow for the most part *forward* rather than backward, because of the more yielding character of the parts in front of them than behind them, rarely producing posteriorly much more than a fullness of the back, in the course of which there is obliteration of the resonance which may be present between the kidney dullness and the vertebral spines. As this forward growth proceeds, a special effect results from the relation of the bowel to the kidney; as the ascending *colon* on the right side and the descending

colon on the left lies *in front* of the corresponding kidney, the effect of enlargement of this organ is to push the bowel in front of it, the hollow viscus being recognized by the tympanitic percussion note. In this respect renal tumor differs from splenic tumor, and less invariably from that of the liver, since the bowel does not intervene between these organs and the abdominal wall, though, rarely, the small intestine may float between the liver and the parietes. Commonly, too, the hand may slide between the renal tumor and the liver on one side and the renal tumor and the spleen on the other, while it never loses the rounded border characteristic of the kidney.

By bimanual palpation with the palm of one hand placed in the lumbar region and the other in front below the ribs, pressure being made in both directions, the tumor may be recognized. In this examination, too, it will be noticed that the kidney permits a much more limited degree of mobility during breathing than does the liver, although it is not totally immobile. The renal tumor, too, commonly resists lateral movement.

Again, *pain* in the region of the kidney is an inconstant symptom. It is often totally absent, at other times exceedingly severe, especially if the vertebræ and spinal cord are encroached upon. It sometimes happens that in consequence of the pressure of the kidney upon the twelfth dorsal nerve and branches of the lumbar plexus neuralgic pains in the abdominal walls are produced.

Diagnosis.—As to differential diagnosis, both varieties of tumor, viz., *carcinoma* and *sarcoma*, produce hematuria, though it is not even a frequent symptom with them. In the event of its presence the blood may be fluid or clotted, and is often molded in the pelvis of the kidney and ureter, an event very rare in the blood poured into the pelvis under other circumstances. Hematuria is more frequent in carcinoma than in sarcoma. Both conditions are likely to produce pain. It is sometimes extreme and boring, when it indicates destructive encroachment on the vertebræ. More frequently it is dull, radiating over the flank into the thighs. These tumors also produce cachexia. Very rarely they may be recognized by the presence of distinctive histological elements in the urine. This occurred in my experience in at least two instances. Frequently the urine is altogether negative.

Of sarcoma and carcinoma between which no distinction was made until thirty years ago, the former is now regarded as the more common. Both may be primary or secondary, more frequently secondary. Sarcoma is a disease of early life, in fact, it is often congenital, when it is represented by that form known as rhabdomyoma, which contains striated muscular fibers. In more than half the cases it affects children under ten. On the other hand, renal cancer is not confined to later life, as are other forms of cancer, and it may even occur in children. May not these tumors, too, have been sarcomata? More usually one kidney only is affected. Such organ is uneven, soft, even to a sense of fluctuation. Carcinoma also selects one kidney whence it may invade the pelvis and ureter. It affects the general health more rapidly, hematuria is more frequent and copious, but intermittent. If there be a superficial primary growth elsewhere and a renal tumor is present, the presumption is that it is of the same nature, but no certain diagnosis can be made between carcinoma and sarcoma unless the rare opportunity occurs to examine fragments discharged with the urine. Unfortunately for diagnosis, the urine is too often quite free from any sediment, even of pus. Carcinoma of the kidney is apt to invade the renal veins and even the vena cava, and as such to cause metastasis in the lungs and in other organs as well.

From *ovarian tumors* renal tumors are distinguished by the fact that in the former the intestines lie in the flanks, giving resonance on percussion in that locality, while an enlarging kidney pushes the bowels in front of it. The ovarian tumor also grows from below upward and drags with it the uterus and appendages, as can be recognized by vaginal examination and by rectal touch.

Much more difficult is it to distinguish the renal tumor from *enlargement of the retroperitoneal glands*, as such enlargement also pushes up the intestines in front of it, giving rise to a tympanitic percussion note. Hematuria is never in retroperitoneal tumor, while it may or may not be present in renal tumor. The retroperitoneal tumor may press upon the ureter and the renal vessels and thus produce obstruction to the descent of the urine. The central situation of the enlargement in retroperitoneal tumors contrasts with the lateral growth in renal tumors.

From *tumors of the liver* renal tumors differ in that the form sooner or later cause a bulging of the right hypochondriac region, while the renal tumors rarely reach as high as to alter the configuration of the lower thorax. The sharper border of the liver tumor as contrasted with the rounded edge of the kidney tumor is characteristic, while the freer movement of the liver with the breathing is also of value. *Splenic tumors* are not likely to be confounded with tumors of the left kidney. Splenic tumor protrudes from above downward and toward the umbilicus instead of from the lumbar region forward. It moves more with breathing, and its sharper edge and indentation may be recognized. It is always above or outside of the colon.

Treatment.—Renal tumor is beyond curative treatment by the physician. As soon as the diagnosis is made, a surgeon should be called and the question of operation considered.

CYSTS OF THE KIDNEY.

Reference is here made only to such cysts as produce clinically appreciable enlargement of the organ. They include:

1. *Retention or obstruction cysts*, solitary cysts ranging in diameter from a centimeter (0.4 in.) to 10 centimeters (4 in.) and larger. They may be present in one or both kidneys. These are probably primarily the result of stenosis of a uriniferous tubule behind which accumulates first urine, which is gradually substituted by an aqueous fluid in which may be found traces of urinary constituents. A trace of albumin may also be present. These cysts rarely give rise to symptoms.

2. *The congenital cystic kidney*, in which both organs are the seat of numerous round cysts varying in size from 1-5 inch (5 mm.) to one inch (2.5 cm.), may produce tumors of large size, so large, in fact, that they have interfered with parturition. They contain a fluid which is at times clear, at others again turbid, colloidal in consistence, and containing albumin, cholesterin, triple phosphates, rarely urea and uric acid, and sometimes fat drops. Persons with these cysts may grow to adult life, and, indeed, such cystic kidneys have been found postmortem when not suspected. Commonly, the subjects die either before birth or shortly after. The exact mode of origin of these congenital cysts is not understood, but they are probably the consequence of a defect in development.

There may be no symptoms beyond that of an enlarged organ, or they may be those of interstitial nephritis with its secondary cardiovascular con-

sequences. There may be a small albuminuria. Blood discs may be found, but no casts.

3. *Dermoid cysts* are also occasionally met in the kidney, while a *general cystic condition* invading the liver and spleen as well as the kidney is described.

4. *Hydronephrosis* is a monocystic degeneration of the kidney starting in obstruction of the ureter, succeeded by dilatation of the pelvis and gradual wasting of the kidney substance, due to pressure of the accumulating fluid.

The obstruction causing this condition may also be congenital. As such it, too, may be large enough to impede labor. An oblique insertion of the ureter at such angle as to interfere with the easy discharge of the secretion may be the cause of its retention in the pelvis of the organ. Among recognized causes during life are, also, occlusion of the ureter by cicatricial adhesion, by lithiasis, tuberculosis of the ureter, by pressure, by tumors, by a retroflexed or prolapsed uterus, by bands of lymph in healed peritonitis and by twists in the ureter of a movable kidney. Finally, carcinoma of the bladder and even hypertrophy of the prostate and stricture of the urethra may be causes.

The contents of the tumor may be purely aqueous; more frequently they are slightly turbid; they contain a few pus-cells, more numerous if they are the seat of inflammation; also uric acid, urea, and albumin.

Its symptoms consist of those already described as common to benign renal tumors of sufficient size. An event which is almost pathognomonic is the occasionally sudden disappearance of the tumor simultaneously with the discharge of a large quantity of fluid from the bladder, followed by gradual refilling of the sac and return of the tumor. This intermittent discharge may be kept up for years. Such an event must be ascribed to a valvular obstruction in the ureter which at times yields to the pressure of the accumulated fluid; or it may be due to the undoing of a twist in the ureter of a floating kidney.

As to differential diagnosis, *ovarian tumor* is the condition with which it is most frequently confounded. I have already (p. 744) called attention to the different relations of the intestine to the tumor in the two instances and other points of difference, all of which need not be repeated. The relative immobility of the renal tumor, as contrasted with the mobility of the ovarian, may, however, be mentioned; also the lumbar origin of the former, as contrasted with the pelvic of the latter, as determined by rectal and vaginal examination. Should the tumor disappear simultaneously with a copious discharge from the bladder, the diagnosis is, of course, conclusive. Aspiration may also be brought to aid the diagnosis, when advantage may be taken of the fact that the characters of the ovarian fluid and that of hydronephrosis are widely different. The dense, colloid fluid of the ovarian cyst, with its numerous cholesterin plates, fatty granular cells, small granular cells, and highly albuminous composition, contrast strongly with the aqueous consistence, the low specific gravity, and the general negative character of the hydronephrotic fluid. Too much stress must not, however, be laid upon these differences, as they do not always exist. The history in the case of ovarian tumor will develop the events of menstrual and sexual derangement, which are absent in hydronephrosis. Hydronephrosis is not likely to be confounded with *ascites*. The changes in the position of the fluid with that of the patient, characteristic of ascites, and its bilateral situation distinguish it at once from hydronephrosis.

From a *circumscribed peritoneal exudate* hydronephrosis is distinguished by the different history, the greater tenderness of the former, and tympany of the subjacent intestine elicited by strong percussion. In renal abscess there is fluctuation, but there are also fever and sometimes chills. The *renal retention cyst* is at times indistinguishable from hydronephrosis. Both may be congenital or due to congenital defects, but should there be intermittent emptying of the sac, with refilling, hydronephrosis may be suspected. The diagnosis from *hydatid cyst*, so far as is possible, follows in the next paragraph.

5. *Echinococcus or Hydatid Cyst*.—Hydatid disease of the kidney is a rare affection, and when the enlargement caused by it is sufficient to produce physical signs, they do not differ essentially from those of hydronephrosis and cystic kidney. Only in the event that the microscope recognizes hooklets or scolices, or fragments of the cyst-wall in the urine or in the fluid obtained by tapping or discharge into other localities, such as the stomach, intestines, or bronchi, can a diagnosis be made with certainty. Such discharge into the pelvis of the kidney, if it produce obstruction, may also cause acute hydronephrosis. The presence of hydatids elsewhere, and of the hydatid fremitus, is presumptive evidence. The chemical and physical characters of the fluid from hydatid cysts is given under hydatid disease of the liver (p. 480). Like hydronephrosis and cystic tumor, the hydatid kidney differs from ovarian tumor by its immobility, unless the disease should perchance invade a movable kidney.

Treatment of Renal Cysts.—The treatment of the whole list of affections included under cysts of the kidney lies in the province of the surgeon, the chief office of the physician in these cases being one of diagnosis and relief of pain.

ANOMALIES OF FORM AND POSITION OF THE KIDNEY.

NORMAL SITUATION OF THE KIDNEY.—The normal situation of the kidney is on the quadratus lumborum and psoas muscles, the inferior end of the left kidney extending a variable distance below the edge of the twelfth rib, while the right extends about 3-4 inch (20 mm.) lower down, the whole right organ being lowered by the position of the liver. The outer edge of the kidney is often in a line drawn vertically through the end of the twelfth rib. Both kidneys descend about 1-2 inch (12.5 mm.) during deep inspiration. The kidney, if in its normal situation, is accessible to pressure just below the last rib at the outer edge of the erector spinæ muscle. Sometimes one or the other, more frequently the left, lies on the lumbar vertebra, on the sacrum, or in the inguinal canal.

CONGENITAL ABSENCE OF THE KIDNEY.—The total *absence* of *both kidneys* is possible in connection with extreme abnormalities and defect of development, but is incompatible with life.

Congenital absence of one kidney is not very rare, the absent one being usually the left. Such absence may be suspected when over the normal situation of the organ a tympanitic note only can be elicited by percussion. In such event, the remaining kidney supplements the work of the absent one, and serious consequences only follow in the event of disease or lesion of the remaining organ. The ureter and pelvis of the absent kidney are

absent also, but sometimes the remaining organ has two pelves and two ureters. Occasionally the rudiment of a ureter is present. Congenital atrophy of one kidney is even more common, but is discoverable only at autopsy.

LOBULATED KIDNEY.—The lobulated kidney is the most frequent anomaly of form. It consists essentially in the persistence of the lobulation natural to the organ in the fetal state. This is acquired by the end of the eighth week of fetal life, after which it gradually disappears in normal development, but is still maintained with more or less distinctness throughout the first year after birth. The abnormal lobulation is variously distinct. Usually partial and superficial, the fissures are sometimes so deep as to divide the organ into separate reniculi, of which there may be from seven to twenty. This lobulation, a rare event in man, is clearly seen in the kidneys of the lower animals, especially in the sheep and ox.

HORSE-SHOE KIDNEY.—The most striking of the anomalies of form is the horse-shoe kidney, in which usually the lower ends of the two organs are united either by true renal tissue or by a band of fibrous tissue. More rarely it is the middle segments which are united, and more rarely still the upper ends. In either event, this coalescence is usually associated with displacement of the organ, which is then lower down than in the normal condition, usually just above the promontory of the sacrum, more rarely in the pelvis, and at times on one side or the other of the spinal column. In the fused kidney there are usually two pelves, with from two to four ureters. More rarely there is but one pelvis. The ureters pass over the front of the kidney. The renal arteries spring from the aorta at points corresponding to the situation in which the organ is found. Thus, when above the sacrum, the arteries spring from the back of the aorta near its bifurcation or from one of the common iliacs, while the veins enter the corresponding parts of the vena cava or iliac veins.

The horse-shoe kidney is generally first recognized at autopsy, but rarely it may be recognized in its abnormal position above the sacrum, especially in thin persons.

THE MOVABLE OR FLOATING KIDNEY.

SYNONYMS.—*Ren mobilis; Floating Kidney; Palpable Kidney; Nephroptosis.*

Description.—The normal kidney is commonly quite firmly retained in position by its capsule of fat and by a covering of peritoneum. The movable or floating organ exhibits a very different degree of mobility in different instances. The mobility may be so slight that it can be recognized only by the expert manipulator, or so great that the organ may be easily grasped by the hand through the abdominal walls. In the latter condition there is a mesonephron or peritoneal fold loosely attaching the kidney to the spine.

Etiology.—The movable kidney is more common in thin persons than in the obese, in women than in men. Indeed, it has been said that one woman out of every four has a movable kidney. It is six times as frequent in the working-classes. The right kidney is far more frequently movable than the left. Repeated pregnancies are assigned causes, as is also me-

chanical violence, as a fall or tight lacing. It is most likely, however, that the majority of floating kidneys are congenitally loose, and that this looseness may be increased by the conditions named.

Symptoms.—The floating kidney often occasions no symptoms. At other times it is responsible for a remarkable train of *nervous symptoms*, mainly reflex in character. These include *obstinate indigestion* of every grade, *flatulence*, *palpitation of the heart*, *cardialgia*, *neuralgic pain* almost anywhere in the body, but especially in the abdomen and cardiac region. Gastric crises identical with those characteristic of locomotor ataxia have been ascribed to floating kidney. *Irritable bladder* and *dysmenorrhea* are also consequences. It is an interesting fact that where the degree of displacement and the mobility are most marked, the reflex symptoms are least so. This is not without a parallel in other diseases, and in illustration may be cited the well-known fact that *prolapsus uteri* of moderate degree often causes decided reflex symptoms, while a complete procidentia produces often trifling local annoyance. The direct result of the displacement, so far as appreciable, is a sense of *dragging* or weight, which especially manifests itself while standing, walking, riding, or dancing, to which may be added a variable amount of *pain*. More serious symptoms sometimes manifest themselves as the result of *torsion* of the ureter, occasioned by complete rotation of the kidney, in which the renal vessels and nerves are also involved. These are agonizing pain, associated with symptoms of collapse, such as nausea, an anxious expression, and scanty urination. They are caused in part by obstruction to the ureter and the backing of the urine on the kidney. Acute hydronephrosis may also be the result of such strangulation, which may be caused, too, by inflammatory bands. This condition ends sometimes as suddenly as it begins. Both hemorrhage and albuminuria are reported as results. Both are certainly rare. There may be other effects of displacement due to the location of the organ at times, of which irritation due to pressure upon the bladder may be mentioned as one. It is often very uncomfortable for the patient to lie on the side opposite that on which the displaced organ belongs.

Diagnosis.—This is variously difficult. The kidney exhibits some mobility in health, descending also always 1-2 inch (1.3 cm.) with each deep inspiration. Movable kidneys are sometimes so loose and movable that they may be felt with ease through the abdominal walls. Between this ready recognition and that which requires the highest manipulative skill of the examiner there is every degree. At the present day, movable kidney is regarded as a much more frequent condition than was formerly believed. So frequently has the set of reflex nervous symptoms described been found associated with movable kidney that their presence should always suggest an examination for the presence of such an organ. The examination may be made with the patient in the standing posture, or when lying on the back. In the first he bends slightly forward, the hands being placed on a table, and the clothing thoroughly loosened. The right hand of the examiner is then placed in front immediately next the skin, below the hypochondrium, while the left is placed over the lumbar region. The patient is directed to respire deeply and regularly, and to relax during expiration. The region between the two hands is carefully palpated, when, if there is any marked degree of displacement, or rather of lowered position, the organ can be felt as a firm, smooth, oval body, somewhat sensitive to pressure, which produces a sickening pain which is quite characteristic. Most rarely the pulsation

of the renal artery can be felt. The right kidney naturally moves with breathing more than the left, being pushed down by the liver. Sometimes the manipulation will be more successful in the knee-elbow position. When in this position, the movable kidney having fallen forward, a resonant note may be obtained by percussing over the normal situation of the organ; or the patient may be placed on the back with the side to be examined toward the edge of the bed, on which the physician may sit. The hands are applied as in the standing position, and manipulation is practiced as described.

The displaced organ is hardly likely to be confounded with anything else. The *spleen*, which corresponds nearly in size, is also sometimes movable. Its shape is, however, different. Its anterior body is sharp and often notched. Sometimes both the left kidney and the spleen are floating. A *movable pyloric tumor* has been mistaken for a movable kidney. The passage of a stomach-tube in case of doubt would clear it up.

Treatment.—As may be inferred, many cases of movable kidney require no treatment. In a few instances the symptoms are relieved by improving the general health; in others the patient is comfortable while lying on the back, and such comfort may continue for a time after rising. When decided symptoms attributable to the kidney are present, surgical treatment for fixing the kidney—nephrorrhaphy—is alone of permanent value, and this sometimes fails. I have known an operation for removal of the kidney—nephrectomy—to be necessary after nephrorrhaphy had been attempted twice unsuccessfully. The use of pads and supports has never proved successful in my cases. Dr. A. Symons Eccles, however, reported* five cases of nephroptosis treated by an abdominal bell and pad, massage and exercise, with relief of all symptoms.

IDIOPATHIC HEMATURIA.†

Definition.—A hematuria the origin of which is unknown. In addition to the various causes of bloody urine already referred to in treating diseases of the urinary organs, and, in addition to malarial hematuria, there remains a form of renal hematuria of not very infrequent occurrence, for which none of the causes named will account. To this the term idiopathic hematuria is appropriate.

Symptoms.—The characteristics of the urine in this form of hematuria are in no way different from those of renal hematuria from other causes. The blood is intimately admixed with the urine, and is not, as a rule, found in the shape of coagula, as is so often the case when the blood comes from the bladder or pelvis of the kidney or in malignant disease of the kidney. There is the usual smoke hue characteristic of acid urine containing a small amount of blood, becoming brighter red as the urine becomes alkaline, and darker red as the quantity of blood is increased. The microscope reveals numerous blood-discs recognizable by their usual characters, and often blood-casts and casts filled with the débris of red discs, or red discs so closely packed as to make it impossible to distinguish their outline. The urine is, of course, albuminous.

Next to the change in the urine, the most striking feature is the absence

* "Lancet," January 29, 1898.

† I realize that the subjects hematuria, hemoglobinuria, and chyluria, next to be considered, are not strictly renal affections, but it is difficult to classify them otherwise.

of other symptoms. The subject is not ill, is not weak, and complains of nothing. Occasionally a dull ache in the back is felt or supposed to be felt, perhaps because the patient thinks that since there is bloody urine, there ought to be pain in the back. The same may be said of weakness, but these symptoms are not usually complained of, though they may be present. Sir William Gull spoke of such hematuria as a "rénal epistaxis." With the lapse of time, however, and the continuance of the symptom, positive weakness gradually supervenes.

Treatment.—Rest is an important and essential condition in the successful management of idiopathic hematuria. The usual astringents, mineral and vegetable, known to be efficient in the treatment of hemorrhagic conditions elsewhere, are often without effect here, though these substances, including gallic acid, ergot, the persulphate of iron, and acetate of lead, alum, catechu, and kino, may be tried. The persulphate of iron has proved of undoubted value in my hands, in doses of from 1-4 to 1-2 grain (0.015 to 0.32 gm.) every four hours in a pill. The astringent mineral waters, especially the alum waters, as those of the Rockbridge Alum Springs, in Virginia, and the Jackson Spring, North Carolina, have apparently proved curative, but I have also failed with them. A case which I saw in consultation with T. Barry Tyson, of Jenkintown, resisted all measures until Dr. Tyson tried the fluid extract of *hamamelis virginica* in doses of twenty minims (1.32 gm.) every three hours, and in thirty-six hours the hemorrhage ceased and has not recurred. As *hamamelis* contains much tannin and gallic acid, it may owe its efficiency to this constituent. One of my cases, after resisting every other form of treatment, finally yielded to electric baths, continued for fifteen minutes every other day for one month.

Gelatin has also been recommended in hematuria, in common with other hemorrhages. As an example, Schwabe injected into each infra-clavicular region 25 c. c. (7 fʒ) of physiologic salt solution containing 2 1-2 per cent. of pure gelatin, followed by the daily administration by the mouth for a week of a pint of 10 per cent. gelatin solution.

HEMOGLOBINURIA.

Definition.—In this interesting condition, the coloring-matter only of the blood is found in the urine; very rarely a few blood discs or their fragments. In their absence, other criteria of the presence of blood coloring-matter must be sought. To do this, one may make Teichmann's hemin crystals, as directed in the footnote on page 79; or if the spectroscope be available, the filtered and diluted urine produces the absorption bands of oxyhemoglobin between Fraunhofer's line D and E, or more frequently the three bands of methemoglobin, of which that in the red near C is distinctive. Sometimes both are present. The urine thus stained with hemoglobin is dark brownish-red, and even black in color. It is also albuminous, and in lieu of the blood-discs are sometimes found yellowish-brown, irregular, and granular flakes, and sometimes cylindrical masses of hemoglobin.

Hemoglobinuria is always associated with hemoglobinemia, which is, however, less easy of demonstration. The hemoglobin is set free from the corpuscles and imparts a red or lake hue to the blood plasma. The discs themselves are paler, and yellowish-brown particles of hemoglobin

may be demonstrated between the corpuscles. The number of corpuscles themselves may be reduced, falling to 4,000,000 and less.

Hemoglobinemia and hemoglobinuria may easily be separated into two divisions, toxic and simple paroxysmal.

TOXIC HEMOGLOBINURIA.—This is produced by toxic substances, which dissolve out the hemoglobin from the corpuscles. Such are sulphuretted hydrogen, arseniuretted hydrogen, carbon monoxid, carbolic acid, pyrogallic acid, naphthol, nitrobenzole; potassium chlorate in large doses, and the poison of certain mushrooms; also sometimes the poison of the infectious diseases, including scarlet fever, diphtheria, pyemia, yellow fever, typhoid fever, malaria, and even syphilis. The last has sometimes seemed to act as a predisposing cause, subsequently to which so trifling a thing as exposure to cold has caused it. I have seen it associated with pregnancy as a probable cause. Hemoglobinemia and hemoglobinuria sometimes succeed on extensive burns when the poison is probably the retained excretions of the skin. High temperature alone is said to have caused it. In malarial poisoning the hemoglobinemia may be the direct result of the action of the malarial plasmodium. The blood of one animal transfused into the vessels of another epidemically, must be added to this group.

Prognosis.—This depends upon the dose of the toxin causing it and the other symptoms produced. Recovery is usual, but some cases are rapidly fatal.

Treatment.—This is that of the disease occasioning it. The same astringent measures may be tried as in hematuria, and restorative medicines may be given to rebuild the blood. Of these, iron is the most important.

PAROXYSMAL HEMOGLOBINURIA.

In this, intermittent attacks occur. They come on suddenly, preceded by chills and fever, headache, and pain in the limbs, the temperature often reaching 104° F. (40° C.). The bloody urine follows in an hour or less, and may last four or five hours, or there may be two or three paroxysms in a day. At other times there is no fever or the temperature is even subnormal. Jaundice is associated with some cases, especially toward the end. At times, instead of the expected hemoglobinuria, there is only albuminuria. Ralfe explains this by supposing that the toxic agent has destroyed only a small number of corpuscles, the coloring-matter from which is used up in the spleen and liver, while the globulin goes off in the urine. Von Leube especially calls attention to a swelling and tenderness of the liver and spleen, and says he has met these symptoms in lieu of the expected hemoglobinuria—in lieu even of albuminuria.

The occasional association of hemoglobinuria with Raynaud's disease is very interesting. The probability is that in most cases where the two conditions are associated, the preliminary hemoglobinemia is due to a separation of the hemoglobin from the red discs in the peripheral asphyxiated part of the nose, ears, fingers, or other parts.

As to other causes of the paroxysmal form, malaria is undoubtedly one, though perhaps not so often as was once supposed. Another cause is excessive muscular exertion, especially when associated with cold, while cold itself is perhaps the most frequent of all causes. Mental emotion is

sometimes a cause. It must be admitted that for the cases not explainable by toxic agency no satisfactory solution has been presented.*

Prognosis.—The prognosis of the paroxysmal form is commonly favorable, though it may continue to recur for a long time.

Treatment.—This depends upon the cause. If it be malarial, the condition is easily curable by quinin. To seek the causes in many cases is to seek the unattainable, and the cases must be treated on general principles. Rest and warmth are essentials. After this, the same astringent remedies as those recommended under hematuria may be tried. As cold seasons and cold weather favor it, a residence in a warm climate should be recommended when the condition persists. Nitrite of amyl is said to have cut short and to have prevented an attack.

CHYLURIA.

Definition and Description.—A state of the urine in which the secretion is admixed with fat in a minute state of division, whereby the urine acquires a milky or chylous appearance.

The proportion of fat varies greatly, being at times only enough to impart a mere opalescence, while at other times the urine is scarcely distinguishable from milk, even the characteristic odor and taste of urine being wanting. The fat, on standing, often rises to the surface, like cream. By the microscope, in addition to this molecular fat and a few oil drops, numerous blood discs are also found. These are sometimes so numerous as to impart a pinkish tinge to the fluid, and at times a spontaneous coagulation takes place, with the formation of a slight reddish clot, showing the presence, also, of fibrin.

Etiology.—To produce chyluria there must be brought about in some way a leakage from chyle vessels into the urinary passages somewhere between the kidney and the neck of the bladder. Yet no such communication has ever been found, so far as I know, though W. H. Mastin noticed the patulous mouths of several chyle vessels opening into the serous sac of a testicle which he laid open for the cure of a chylous hydrocele or lymph scrotum. Having ligated them, no recurrence of the hydrocele occurred. Supposing such a communication to exist, how is it brought about? In most cases probably by the blocking of lymph channels by prematurely discharged ova or embryos of the *filaria Bancrofti*, to be described when treating of animal parasites. Undoubtedly there occurs, on the other hand, what may be termed, under the circumstances, an idiopathic chyluria, the most searching examination of the blood during life, and careful dissection after death, of lymph glands and vessels in certain cases, failing to discover either ova or embryos. On the other hand, by no means every case of filariasis is attended by chyluria.

Symptoms.—Few symptoms other than those of the chylous urine are present. It is usually intermittent, but may be persistent. There is sometimes a loss of strength from the draining off of fluid which is undoubtedly nutrient; at other times there is some pain in the back, and at others again painful urination due to obstruction of the urethra by coagula of fibrin, but in most cases the patient feels well and would not know there

* It is well known that horses are subject to hemoglobinuria, and that it occurs in them after exposure to cold, especially after having been stabled for several days.

was anything the matter with him had not his attention been called to the urine.

Treatment.—No means have been discovered to destroy the filaria in parasitic chyluria, nor to check the leakage in the idiopathic form, which often persists for years and then subsides spontaneously. Should the mosquito be its cause, the same measures which will ultimately be found for its eradication will apply to the filarial disease.

THE RELATION OF HEART DISEASE TO KIDNEY DISEASE.

Allusion has more than once been made in the foregoing pages to the relation of kidney disease to heart disease, and the association of lesions in the two organs. Of such importance is a proper understanding of this relation, that a few pages devoted to its consideration may be helpful to the student. The association admits of classification:

1. *Renal Disease Associated with Hypertrophy of the Left Ventricle without Valvular Disease.*—Modern studies have made it quite certain that this form of combined heart and kidney disease may originate in two ways: (a) The heart affection may be secondary to the kidney disease as its direct consequence; or (b) both conditions may result from one and the same cause—viz., arterial sclerosis.

(a) *The Renal Condition Precedes.*—The condition which precedes is commonly the contracted kidney of interstitial nephritis, and its result is hypertrophy of the left ventricle.

How is the cardiac hypertrophy to be accounted for? I will first review the theories which have been given from time to time, for theories alone they must be acknowledged to be. The oldest, which may be termed the "retention" or "chemical" theory, was advanced in its cruder form by Bright himself, whose acute observation had not failed to notice the association of cardiac hypertrophy without valvular disease with the disease so deservedly coupled with his name since 1827. Bright suggested two alternative explanations: "Either that the altered quality of the blood affords irregular and unwonted stimulus to the organ immediately, or that it so affects the minute and capillary circulation as to render greater action of the heart necessary to force the blood through the distant subdivisions of the vascular system." The late Sir George Johnson held this last view, and his pupil, Nestor Tirard, in England, and Senator, in Germany, still entertain it. At one time Johnson held that the hypertrophied state of the muscular coat was the result of an *effort* of the vessels to aid the onward movement of the blood. More recently he ascribes the thickening of the muscular coat, which exists not only in the kidneys, but in the systemic arterioles generally, to a constant exercise of the normal stop-cock action whose object is to resist the passage of this abnormal blood; while the hypertrophy of the left ventricle is ascribed to an effort to overcome this resistance. Dr. Johnson maintained that there is a true hypertrophy of the muscular coat of the arteries in all the tissues, associated with thickening of the intima only, in the kidneys, but of the adventitia also in the hypertrophied arterioles of other tissues.* Recent histological studies, made for Dr. Johnson under the direction of Dr.

* "The Pathology of the Contracted Kidney," by Sir George Johnson, London, 1876.

Halliburton, confirm this view. Unfortunately, other recent studies by modern methods, notably those by W. T. Councilman and Arthur V. Meigs, to be again alluded to, do not find the changes in the middle coat early described by Johnson and now again by Halliburton. Until lately, experiments which have for their object determining the effect of toxic substance introduced in the blood on the heart and vessel walls have proved negative. More recently a number of experimenters, notably Alfred Croftan, have succeeded in producing increased arterial blood-pressure, arterial spasm, thickening of arteries, and hypertrophy of the heart, as well as granular and fatty degeneration of renal-cells. Croftan used the alloxuric bases xanthin and hypoxanthin, while Ustimovitsch, Grützner, von Cavazano, and Robustello injected urea into the blood.* It is to be regretted that a histological question seemingly so simple cannot be settled by the refinements of modern histology.

The so-called "mechanical theory" of cardiac hypertrophy was advanced by Traube, whose researches in 1856 gave a decided impulse to clinical study of the subject. According to Traube, the increased arterial resistance was caused by two erroneously-supposed states—the first, an overfullness of the vessels due to the diminished renal secretion; second, a resistance to the admission of arterial blood into the kidney, due to the renal contraction itself. The first hypothesis was erroneous for contracted kidney where the urinary secretion is really increased, while the second is opposed by the fact that even ligation of the renal arteries fails to increase arterial pressure. This is because of the ample vascular space elsewhere for the blood thus diverted. Nor did Cohnheim's further elaboration of the mechanical theory, which located the increased resistance more precisely behind the wasted glomerule, give any more permanent life to it.

I incline to the belief that we should not lose sight of the possibility that the primary changes in the heart may be *compensatory* in their nature, set up with a view to supplementing the gradual loss of renal substance. Such an action is paralleled everywhere in the physiological economy. Nowhere do we meet with loss of function which is not at once met by an attempt of nature to compensate it. The dependence of the urinary secretion upon cardiac pressure is well understood, and an increase of cardiac power is the most reliable means available for stimulating the action of the kidneys, when desired, in therapeutics. The diuresis which is so constant a symptom of the contracted kidney is acknowledged to be the direct result of a supplemental contraction of the left ventricle, which it is reasonable to suppose is induced for the purpose named, and results in hypertrophy.

This view receives confirmation in the subsequent course of the disease. So long as the free secretion which is the result of the compensatory action of the heart is kept up, so long the patient remains tolerably comfortable, and perhaps even for a time unconscious of the presence of disease. But an organ thus overgrown is sure, sooner or later, to suffer in its nutrition. Especially is this the case if its arteries be the seat of an endarteritis, interfering with the free movement of the blood and producing also fibromyocarditis. And what are the further consequences? The strong propulsive power of the heart declines, the pulse falls away in tension and power and becomes more frequent and sometimes irregular. The urine secreted di-

* See Croftan's paper on "The Role of Alloxuric Bases in the Production of the Cardio-vascular Changes of Nephritis," published in the "American Journal of the Medical Sciences," November, 1900, where the reader will find references to papers by the other experimenters mentioned.

minishes in quantity and assumes a darker hue. Fortunate is the patient if the specific gravity of the urine rises inversely with its reduced quantity, as it indicates that the normal excretion of solids is kept up. Too frequently however, this is not the case, and excrementitious substances accumulate in the blood, laying the foundation for uremia. Headache, nausea, a foul and even a urinous breath may be superadded, and uremia sets in, preceded by drowsiness, or it may be ushered in suddenly with convulsions. Or another set of symptoms may supervene; the patient becomes short of breath, first on slight exertion, and later this very distressing symptom occurs without such exciting cause. This sort of asthma, known as uremic asthma, has been discussed on page 689. For a time this symptom may be averted by whipping up the heart by cardiac stimulants, and the right ventricle even comes to the rescue for a time and hypertrophies in its effort to overcome the now disturbed compensation. Subsequently this, as well as the left ventricle, may become dilated, and edema of the lungs sets in, with annoying cough and serous frothy expectoration, sometimes blood-tinged. Nor does general dropsy continue absent, but ensues sooner or later with the growing heart failure. Our resources are now almost at an end, but are not exhausted, as even these symptoms sometimes subside.

It should be stated that not every case of interstitial nephritis is attended with hypertrophy of the left ventricle. In addition to the cases of contracted kidney from senile endarteritis already referred to, cardiac hypertrophy is apt to be absent in the interstitial nephritis of the weak and cachectic.

(b) *Both the Hypertrophy of the Left Ventricle and the Contracted Kidney are the Result of One and the Same Cause—Arterial Sclerosis or Arterio-capillary Fibrosis.*—It should be stated, first, that a certain school explains all cases of contracted kidney in this way. The changes described in the arteries differ chiefly from those described by Dr. Johnson in that they are held to be degenerative, so far as the muscular coat is concerned.

The late Sir William Gull and H. S. Sutton, in a paper which has become classic, announced in 1872* that the changes in the muscular coat were chiefly of an atrophic character, and, although the methods of these observers have been much criticised, the most recent studies on this subject by W. T. Councilman and Arthur V. Meigs go to confirm their conclusions both as to the seat and the nature of the changes. Councilman † finds atrophic changes in the muscular coat, including greater or less destruction of the muscular fiber-cells and the formation of a homogeneous hyaline tissue invading both coats, but especially the intima, where it produces decided thickening, and encroachment to a varied extent upon the lumen, sometimes amounting to occlusion. The capillary walls are likewise thickened, and sometimes, especially in the glomerule of the kidney, obliterated. Meigs' ‡ studies also find these changes for the most part confined to the intima, which is decidedly thickened. To a less extent, the intima of the veins is similarly involved. The picture of the changes thus briefly described may be obtained from a small artery taken indifferently from any tissue or organ of the body—for example, from the muscular substance of the heart, the kidney, or the liver. It is this diffuse form of arteritis, rather than the nodular, which is the link between the hypertrophy of the left

* "Arterio-capillary Fibrosis," "Med., Chir. Trans.," London, 1872.

† "On the Relations Between Arterial Disease and Tissue Change," "Trans. Assoc. Amer. Phys.," vol. vi., 1891.

‡ "New York Record," July 7, 1888.

ventricle and the contracted kidney. In the nodular form of arteritis the changes are limited to small areas in the aorta and large arteries—atheromatous patches, sometimes calcareous and sometimes fatty, the so-called senile arteritis. The resistance offered the free movement of the blood is evidently less than in the diffuse form.

Of the consequent results of such thickening, the hypertrophy of the ventricle is most easily explained. The resistance in the blood-vessels stimulates the ventricle to increased effort, and there result increased arterial tension and hypertrophy. The degree of cardiac hypertrophy is sometimes enormous, the organ weighing as much as 850 grams (28 ounces), and the average in twenty-seven cases studied by Councilman being over 400 grams, (13 ounces), as contrasted with the normal, 10 to 12.

According to this view, the alterations in the kidney, which vary greatly in extent, being sometimes scarcely noticeable and sometimes extreme, are the direct result of an interference with its nutrition. The blood supply to the renal elements being cut off, these gradually waste and ultimately disappear. The cells and tubules thus destroyed are gradually, but irresistibly, replaced by fibrous connective tissue, in obedience to the pathological law elaborated by Weigert, but which was announced, at least so far as the kidney is concerned, fifty years ago by Dr. Johnson,* that parts destroyed are partially replaced by cicatricial connective tissue. This contracts and reduces the size of the kidney, and perhaps also, in this contraction, further destroys the proper kidney structure, and thus increase the atrophy.

It has been said that in this form of combined kidney and heart disease there is no cardiac murmur. Nor is there, as a rule. It is not impossible, however, for the endarteritis of which we are speaking to creep along the walls of the aorta until it reaches the aortic valves, and so structurally changes them as to make them rough or incompetent and give rise to murmurs.

The causes of this form of Bright's disease are, therefore, the causes of the endarteritis, which have been discussed on page 624. To a less degree, probably, the specific causes of all the infectious diseases must be included in this category—possibly even malaria. The subjects are usually middle-aged men, between the ages of forty and fifty-five, but they may be younger. Councilman has found these changes more common in the negro than in the white race.

Treatment.—The treatment of this form of combined kidney and heart disease is not different from that of interstitial nephritis. Even greater rigidity is necessary in eliminating nitrogenous food, and all food should be reduced to a minimum. A diet of milk diluted with water is the safest of all. Bread and butter may, however, be allowed, and even succulent vegetables easy of digestion, such as rice, potatoes, peas, and string-beans, while simple fruit-juices, as those of oranges and lemons, are allowable. Mental excitement and immoderate muscular exertion must be avoided, and the heart should not be overworked in any way.

The medicinal treatment especially directed to the arterio-sclerosis may be divided into that intended for the cure of the endarteritis and that directed to the relief of symptoms. The only drug from which results may be expected for the former purpose is the iodid of potassium, which should be

* "Medico-Chirurg. Trans.," 1847.

given a fair trial in doses as large as can be borne without deranging the stomach. For the relief of the symptoms more especially due to the sclerosis,—viz., headache, throbbing, and vertigo,—the nitrites are often useful. Nitroglycerin should be given in doses of 1-100 grain (0.00065 gm.) every four hours or oftener, rapidly increased to 1-50 grain (0.0013 gm.) if the smaller dose is without effect. The aim should be to produce the physiological effect, which is a sense of fullness or a flushing. The sodium nitrite may be substituted in three- to five-grain (0.19 to 0.32 gm.) doses. It has the advantage of being more permanent in its effect, although it is slower in its action.

2. *Valvular Heart Disease Associated with Renal Disease in which the Heart Disease is Primary.*—The heart disease is commonly disease of the mitral valve. The kidney involvement does not occur in connection with aortic valvular disease until mitral insufficiency is superadded. It is well known that in mitral regurgitation as soon as compensation ceases the blood accumulates first in the lungs, then in the right side of the heart, and finally in the venous system, engorging especially the liver, stomach, and kidneys. The effects upon the first two were discussed in treating of heart disease. They generally manifest themselves sooner than the renal symptoms. The result in the case of the kidney is the kidney of passive congestion or cyanotic induration, already described on page 694.

Much more decided are the clinical phenomena resulting from such congestion. It is a well-recognized condition of copious secretion of urine that the blood should move freely through the kidney. A stasis is followed immediately by diminished filtration of water, the twenty-four-hours' quantity being reduced to from thirty to twenty ounces, and even to less. The solids at first at least remain the same, the urine is dark-hued, the specific gravity is high, the reaction is markedly acid, and a copious sediment of urates and uric acid makes its appearance as soon as the urine cools off. There is almost always a small amount of albumin found, but as the congestion increases, albumin becomes copious. Casts are sparsely, if at all, present, and are of the hyaline and faintly granular variety. Both red and white blood-corpuscles are also sometimes detected, as might be expected. This condition of the kidney and the symptoms are the direct results of the cardiac valvular disease. Yet I often see these cases diagnosed as Bright's disease as though it were the primary and principal affection. They may also be produced by any cause producing venous stasis, as pulmonary emphysema, chronic pleurisy, and thrombosis of large veins. Their effect is further to augment the symptoms of the cardiac disease. The circulation, already everywhere obstructed, is further impeded, there is dyspnea, dropsy increases, appetite fails, and there are nausea and constipation. Sleep, already disturbed by dreams, becomes more so, and a more distressing picture than is presented by such a case is rarely met.

Treatment.—Yet these symptoms are often easily amenable to treatment so long as the heart muscle remains capable of being influenced by digitalis. I have seen many a patient, apparently *in extremis*, gasping in orthopnea and with legs heavy and almost bursting with dropsical effusion, completely relieved by a few large doses of this drug. But they must be large doses—not less than from eight to ten minims (0.5 c. c. to 0.6 c. c.) or from fifteen to twenty drops every three hours until an effect is produced. If digitalis fails, the tincture of strophanthus may be given in the same doses, or caffein citrate in three-grain (0.2 gm.) doses, each every four hours, or spartein sulphate in

doses of from 1-4 to 1-2 grain (0.016 to 0.03 gm.). Purgation should not be omitted, but should rather be pushed to the production of watery catharsis. The ingestion of fluids should be restricted, and Hay's treatment of dry diet with purgatives is sometimes useful. But I have found a restricted milk diet limited to two ounces every two hours, associated with the drugs previously named, equally efficient.*

Such a kidney is, of course, more liable to become the seat of an acute or a chronic nephritis than the normal organ.

3. *Renal Infarct the Result of Heart Disease.*—The next form of kidney involvement secondary to disease of the vascular apparatus, commonly heart disease, is more frequently seen on the postmortem table than recognized in the living subject. It is *embolic infarction*, produced by the lodgment in some branch of the renal artery of an embolus derived from the heart or a blood-vessel. Its most frequent source is a fragment of vegetation or clot from a diseased heart-valve, commonly the aortic. An embolus may also arise from a thrombus in a vein. If from the latter, it must be carried first to the right heart, and thence through the lungs into the left heart, and thence by the aorta to the kidney, and must, of course, be small.

The effect of the lodgment of an embolus in the kidney is a wedge-shaped hemorrhagic infarct which at first is dark red in color, standing out above the surface, but which in time whitens, contracts, and is ultimately absorbed, leaving a mere cicatricial mark.

Most frequently a renal infarct occurs without noticeable symptoms. Its occurrence, if looked for by reason of the presence of valvular heart disease, may be suspected if there is the sudden appearance of blood in the urine. A sudden pain in the region of the kidney occurring at the same time with hematuria would go to confirm the diagnosis. No treatment, except rest, is indicated, even if the event is recognized.

4. *Accidental Coincidence of Renal Disease and Heart Disease.*—Finally, kidney disease and disease of the vascular apparatus, and especially cardiac disease, may coincide accidentally, each the result of its own cause, and reacting the one upon the other in various degrees and variously aggravating the symptoms of each, so that it often becomes a very nice question to determine which is the preponderating disease. Fortunately, this difficulty does not always extend to therapeutics, the same remedies which are useful to one affection being commonly indicated for the other. A careful study of each case should, however, be made on its own merits, and due weight assigned to each factor of the disease.

* See some cases reported by the author in a paper "On the Management of Obstinate Dropsies," "Med. News," June 21, 1890.

DISEASES OF THE BLADDER.

CYSTITIS.

SYNONYMS.—*Catarrh of the Bladder; Vesical Catarrh.*

Definition.—Cystitis is an infectious inflammation of the bladder excited usually by different varieties of pathogenic bacteria.

Etiology.—Among these are the *bacillus coli communis*, the *gonococcus*, *staphylococcus pyogenes* and *bacillus tuberculosis*. The typhoid bacillus is not an infrequent cause.* The causes formerly assigned to such inflammation, though relegated by the above definition to favoring causes, are still very important. They include foreign bodies, such as stone, trauma, obstruction to the outflow of urine by enlarged prostate or stricture of the urethra. A frequent medium of introduction of bacteria was formerly catheters. The number of cases caused by catheterization has diminished because of the greater precaution taken of late in the care of instruments. Of acknowledged bacterial origin is also gonorrhoeal cystitis, which, succeeding an attack of gonorrhoeal urethritis, invades the bladder by extension.

Cold was formerly recognized as a cause of cystitis, especially in women and children, but it is subject to the same conditions as the causes just named. On the other hand, cystitis succeeds upon the introduction of substances in the blood, as cantharides and capsicum. Even the ingestion of certain articles of food has been followed by it. Traumatic agencies may be classed among predisposing causes rather than exciting, furnishing the conditions favorable to the operation of bacteria.

Morbid Anatomy.—The bladder of cystitis is a varied picture. There may be degrees so slight as to produce scarcely appreciable change in its appearance. At other times the mucous membrane is hyperemic and bathed with a mucoid or mucopyoid secretion of dirty-gray color. In many cases only the neck of the bladder and the part of the urethra passing through the prostate are involved. Again, the bladder is "ribbed," a result of straining. During this act the mucous membrane between the muscular trabeculae yields, producing depressions bounded by the more unyielding muscular bands. On the other hand, in chronic cases permanent thickening of the bladder-walls may result. Finally, in the severest forms of inflammation due to pathogenic organisms, such as those associated with putrid urine, the mucous membrane may be covered with patches of false membrane, or the wall of the bladder may be infiltrated and undermined with pus, constituting the so-called phlegmonous or diphtheritic cystitis, from which there may result urethral and perineal infiltration. A further extension of the cystitis into the pelvic connective tissue about the bladder is known as paracystitis; this belongs to the province of the surgeon.

Symptoms.—While a division of cystitis into acute and chronic is justified by the suddenness and severity of symptoms in certain cases as contrasted with their slow development in others, yet the conditions so constantly verge into each other that a separate consideration of the two forms is not necessary. The first symptom is usually a *frequent desire to pass water*.

* See an admirable paper by Thomas R. Brown on "The Bacteriology of Cystitis Pyelitis," etc., "John Hopkins Hospital Reports," vol. x., 1901.

Such frequency varies greatly in intensity. It may be every few minutes or almost incessant, several times an hour or once in two hours. After the primary frequency of disturbance it usually diminishes somewhat. Such frequency is often attended by painful straining. In severe cases there is always *tenderness* over the region of the bladder above the pubes, and in some cases there is constant *pain*. In these tenderness can also be elicited by pressure from the vagina and rectum, while catheterization is especially painful. In calculous cystitis pain is excited or aggravated by motion, especially such as is communicated to one riding in a wagon over a rough road.

As commonly met, there is rarely fever with cystitis, but the severe forms are attended with *moderate fever* and sometimes, in the diphtheritic variety, with *high fever*. Even when there is fever, the temperature does not exceed 100° to 102° F. (37.8° to 38.9° C.), though it may be higher. In certain acute diphtheritic cases of great virulence there are *chills*, *sweats*, and *high fever*. In advanced stages there may be *sepsis*, due to absorption of retained putrid matter from the bladder.

The *urine* presents striking changes, from which alone the diagnosis can be made. *First*, it contains pus in varying quantities, but it is especially characteristic of the pus of cystitis that it is associated with mucus, which imparts a glairy, stringy character to the urine, that increases the difficulty of its discharge from the bladder. The reaction of the urine when passed is commonly either alkaline or faintly acid, and if acid, it promptly becomes alkaline. This is due to the formation of ammonium carbonate out of the normal urea, the result of the operation of bacteria. The greater alkalinity thus resulting reacts upon the pus and converts it into a glairy matter resembling mucus, thus further increasing the difficulty of micturition. Under the circumstances the pus is loaded with amorphous phosphates of lime and glistening crystals of ammonio-magnesium phosphate. It is so viscid that it will not rise in the pipette, and must be cut with scissors to be manipulated for microscopic study. Blood is an almost constant constituent of the urine in calculous cystitis, and in the grave diphtheritic forms shreds of gangrenous bladder tissue may be discharged.

Diagnosis.—Ordinarily, the diagnosis of cystitis is easy, yet there sometimes occur mild forms which it is difficult to differentiate from mild degrees of *interstitial nephritis*, while it not very rarely happens that the two conditions are associated. In contracted kidney there are also sometimes a good many leukocytes. The presence of hyaline casts, even when scanty, points to nephritis, while hypertrophy of the left ventricle and increased arterial tension settles the question. Still more emphatic is the diagnosis if there is retinitis albuminurica.

The question as to whether there is *pyelitis*, separate or associated with cystitis, is still more difficult. It is true that the pus in pyelitis is very much less glairy and viscid than that of cystitis pure and simple. I know, however, no distinctive cellular elements which settle this question, though some assert there are. Even spasm of the bladder, commonly regarded as peculiar to cystitis, may be present in pyelitis. Rather must we rely upon tenderness in the neighborhood of the kidney on the one hand and in that of the bladder on the other. Marked intermission in the purulent discharge, especially if associated with attacks of nephritic colic, which imply an obstruction of the ureter, point to *pelvic involvement*.

Calculous cystitis may be suspected when pain in the region of the blad-

der is excited by motion, as in riding over a rough road, or at the end of the penis after micturition; also when there is blood in the urine or when the stream of urine is suddenly interrupted. These symptoms should immediately suggest the use of the sound, negative results with which must not, however, be accepted without qualification, as the stone may be concealed in a diverticulum.

Prognosis.—The medical treatment of cystitis does not furnish a very satisfactory chapter in therapeutics. It includes such treatment as the physician is called upon to use, supposing the exciting cause, such as a stone in the bladder or obstruction in the urethra, to have been removed, whenever possible: I say whenever possible, because the enlarged prostate which is responsible for so many cases of cystitis is, in the vast majority of cases, not removable even in these days of brilliant surgical results. Many cases get well; others are only partially relieved. Some of the most virulent acute cases terminate favorably with rupture into the vagina or rectum if the patient resist the primary attack of the disease.

Treatment.—*Acute Cystitis.*—Of this form the treatment is far more satisfactory, at least so far as the removal of the acute symptoms is concerned, than that of the chronic form. Rest in bed is a primary and essential condition. Leeches to the perineum should be applied more frequently than they are. A poultice to this same region and over the lower abdominal region is always useful, while a brisk saline cathartic should never be omitted.

As the feverish state which always accompanies cystitis is more or less constantly associated with scanty urine, concentrated and irritating to the inflamed mucous membrane, it is desirable at once to increase the secretion and thus dilute it. Copious libations of pure water, to which the citrate or acetate of potassium is added, in fifteen to twenty-grain (1 to 1.3 gm.) doses for an adult, should be allowed. The ordinary spirit of nitric ether in dram (3.4 c. c.) doses every two hours is an admirable adjuvant, and may be combined with the official liquor potassii citratis, which contains about twenty grains (1.3 gm.) of citrate of potassium to 1-2 ounce (15 c. c.). Formerly, the mucilage of flaxseed or flaxseed tea was much used as a diluent menstruum for the diuretic alkalies indicated, but it is doubtful whether it is any more efficient than a like quantity of water. When there are much pain and straining, as is often the case, especially when cantharides is the cause of the inflammation, opium is indispensable, always in the form of a suppository, 1-2 grain (0.03 gm.) to one grain (0.065 gm.) of the extract, or a corresponding amount of morphin. Iced-water injections into the rectum, or pieces of ice similarly applied, are very efficient in allaying the pain and irritation when additional measures are needed. I have recently found injections of cocain into the bladder useful in allaying the intense irritation. Not more than two grains (0.13 gm.) of cocain should be introduced into the bladder at one time.

Chronic Cystitis.—The successful treatment of chronic cystitis is a much more difficult task, for three evident reasons:

1. The constant presence in the bladder of the urine with its irritating qualities, especially so to an inflamed mucous membrane.
2. The difficulty in getting remedies to reach the inflamed surfaces.
3. The pent-up inflammatory products, which in their decomposition often make the urine still more irritating by exciting in it ammoniacal changes.

There is no doubt that, if the urine could be kept from entering the

bladder during the existence of an inflammation, the latter would rapidly heal; that cure would be facilitated by obtaining ready escape for the pus and mucus; while happier results might also be reasonably expected if we could secure readier access for remedies to the inflamed areas. None of these indications can be met entirely. They remain, however, the conditions to be fulfilled, and while none can be thoroughly fulfilled, they may be variously approximated.

First, the irritating qualities of the urine may be diminished by the use of diluents, already recommended in the treatment of acute cystitis. Almost any of the negative mineral waters, so highly recommended by their owners, are useful for this purpose. Just as good is pure spring water, and even better is distilled water. From one to two quarts should be taken daily. If the kidneys are equal to their office, a large quantity of light-hued urine of low specific gravity and relatively weak in solids will be secreted.

When it is purposed to go further and add to the efficiency of diluents, mistakes are often made. While one can scarcely go astray in adding alkalies to the fluid ingested in acute cystitis, it is very different with the chronic form. In this the urine is often alkaline, or ready to become so on the slightest addition of alkali to the blood. Such alkalinity of urine in turn favors decomposition, the effect of which is to convert the pus, if present, into a tenacious, glairy fluid which the bladder cannot evacuate. Notwithstanding this tendency, liquor potassæ and other alkalies are sometimes administered under precisely these conditions—adding "fuel to the flame." The indication under these circumstances is to render the urine acid, if possible, although the means to this end are unsatisfactory. Benzoic acid has the reputation of doing this, and it is probably true of it when administered in sufficient doses. It may be given in the shape of a five-grain (0.32 gm.) capsule, of which at least six must be given in a day to produce any effect. Benzoate of sodium may be given in ten-grain doses (0.6 gm.) every two hours. The same property has been assigned to citric acid, but this is a mistake, as all of the vegetable acids, when ingested, are eliminated as alkaline carbonates.

The second indication is to medicate the inflamed surface. Two ways suggest themselves:

1. By the internal administration of drugs.
2. By the injection of medicated liquids into the bladder.

To carry out the first method, an enormous number of infusions, decoctions, and fluid extracts of vegetable substances have been suggested, the vast majority of which are absolutely useless, except as they serve by their quantity to act as diluents. Among the best known of these are buchu, *pareira brava*, *uva ursi*, and *triticum repens*. I have never known any beneficial results to be obtained from any of them, except perhaps buchu, and seldom prescribe them except as vehicles.

The remedies heretofore most efficient in cystitis through their internal administration are the balsams. Of these, the balsam of copaiba is practically unavailable, because not one stomach in a hundred will bear it in sufficient doses or for long enough time to permit it to be of any use. Sandalwood oil is more easily borne, and is also an efficient remedy. It is best administered in capsules containing ten minims (0.6 gm.). Contrary to the usual custom of giving these and like remedies after meals, I have given them on an empty stomach before meals. They are as well and even better borne than when given after food, and they pass into the blood much more quickly. It

is desirable to impregnate the blood and to impart a balsamic odor to the urine. This is scarcely possible with less than eight capsules a day—two before each meal and two at bedtime. They should be followed by a little milk rather than water.

A valuable addition to drugs useful in the treatment of cystitis is urotropin or formin, and it has been in my hands most efficient. It has seemed to me to be most indicated in subacute and chronic stages. The dose is 5 to 7 1-2 grains (0.3 to 0.5 gm.) in a capsule three times a day. I have not found it always superior to sandalwood. Occasionally this balsam is more efficient.

Both boric acid and benzoic acid are useful adjuvants to the treatment of chronic cystitis through their antiseptic effect on the urine, each in five-grain (0.32 gm.) doses, rapidly increased to ten grains (0.65 gm.). They may be given jointly, as in the following prescription:

℞ Sodii bibeorat., } aa gr. x (0.65 gm.)
 Ac. benzoic., }
 Infus. buchu, f ʒ ij (60 c. c.).
 Three times a day.

Resorcin in five to ten-grain (0.32 to 0.65 gm.) doses and naphthalin in two-grain (0.13 gm.) doses are recommended for the same purpose. Salol has become a popular remedy, very large doses being advised,—from fifteen to thirty grains (1 to 2 gm.) every three hours,—but in my experience these doses are not well borne, ten grains being a maximum dose.

The application of remedies to the bladder by injections is best considered in connection with the third indication—the getting rid of inflammatory products, the pus and mucus, and the matters resulting from their decomposition. The latter are not always present, but all who have had much experience with cystitis are familiar with the tenacious, glairy, mucoid matter, which will not drop or rise up in a pipette, glistening with large crystals of triple phosphate, and exhaling a stinking, ammoniacal odor which quickly contaminates an entire apartment. There is only one way to get rid of this, and that is to wash out the bladder, and often this is too long deferred. Tepid water should be used first, and the injection made through the soft, flexible catheter. Sir Henry Thompson is very emphatic in his directions that no more than two ounces should be thrown in at a time, and that this should be allowed to run out, a like quantity again injected and allowed to run out, and this repeated until the water comes out as clear as it enters. But double this quantity may be used with entire safety, and with such quantity used, a much shorter time is necessary to cleanse the bladder thoroughly. After the capacity of the bladder has been determined, even more may be thrown in, because it is sometimes useful to distend the viscus a little, in order to reach the depressions and inequalities always present in advanced bladder inflammations. These simple injections, practiced once a day, or in severe cases twice a day, often result most happily. After a few injections with plain water some medication may be added. Salicylate of sodium, in the proportion of a dram (4 gm.) to the pint (1-2 liter), is one of the best. Its disinfecting qualities are undoubted. Boric acid, in the proportion of a dram (4 gm.) to the pint (1-2 liter), is also very satisfactory. Sir Henry Thompson's soothing lotion—of bibeorat of sodium an ounce (30 c. c.), glycerin two ounces (60 c. c.), water two ounces (60 c. c.), and of this mixture 1-2 ounce (15 c. c.) to four ounces (120 c. c.) of tepid water—may also be used. Nitrate of silver of the strength of 1-4 grain (0.016 gm.) to the ounce (30 c. c.), increased to 1-2

grain (0.03 gm.), is often very efficient in diminishing pus. The bladder, if previously washed out by boric acid solution, should be irrigated with plain warm sterilized water in order to avoid chemical reaction between the nitrate of silver and the boric acid.

Alum is an astringent which has been too often overlooked of late in suppurating processes in mucous membranes, and may be substituted for the salicylate with advantage when the pus does not disappear so rapidly as is desired. It should be more cautiously used than the salicylate of sodium. Sufficient of the powdered alum should be first added to a pint of water to give it a distinctly astringent taste, when the bladder should be washed out as described, while a small quantity may be allowed to remain after the last injection.

When there is a foul odor present, the bichlorid of mercury may be used in exceedingly dilute solution,—not more than 1 to 25,000 at first,—gradually increasing the strength if it is well borne. Carbolic acid may also be used in weak solution,—1-4 to 1-2 per cent.,—also peroxid of hydrogen, one part to four or five of water. Among other remedies recommended for use in the same way are acetate of lead, one grain (0.06 gm.) to four ounces (120 c. c.); dilute nitric acid, one or two minims (0.06 or 0.12 c. c.) to the ounce (30 c. c.).

Anodynes are indispensable in many cases of cystitis to relieve the patient of extreme pain and of the frequent desire to pass water, which are the result of the same cause. Opium and its alkaloids are the most efficient, and they are best introduced by the rectum. There appears to be no absorbing power in the bladder for opium, and there is no use in attempting to administer anodynes by that channel. Cocain, from which so much might reasonably be expected, is disappointing, though it should not be overlooked. I have injected as much as two ounces (60 c. c.) of a one per cent. solution into the bladder, representing eight grains (0.5 gm.), without effect, except to produce some of the symptoms of cocain poisoning. Disappointing, too, has been the use of cocain to remove the exquisite tenderness of the urethra which sometimes attends this condition, and is a serious drawback to the use of the catheter; yet it may be tried for both purposes. For catheterizing, a two per cent. solution may be injected into the urethra, allowing two or three minutes to elapse before the catheter is introduced. Then, through the soft catheter itself, a few drops of this solution may be injected in advance of the catheter, which is again pushed a little further; then a few more drops are instilled, the catheter is introduced a little further, and so on until the instrument enters the bladder.

When there is greatly enlarged prostate, catheterization is indispensable, and is often attended with the most happy results. It is often too long deferred because of the natural repugnance to the use of the instrument. The patient or his friends should be taught to use the catheter and to wash out the bladder. In these days of refined antisepticism it is scarcely necessary to say that the greatest precautions should be taken to cleanse the catheter after its use, in order to avoid sepsis. There is nothing better for this purpose than the bichlorid solution, 1 to 1000, in which the catheter should be allowed to lie for a short time after being cleansed with boiling-hot water.

How much can be accomplished by such treatment as that just described? An absolute and total cure in chronic cystitis is a rare event. On the other hand, a life of suffering may be converted into one of comparative comfort, and I have many times seen it. It occasionally happens, of course, that all

treatment of this kind fails, and yet the patient lives to be tortured by the discomfort of the situation. In such cases perineal section may be recommended, and I have had the operation done several times with some relief to the patient, although with less than was hoped for. Of late years suprapubic cystotomy has come into favor. The operation of castration, strongly advocated by J. William White, offers some prospect of relief in cases due to enlarged prostate. It recommends itself by its comparative freedom from danger. Vasectomy is even a much simpler operation, but less effectual. Excision of a portion of the prostate itself is becoming more common.

STONE IN THE BLADDER.

All that has been said in a general way of stone formation and the treatment of its tendency when treating of nephrolithiasis may be applied to stone in the bladder.

Symptoms.—The symptoms of stone in the bladder are practically those of cystitis, already described, aggravated by motion, especially riding over rough roads. As further distinctive of stone in the bladder may be mentioned pain at the end of the penis immediately after micturition. The only proof, however, of the presence of stone is its recognition by the sound, which should be used in every case of cystitis.

Treatment.—For removal of stone in the bladder medicinal treatment is even less efficient, and operative treatment is, if possible, more imperative.

NEUROSES OF THE BLADDER.

Physiology of the Bladder and Its Derangements.—A proper understanding of nervous derangements of the bladder will be facilitated by a review of its physiology. The control of the bladder over the urine is partly reflex and partly voluntary. The reflex center is in the lumbar enlargement of the cord; the voluntary, in the cortex of the brain. In the lumbar cord seem, however, to be lodged two reflex centers, one for the *detrusor vesicæ* and the other for the *sphincter*. If the bladder be partly filled and at rest, its control is given over to the sphincter, whose striated fibers are reflexly active. As the bladder becomes more nearly full, the unstriated fibers of the detrusor muscle are more and more stimulated, and a time arrives when the sphincter can maintain itself only by the assistance of the will if the subject be in a normal state. In such state, too, under suitable circumstances, the will suspends its control over the sphincter and the bladder is emptied.

PARALYSIS OF BLADDER.

If the spinal cord is cut above the lumbar enlargement, voluntary power to aid or suspend the action of the sphincter is lost, the bladder is given over to the lumbar cord as a pure reflex center. The urine accumulates as long as the action of the sphincter prevails, but as soon as a sufficient amount accumulates to stimulate the extrusor, the bladder is emptied more or less completely. Thus is produced one of the forms of incontinence, as when there is extensive lesion of the cord above the lumbar region.

If, on the other hand, there is paralysis of the *detrusor* muscle and the

sphincter remain intact, there will be retention of urine. If, however, communication with the brain remains intact, by an act of the will the reflex contraction of the sphincter may be suspended and the bladder partially emptied by a straining effort, at least so far as pressure can be exerted by the abdominal muscles. Should the afferent or sensory nerves of the reflex arc be paralyzed either alone or in conjunction with the efferent to the detrusor, the bladder will become enormously distended; but if the distention continue, a point is reached when the sphincter is paralyzed by overstretching, when incontinence occurs and the urine dribbles away. There is the same effect if there be destruction of the cord at its lumbar enlargement. So long as the cord is intact the patient may partially empty the bladder by abdominal pressure. Again, if paralysis of the *sphincter vesicæ* occurs, incontinence succeeds as soon as urine has accumulated sufficiently to overcome the elastic closure of

Fig. 78.—Diagram Showing Probable Plan of the Center for Micturition—(Gowers).

MT. Motor tract. ST. Sensory tract in the spinal cord. MS. Center, and *ms* motor nerve for sphincter. MD. Center, and *md* motor nerve for detrusor. *s* Afferent nerve from mucous membrane to S, sensory portion of center. B. Bladder. At *r* the position during rest is indicated, the sphincter center in action, the detrusor center not acting. At *a* the condition during action is indicated, the sphincter center inhibited, the detrusor center acting.

the bladder orifice. It may also be slightly delayed by voluntary innervation of the sphincter, but is unrestrained during sleep. Hence at such time the patient wets the bed. Such incontinence is also manifested when the patient coughs or when in any way sudden pressure is brought to bear on the bladder. It is often seen in women who are said to have "weak" bladders. Combined detrusor and sphincter paralysis is followed by *dribbling* away of urine as soon as enough accumulates to overcome the elastic closure of the urethra, because there is no contraction of the bladder, and the outflow is a mere overflow.

MUSCULAR SPASM OF THE BLADDER—CYSTOSPASM.

Symptoms.—In detrusor spasm sudden evacuation of the bladder takes place. This occurs in hyperirritability of the mucous membrane of the bladder or of the reflex center in the cord as soon as a small amount of urine accu-

mulates in the bladder. It may be controlled to a degree by a voluntary impulse to the sphincter, but at other times it is irresistible, and is especially prone to occur during sleep. To this class of cases belong many of the instances of incontinence in children.

In spasm of the sphincter, on the other hand, the orifice is kept forcibly closed, though this closure, too, may be intermitted by action of the will, permitting thus a small quantity of urine to be discharged at a time. As the urine accumulates the discomfort increases still further, when an attempt is often made to empty the bladder by straining efforts. This sometimes reacts on the sphincter, producing further contraction, which may extend to the bulbo-urethral and sphincter ani muscles, causing painful spasm. Such spasm, too, forcibly resists the introduction of a catheter. It may be due to hyperexcitability of the sensory reflex center or to irritation directly in the neighborhood of the sphincter, such as intense inflammation.

A combination of spasm of the detrusor and sphincter muscles may exist, giving rise in high degrees to intense suffering. It may be caused by a simultaneous irritation of the two reflex centers in the cord or by intense irritation of the mucous membrane of the bladder reflected to both sets of muscles.

In addition to the nervous affections, chiefly of the cord, which may occasion these symptoms, modifications in the sensibility of the mucous membrane of the bladder, deeper urethra, and prostate may also occasion them. These changes may be associated with inflammation or they may be purely neurotic. R. Ulzmann has refined the subject of neuroses of the genito-urinary system to a high degree, referring many symptoms of the kind described to an "exalted reflex excitability" caused by "overstrained physical, but especially by exciting mental activity," long kept up. Among these he mentions fright, pain, grief, loss of property, and the like, as well as the "gonorrhoeal process," excess in venery, and masturbation, apart from the organic processes of hyperemia, and even inflammation, which may be due to gonorrhoea. The pure neurotic representatives of this class are unattended with changes in the urine, which is normal in every particular. These are not very uncommon, and they are often extremely difficult to treat successfully.

A comparatively frequent representative of this class is due to a hyperesthesia of the vesical mucous membrane, as the result of which the presence of the smallest quantity of urine gives rise to a pressing desire to empty the bladder, which is accomplished with spasm, pain, or other discomfort. As the result of this the patient must empty his bladder often—several times an hour, but much less frequently, if at all, at night. The urine is, as a rule, normal, and though sometimes concentrated, with a proportionate specific gravity, is still no more so than that which is commonly retained with perfect comfort. This occurs also sometimes in women.

Occasionally there is absolute loss of sensation in the vesical mucous membrane, apparently also functional, in consequence of which the urine accumulates without exciting the attention of the patient, and the bladder becomes thus overdistended.

Treatment.—*Of Incontinence or Eneuresis.*—Previous to instituting treatment for these conditions the most careful inquiry must be made as to the cause, and its removal sought. This is often impossible, and treatment must then be empirical.

Incontinence most frequently calls for treatment. If due to disease of the cord, it is amenable to treatment so far as such disease is, and in the mean-

time the patient must be protected by catheterization from the overdistention which is so apt to precede incontinence. Incontinence due to weak sphincters demands that this weakness should be treated by full doses of strychnin, which may be advantageously given in gradually ascending doses. Tincture of *nux vomica* may be substituted in ascending doses until fifteen-minim (1 c. c.) doses are attained. Electricity has lately been highly commended for this form of incontinence, in the shape of faradization, one pole being applied to the lumbar part of the spine and the other in the urethra, in the vagina, or to the perineum, the sittings being continued for a few minutes each day or every other day. Cold douches to the perineum are also useful.

If incontinence is due to hyperesthesia of the mucous membrane or to irritability of the bladder, belladonna is the accepted remedy. It should be given in ascending doses, and toward evening if it be nocturnal incontinence, so common in children. The physiological effect of the belladonna should be produced. The bromids may be combined with it or used separately. If there is irritability of the lumbar cord, ergot commends itself through its effect of diminishing congestion of the cord. The urine should receive attention, since a high degree of acidity or the presence of sediments of uric acid and of oxalate of lime may become the exciting causes of incontinence.

Incontinence in children (which is the most frequent variety met in practice) is a source of great annoyance, but in the majority of cases it subsides spontaneously not later than the twelfth year. In its treatment in addition to the measures suggested, close investigation should be made for causes which should be removed.

Habit is sometimes a cause of incontinence in children, and encouragement of a cautious practice of holding the water may gradually correct the evil. Children should *not* be punished for incontinence, as the nervous apprehension excited only serves to make matters worse. General ill-health and irregular habits are sometimes responsible, and when these are corrected the patient recovers. Phimosis is sometimes a cause, and should be corrected if present.

Of Retention.—An overfull bladder should always be relieved by the catheter, and catheterization should be repeated as often as necessary to prevent recurring distention while the cause is being treated. When the retention is due to weakness of the detrusor muscle, strychnin will be of service. Electricity may also be used—one pole being placed behind the pubes and the other applied to the lumbar region.

If retention is due to spasm, the cause should be carefully sought. The same irritations referred to as causes of incontinence may produce spasm, and some of the same remedies are useful to relieve it, as belladonna and the bromids. Warm sitz-baths and full baths and enemas of warm water may be used at a temperature of 95° F. (35° C.) two or three times a day. In the event of failure with these measures, more powerful anodynes may be used, including opium and morphin. These are best administered in the shape of a suppository containing from 1-2 grain to one grain (0.033 to 0.0066 gm.) of extract of opium, and 1-4 grain (0.0165 gm.) of morphin. Ultzmann recommends, in cases of frequent micturition due to hyperesthesia of the prostate, injections through the prostatic urethra by a catheter which just reaches the membranous portion of the urethra. The solutions used are a 1-4 to 1-2 per cent. of carbolic acid and a 1-2 per cent. solution of sulphate of zinc, increasing the strength as it is borne to three, four, and five per cent. These should be used once a day with a syringe holding four ounces

(100 gm.), and the whole quantity should be thrown into the bladder in the manner prescribed.

Other forms of spasm must also be treated by sedatives, and, strange as it may seem, the passage of a sound will sometimes relieve such spasms.

Unfortunately, the causes of either of these conditions cannot always be ascertained, and a cure must be secured by passing from one remedy to another until the correct one is arrived at.

HEMORRHOIDAL VEINS OF THE BLADDER.

Excluding all other causes of hemorrhage of the bladder heretofore considered, such as villous cancer, stone, and tuberculosis, there remains a cause of hemorrhage which, by exclusion, resolves itself into a hemorrhoidal state of the veins. Its subjects are only older persons, rarely under sixty; it is rather copious and yet rarely fatal,—in my experience never so,—though fatal cases are reported.

Great care should be taken in the study of cases of this kind in order to make sure that the hemorrhage is not due to the more serious causes already considered, otherwise a grave mistake in prognosis, as well as in diagnosis, may occur. The bladder should be carefully explored by the sound and, if necessary, by the endoscope.

Treatment.—Hemorrhages from this source may occur and not be repeated, and it is this favorable termination, in the absence of stone or malignant disease, on which we are sometimes unfortunately compelled to rely for the diagnosis. Should the hemorrhage continue, astringent solutions—1-2 per cent. and upward of alum and sulphate of zinc—may be injected into the bladder, always using the soft catheter. Absolute rest in bed should also be insisted upon. At the same time, the astringent drugs and mineral waters recommended under the treatment of hematuria may be tried, but it is hardly to be expected that astringent effects can be produced in the bladder through the route of the circulation by medicines administered by the mouth. In some cases, ergot appears to have been efficient in controlling these hemorrhages.

MORBID GROWTHS OF THE BLADDER.

The bladder is subject to myoma, myxoma, sarcoma, and carcinoma, especially the variety known as villous cancer or papilloma; also to tuberculosis. Carcinoma may be primary, but is commonly secondary. The simplest hisioid tumors are not clinically recognizable, one from the other.

Symptoms.—*Carcinoma of the bladder* may be suspected if, in addition to the usual symptoms of cystitis, hemorrhage is copious and persistent, if there is carcinoma elsewhere, and if there is rapidly-developed cachexia, and especially if there are other signs of secondary cancer in the vicinity. Occasionally villi of the papillomatous growth are passed in urine and easily recognized. Unless thus fortunate, the only certain means of diagnosis in the male, though not always to be relied on, is the endoscope, which, in the hands of a skillful manipulator, affords valuable assistance. In the case of the female it is easier and quite as satisfactory to dilate the urethra under ether and explore with the finger, though the endoscope may also be used.

The symptoms of *tuberculosis of the bladder* are those of cystitis, and the recognition of the bacillus of tuberculosis by microscopic examination affords the only sure means of differential diagnosis between it and other forms of inflammation of the bladder. It is, however, relatively easily found when present, especially if the urinary centrifuge is used.

Treatment.—If the diagnosis of villous cancer can be made early, the life of the patient may be prolonged by scraping the bladder, but in my experience the growth returns, sooner or later. In a few instances in which I have had surgeons operate for me in true cancer of the bladder, the result has been unfortunate—the patient perishing soon after the operation. The palliative treatment is that of cystitis. At the same time the counsel of a surgeon should be promptly sought.

The local treatment of tuberculosis of the bladder is that of cystitis. It demands the same general treatment as tuberculosis occurring elsewhere.

SECTION VIII.

CONSTITUTIONAL DISEASES.

RHEUMATISM.

Historical.—The term rheumatism was originally used to indicate morbid conditions associated with mucous discharges (Gr. *ρευμα*, a flux), conditions to which the term catarrh was later applied and for which this term is still used. Rheumatism and gout were originally confounded under the name *ἄρθριτις*, first applied to gout and so used by Hippocrates (B. C. 460-357) and Aretæus (the latter half of first and beginning of second century A. D.). Sydenham (1633) was the first to separate the two conditions and to describe them intelligently.

ACUTE ARTICULAR RHEUMATISM.

(See Infectious Diseases).

MUSCULAR RHEUMATISM.

SYNONYMS—*Rheumatic Myositis; Myalgia.*

Definition.—A painful condition of voluntary muscles and their aponeurotic coverings, especially aggravated by motion and pressure. It affects especially large muscles, such as those of the neck, the shoulders, the arms, the back, the thighs, and the calves of the legs, and the intercostal muscles.

Etiology and Pathology.—Exposure to cold, and especially to drafts of cool air, as from an open door or window, is the most frequent cause. The acute form, at least, does not move about, but persists in the muscles primarily attacked until relieved.

Its true nature is unknown, and whether it is an affection of muscular substance, or of the intermuscular connective tissue, or of the minute branches of sensory nerves distributed throughout the muscles is also unknown. Certain forms of muscular rheumatism, especially that of the back, are ascribed to gout. An infectious origin has been suggested. It is sometimes associated with articular rheumatism, but has probably a different etiology, though like exciting causes operate to produce it. Similar pain often succeeds muscular strain, but it is doubtful if this should be called muscular rheumatism.

The division of muscular rheumatism into *acute* and *chronic* is based upon the duration of the pain and upon its disposition to recurrence. The term chronic is justified by those forms which recur with changes in the weather, and are either excited or relieved by them. It, too, is less localized than the acute. On the other hand, it is not inaptly at times called wandering. It is more common in men than in women, because of their more frequent exposure to its cause.

Symptoms.—The only invariable symptom is *pain*, aggravated by motion or pressure. Sometimes there is *swelling*. It is usually rather sudden in its onset, requiring at most but a few hours, and often less, to develop it. It is never accompanied by marked constitutional disturbance. The *pulse* may be somewhat accelerated, and the *temperature* may approach 100° F. (37.8° C.), but more often there is no fever at all.

Muscular rheumatism is especially named according as it involves special muscles. Thus, *lumbago* is a painful affection of the lumbar muscles and their tendinous attachments. The attacks come on under the conditions already named, but sometimes suddenly without discoverable cause. The suddenness of its occurrence under these circumstances—as, for example, subsequent to a simple twist or stooping—has given rise to the term “kink in the back,” or, among the Germans, to the word *Hexenschuss*, or “witches’ shot.” It has seemed to me that this sudden pain was really a “cramp,” being entirely analogous to the cramps which seize the muscles in other localities. The strain in most cases is altogether too insignificant to cause laceration. As a consequence, the body is at times immovable as in a vice, so excruciating is the pain caused by motion.

Stiff neck, or *torticollis*, is an affection of the side and back of the neck, forcing the patient to hold his neck to one side as the situation of least discomfort, and when he desires to turn his head he is forced to turn the whole body. Sometimes it becomes chronic and is rather difficult to cure. It is more frequently met in children and young adults. *Omalgia* is a similar condition of the muscles of the shoulder and upper arm, making motion exquisitely painful. Ankylosis of the shoulder joint may be caused by delayed motion. *Pleurodynia* affects the intercostal muscles and makes breathing and coughing very painful, while a deep breath becomes impossible and sneezing an agony. The pectoral and serratus muscles may also be involved when the pain is higher up. It occurs more frequently on the left side.

Cephalodynia, or rheumatism of the muscles of the scalp, *scapulodynia*, and *dorsodynia* are all forms of muscular rheumatism which explain themselves. It also affects the *abdominal muscles*, and a most interesting instance of this form simulating peritonitis was published by myself in the “Philadelphia Medical Times,” volume x., 1880.

The duration of the acute form is brief, seldom lasting for more than a few days, though there may be a tendency to relapse. The chronic forms are indefinite in duration.

Diagnosis.—This is easy for the coarser acute forms of *omalgia*, *stiff neck*, and *lumbago*. Muscular rheumatism may, however, be confounded with *neuritis* and *neuralgia*. In muscular rheumatism the pain is more diffuse; in *neuritis* there are pain and tenderness more localized and along the course of large nerve trunks. Muscular rheumatism and *neuritis* are distinctly worse on motion; *neuralgia*, less so. Rheumatism is commonly relieved by the warmth of the bed; *neuritis* may be aggravated, while *neuralgia* is uninfluenced by this cause, while increased by cold winds. *Pleurodynia* is sometimes difficult to distinguish from intercostal *neuralgia*, but attention to the points named will prevent mistakes. *Neuritis of the brachial nerve trunks* resembles *omalgia*, but the former is early followed by atrophy, while muscular rheumatism is not. From *pleurisy*, *pleurodynia* is easily distinguished by the absence of fever and of physical signs. The lancinating pains of *locomotor ataxia* and the pains of *incipient disease of the vertebrae* resemble at first those of *lumbago*, but the special symptoms of these diseases are soon superadded.

Treatment.—The *acute* form of muscular rheumatism is occasionally amenable to treatment by the *salicylates* and *salicin*. Some phenomenally good results sometimes follow the use of these remedies. They are, however, inconstant, and if, after a fair trial, such results are not promptly attained,

the drugs should be omitted. If efficient, the same rules as to their continued use in reduced doses after relief has been obtained apply as in acute articular rheumatism. The group of muscles treated must be placed at *absolute rest*, and in the case of the thorax this is best accomplished by strapping the side with adhesive plaster. Rest may, however, be overdone, and in the case of muscles like those of the shoulder, atrophy may result from too prolonged a rest. Another measure of great value is *dry heat*, applied by means of a hot-water bag covered with flannel, or by a warm flat-iron. To use a popular expression, a muscular rheumatism may thus be sometimes "ironed out." A flannel cloth should be interposed. With these measures may also be associated massage. Sometimes a single efficient treatment by massage is enough to "rub out" such a rheumatism. Of less permanent utility are hot poultices, although they allay pain, at least. The same effect is accomplished by moist hot-air or vapor (steam) baths, which, in special establishments, can be localized.

The chronic form is also treated by massage, passive motion, and electricity, either the induced or direct current. Counterirritation by liniments, such as those made with chloroform, ammonium hydrate, or turpentine, have long enjoyed a reputation, but at the present day it is beginning to be questioned as to whether, after all, it is not the friction, rather than the liniment itself, which produces the good effect. Some efficiency in the liniment itself, I think, must still be admitted, and I would advise its use as determined by circumstances. Acupuncture, consisting in the puncture by needles thrust deeply into the skin, is a measure which has some advocates, especially in the treatment of lumbago. My experience with it is limited. Hydrotherapy is more likely to be useful, and here the warm or cold pack is the better method of application. Dry-cupping is also often of service. Small blisters should not be forgotten.

General treatment should not be neglected: cod-liver oil, iron, strychnin, quinin, and good food are necessary measures when the patient is run down. Among diseases which need nutritious food, chronic muscular rheumatism is pre-eminent.

CHRONIC ARTICULAR RHEUMATISM.

Definition.—A term, often vaguely applied, which should be restricted to chronic inflammatory swelling involving the soft tissues of the joint, not due to sepsis or traumatism.

Etiology.—Occasionally a sequel of acute rheumatism, it is more frequently of independent origin in those subject to prolonged exposure to cold and dampness or to changes in the weather. It is often a sequel of the subacute form, as the subacute is of the acute. On the other hand, it sometimes precedes the acute and subacute forms. It is a disease usually of middle life, and is more frequent among the poor and the working classes.

Morbid Anatomy.—This, superficially, is similar to that of acute rheumatism, but the internal joint changes are more marked. The joint is enlarged chiefly because the capsule and tendons are thickened, as are also the sheaths of the tendons, explaining the difficulty of motion and the stiffness. The cartilages may be involved and eroded in chronic cases. On the other hand, the joint tissues may be unaltered. In protracted cases, especially when there is neuritis, atrophy of the muscles covering the joints

takes place, producing marked deformity. In these cases, too, there may be ankylosis. At other times there is distention of the joint with effusion, the pressure of which upon the muscles themselves or on the vessels leading to them may be responsible for the atrophy.

Symptoms.—These are chiefly *stiffness* and *pain in the joints*, including their muscular and fibrous coverings. The latter pain is characteristically increased on motion, while the stiffness is often diminished by exercise. There may be little swelling, but marked *tenderness* to the touch, though not always. All the symptoms are aggravated by cool and damp weather, and often by other unknown meteorological influences. They are almost invariably improved by warm weather. There is rarely slight fever, nor is the pulse much altered. The stiffness may pass into actual immobility due to ankylosis, and there may be distortions of the joints, as described under morbid anatomy. Cardiac lesions as the direct result of the cause do not occur, but the valves may gradually be sclerosed, and fibroid changes may take place in the muscle.

Diagnosis.—This is not usually difficult. The age of the patient, the family history, the varying amount of the pain, the multiple joint affection, and the large size of the joints involved, the effect of motion, and the slight fever are sufficient to distinguish it from *gout* and *surgical monarthrititis*.

Prognosis.—This, as to cure, is unfavorable, unless the patient can be removed to a warm climate. Generally, in spite of treatment, the symptoms gradually grow worse as the patient ages, though his life is rarely shortened. Yet unaccountable improvement sometimes takes place.

Treatment.—The remedies useful in acute rheumatism are not usually efficient in the chronic form. Occasionally acute exacerbations are relieved by the salicylates. Of drugs sometimes serviceable, the iodid of potassium and bichlorid of mercury may be named. Cod-liver oil, iron, and tonics are often useful by building up the strength of the patient. Guaiacum is a drug which still maintains some reputation in the treatment of chronic rheumatism. It is usually given in the form of the tincture or ammoniated tincture, five to thirty minims (0.3 to 2 c. c.), four times a day, preferably in milk.

Local treatment is more important than internal medication. Counter-irritation by iodine or blisters persistently kept up is sometimes useful. Encasing the joints in red-flannel bandages occasionally gives relief and is a convenient adjuvant. Massage is undoubtedly an efficient measure, though its effects are not always permanent. It is especially useful when there is atrophy of muscles, in which condition it may be combined with electricity and passive motion.

Hot baths, which should always be taken at night, give temporary relief, but in my experience it is not always permanent. Even the systematic baths at the various hot springs, as those of Virginia, Arkansas, St. Catharine's and Banf, in Canada, and elsewhere, which are undoubtedly serviceable, are apt to be followed by relapses. More satisfactory is permanent residence in a warm climate for those who can afford it.

In some of the obstinate forms of this affection, the Tallerman-Sheffield hot dry-air treatment may reasonably be expected to be of service, and should be tried. In this treatment the affected part is exposed to a temperature of 250° to 300° F. (121° to 148.7° C.).

See also treatment of rheumatoid arthritis.

JOINT AFFECTIONS SIMULATING RHEUMATISM.

These include numerous joint inflammations of septic origin, such as occur in septicemia, scarlet fever, diphtheria, and the like. They have all been appropriately referred to when treating of the infectious diseases.

ARTHRITIS DEFORMANS.

SYNONYMS.—*Chronic Rheumatic Arthritis; Rheumatoid Arthritis; Osteoarthritis; Rheumatic Joint.*

Definition.—A deforming disease of the joints, regarded by most authorities as distinct from gout and rheumatism, and characterized by destructive changes in the synovial membranes, cartilages, and bone, and by bony outgrowths restricting the motion of the joint.

Historical.—Sydenham (1633), Musgrave (1763), Haller (1764), and de Sauvages (1768) allude to the characteristic changes in the bone due to arthritis deformans, but the first correct description was read by Landre Beauvais before the Paris Academy of Medicine, August 3, 1820, under the name "Goute Asthénique Primitive." William Heberden, Sr. (1710–1801), of England,* was, however, the first to recognize its true clinical position as something distinct from gout and rheumatism on the terminal finger-joints, since known as Heberden's nodosities. Haygarth's paper on "Nodosity of the Joints," in 1805, describes the disease clinically, and he remarked upon the peculiar liability of its occurrence in the female sex. Robert Smith (1835), R. Adams, and Charcot (1868) contributed to its morbid anatomy; Trastour (1853), Vidal (1853), and Charcot to its clinical aspects. Charcot and Trastour regarded it as a variety of chronic rheumatism, as do Mitchell Bruce of England, and Kahler of Vienna, at the present day. H. W. Fuller (1852) and A. B. Garrod (1859) described the disease accurately as something distinct from gout and rheumatism, basing their views on the absence of the visceral complications of these two diseases. Jonathan Hutchinson and others at the present day still hold that the disease is the product of a blending of gout and rheumatism. J. K. Mitchell suggested a nervous origin for the multiple form, and this idea has been developed by Senator (1877) and R. Wichmann (1890) in Germany, W. M. Ord (1884) and Dyce Duckworth (1884) in England, L. Weber (1884) in America, and others, until at the present day this neurotrophic view seems to be the most popular. Arbuthnot Lane (1891) attaches much importance to mechanical wear and tear in the production of the lesions. Archibald E. Garrod contributed an exhaustive paper to volume ii. of the "Twentieth Century Practice of Medicine," 1895, from which the facts of this historical sketch are mainly drawn. In 1897, James Stewart of Montreal read before the Section on Medicine of the British Medical Association, a paper in which an infectious origin of the disease was supported.

Etiology.—Although in the clinical features of its incipency arthritis sometimes closely resembles the mild form of acute rheumatism, its independence of rheumatism and gout and their causes is generally conceded. Heredity, however, plays a likely, if not an important, rôle. Some relation to gout is still claimed. Thus, the late J. M. DaCosta said rheumatoid arthritis is the form assumed by hereditary gout in the female. Females are much more liable to the disease than males, especially sterile women and those who have had uterine or ovarian disease. A. E. Garrod collected 500 cases, of which 411 were females and only 89 males. It is a disease said to be as common in the rich as in the poor, though I have seen many more of the latter, perhaps because of hospital practice. It usually begins between the ages of twenty and thirty, but it may occur in children under

* "Commentaries on the History and Cure of Diseases" by William Heberden, Sr., a posthumous work, edited by his son, W. Heberden, Jr., was published in English and Latin in London in 1802 by T. Payne. It was arranged in 1782 by the elder Heberden, who was born in 1710 and died in 1801. On page 148 of the English edition appears the short article on "Nodes of the Fingers," in which he says: "They have no connection with the gout, being found in persons who never had it."

twelve and as late as fifty. The beginning of the menstrual period in women is a favorite time for its incipency.

Traumatism, often assigned by the subjects of the disease as a cause, has commonly no well-sustained relation, but must be allowed as a factor in *monarthritic* cases. Exposure, cold, and dietetic errors are ruled out at the present day as exciting causes, yet sometimes it seems impossible to exclude them. Certainly, insufficient food seems to favor the disease. Uterine disease, shock, worry, care, and grief are alleged causes.

Nature of the Disease.—The neurotrophic theory of the disease suggested by the late J. K. Mitchell, and additionally supported by Charcot's studies of the arthropathies, certainly explains the phenomena better than any other. According to this view, there must be allowed a lesion of the spinal cord, either primary or secondary to peripheral irritation, the result of uterine or traumatic disease. The reasons in favor of it are, briefly, the symmetrical distribution of the articular dystrophies in the multiple form, the primary invasion of peripheral joints, and the centripetal extension of the disease; its etiology, the atrophy of muscles, the contractures, the occasional skin dystrophies manifested by pigmentation and local sweating. All these are, however, offset by the absence of anatomical evidence of spinal cord lesion, without which evidence the theory must still be regarded as not proved. The reflex origin of the cord lesion is especially supported by W. M. Ord.*

Morbid Anatomy.—All three of the structures which enter into the formation of the joint share in the process, but the changes probably begin in the cartilages. These consist in a proliferation of the cartilage cells, succeeded by fibrillation of the intercellular substance, which subsequently undergoes mucous degeneration, liquefaction, and absorption. Thus, the bone ends are laid bare. These subsequently become atrophied, smooth, and eburnated. The bone ends and joint cavities are alike distorted; concavities may become convexities, and convexities concavities. The edges of the cartilages, where overlapped by synovial membranes, thicken and form outgrowths, which subsequently ossify and become the osteophytes which contribute to the deformity of the bone, sometimes also forming rims or lips. The effect of the latter is to impair motion without producing actual ankylosis, except in very rare instances, which may include even vertebræ. The synovial membranes also become thickened and the fringes hypertrophied. Effusion is sometimes present in the joints and in the bursæ. Fragments of cartilage may be attached to the tufts, or, becoming detached, they may lie loose in the joint. Muscular atrophy also makes a conspicuous part of the morbid changes.

Symptoms.—If the joint lesions be made the criterion of the presence of arthritis deformans, any remaining difference in symptoms depends mainly upon the grouping and extent of these lesions. Hence it is more convenient to subdivide them into clinical varieties. Two such are easily made:

1. Multiple arthritis deformans, including (*a*) Heberden's nodosities on the small joints and (*b*) the progressive form, in which large joints are successively invaded in an acute or a chronic manner.

2. The monarthritic or partial form, in which one or two joints are alone attacked.

* "Trans. of the Clinical Society," 1879, xliii.

I. MULTIPLE ARTHRITIS DEFORMANS.

(a) **HEBERDEN'S NODOSITIES.**—These are prominences or nodules which develop gradually on the sides and ends of the distal phalanges, especially of the fingers and sometimes also of the toes. Women are the most frequent subjects, and the development begins usually between the thirtieth and fortieth years, and gradually increases with age, but varies also at times and seasons independently of this gradual increase. The pain and tenderness also vary, being usually worse when the hands become cold, and especially when accidentally struck. At other times they are insensitive. These same nodosities occur in gout, and are especially attributed by the laity to gout, but this is an error. They may be considered of probable gouty nature when they are aggravated by errors of diet. They are quite independent of the tophaceous deposits of gout, which are altogether absent in arthritis

Fig. 79.—Heberden's Nodosities.

From a photograph of the hand of a patient of the author.

deformans. Persons in whom they are permanently present rarely have the large joints invaded, and, indeed, are said to have promise of long life. Subcutaneous nodules, similar to those characteristic of acute rheumatism, are also found in rheumatoid arthritis.

(b) **THE PROGRESSIVE FORM.**—This may be acute or chronic. The *acute* form simulates in its beginning a mild form of rheumatic fever in young women of from twenty to thirty years, but it may occur also in children. There are swelling of the joints, tenderness, and fever. These may continue without material change for weeks, or may abate to recur with increased severity; on the whole, however, growing worse, until the permanently enlarged and distorted state to be described is established.

In the *chronic* form the same changes develop more slowly and without fever, maintaining with remarkable constancy a symmetrical order of development, the order of frequency being the hands, knees, feet, ankles, wrists,

elbows, shoulders, jaws, cervical spine, hips, and dorsal spine. The most striking changes are seen in the knees, which become enlarged and so fixed that the legs are constantly flexed on the thighs; and the thighs on the trunk. These *flexions* may be contributed to by *contractures*, which may, however, arise secondarily, subsequent to the flexion, or form *pari passu* with it. They are seen in the upper extremity as well as in the lower, producing the "seal-fin" deflection at the wrist and a rectangular bend at the elbow. The actual *enlargement* is exaggerated in appearance because of wasting of the adjacent muscles and thickening of the capsular ligament. Its surface becomes hard and shining. There may also be some *effusion* in the joint, though the condition has been called by the French *arthrite sèche*. Motion grows more and more difficult, until the joint is almost locked, and grating and crackling attend attempt at motion. *Pain* varies greatly: at times it is very severe, at others it is quiescent, but it is always excited by attempt at motion. *Tingling*, *numbness* of the hands and feet, and *local sweating* and *skin pigmentations* are not uncommon among the early symptoms, and are regarded as trophic in origin. Day by day the patient becomes more helpless and, in the absence of fresh air, wan, weary, and anemic. Fortunately, in many cases the fingers are unencumbered, and the patient may be able to occupy himself or herself in some handiwork, such occupation serving to make more bearable a life of virtual imprisonment. *Weather* has its influences; diet rarely. The condition is singularly free from complications of all kinds.

2. THE PARTIAL OR MONARTHROTIC FORM.

This affects men more frequently than women, and of these, elderly men. The hip-joint is a frequent site, constituting the *morbus coxæ*, or chronic rheumatic arthritis of Adams, whose studies of this subject have added so much to our knowledge of the morbid anatomy. The other joints affected are the knee, the shoulder, and the vertebral articulations. It is often traced, rightly or wrongly, to injury. It is not always unassociated with disease in other joints, as there may be Heberden's nodosities, or the disease may involve in a less degree the corresponding joint on the other side. *Wasting* of the muscles of the buttock and thigh is a conspicuous associated symptom. The *knee-jerk* is commonly increased on the affected side. An interesting, though unusual, symptom, when the hip is affected, is the presence of a large *cyst* at some distance from the joint, ascribed by W. Marrant Baker* to an outflow of the serum from an overfilled joint to a point at which it is restrained by the muscular and other tissues of the part.

Diagnosis.—This is rarely difficult. Arthritis deformans differs widely from *gout* in the total absence of tophaceous deposits, and from *acute rheumatism* in the absence of fever, though in the incipency of the progressive multi-articular form there is a certain resemblance to acute rheumatism, while in the more advanced stage, a stage in which the joint lesions are conspicuous, it resembles also chronic articular rheumatism. This will be appreciated when it is remembered that some regard it as only a further development of chronic rheumatism. The lapse of time may be necessary to determine which it is. The atrophied shoulder of *omoneuritis* also somewhat resembles the monarticular form, but the greater tenderness and painfulness, as well as acuteness, of this affection distinguish it. The arthro-

* "St. Bartholomew's Hospital Reports," 1877, xiii.; 1885, xxi.

pathies attending *locomotor ataxia* and *syringomyelia* are distinguished by the symptoms peculiar to them and by the absence of osteophytes.

Treatment.—This is not generally promising, and the usual remedies for rheumatism are of little avail. Yet treatment is by no means unavailing, especially if instituted early, and we may always hold out to the patient the hope of arrest at some stage. The principle of treatment consists in efforts to *improve nutrition* by means of good food and tonics, of which cod-liver oil, iron, iodine, and arsenic are the most efficient. A systematic course of these remedies, continuous, except so far as judicious intermission may be necessary, will sometimes accomplish surprising results if instituted early and continued perseveringly. The iodid, either in the form of the pill or syrup, is the best preparation of iron. A grain (0.066 gm.) of the former and fifteen minims (1 c. c.) of the latter are suitable doses three times a day. Massage is, perhaps, the single measure calculated to be of most use, and if cod-liver oil and iron be used in connection with it, further benefit may be expected. Disappointing as the treatment often is, in a few cases surprising results may be obtained. One of the most serious drawbacks in certain cases is the difficulty in securing outdoor life and the advantage of exercise. One of the objects of massage must be to substitute the latter, while every possible effort should be made to have the patient in the open air as much as possible, and when his means will permit it, to take advantage of residence in warm but dry climates. It is very important to avoid the use of anodynes altogether, if possible. The relief afforded by them is but temporary, they militate against the effort at securing an improved nutrition, and, above all, there is danger of forming the morphin habit. Simple support by splints is sometimes a comfort to patients. The treatment by *hydrotherapy*, as carried out at Aix-les-Bains and Aix-la-Chapelle in Europe, undoubtedly affords temporary relief. The same may be said of the treatment at the Hot Springs of Arkansas, Virginia, and North Carolina in this country, and at St. Catharine's in Canada. While general steam baths are contra-indicated by reason of their debilitating effect, local vapor baths applied to separate limbs or portions of limbs by a specially constructed apparatus are sometimes useful. Some mention should be made of the electric bath. Like so many remedies, it is often of service at first, but I have yet to see any permanent good results follow its use. It may, however, be tried in cases which have resisted other treatment. The bath should be given under intelligent supervision and the current should be weak at first.

Much was expected first from the hot dry-air or Tallerman-Sheffield treatment of this disease. Temporarily it does produce relief of pain, but I have been unable to learn that any permanent benefit has been secured.

The bowels should receive close attention, the body should be frequently bathed, preferably in warm water, and all measures desirable to secure the most perfect personal hygiene should be practiced. This is another of the few diseases with an abundance of good, nourishing food is necessary. This is the more important when we remember that many cases originate among the poor and badly fed. The use of wine, porter, stout, and ale should be encouraged.

Having a highly intelligent friend afflicted for many years with rheumatoid arthritis whose circumstances permitted him to seek every available means of relief, I asked him to give me the benefit of his experience. He replied in a letter so sensible, and which appeared to me to contain the truth so well condensed, that I append it with the belief that it will be useful.

“ I received no benefit at any of the following places: Aix-les-Bains,* Bourboule, Royat, Wiesbaden, Homburg,* Carlsbad,* Gastein,* Wiltbad,* Acqui,* Montesumano, Richfield (N. Y.), Green Sulphur (Fla.). In all the places marked with an * there were people to all appearances affected similarly to myself who did receive benefit, and at the same time there were others also so afflicted who were made worse. In short, I am convinced from my experience that no physician can definitely settle what spring will be of the greatest service to any patient, and that the only chance of finding this out will be for him to select those which he thinks will be of the most service and let the patient try them in turn. In this way the patient will perhaps find one which will either materially alleviate or absolutely cure him. I found that the mud baths of Battaglia, Italy, did me the most good, but they, at the same time, nearly cost me my life. I am also convinced that rheumatoid arthritis cannot be successfully treated by giving the same remedies to different people suffering from it. There must be variations in our general make-up as there are in our features. In my judgment, therefore, each patient must be a law to himself. He must find out for himself by judicious experiments the food and drink that he can best assimilate, and confine himself to them, even if the usual practice would indicate that they ought to injure him. I also think that no patient ought to take any hot baths anywhere without ample nourishment of some kind, for a depleted diet and terrific perspiration have done me great harm, for it was like ‘burning my candle at both ends.’ My experience has convinced me that careful attention to diet, outdoor exercise, freedom from anxiety, and good digestion are much more serviceable than any springs in the world.”

GOUT.

SYNONYM.—*Podagra*.

Definition.—An acute and chronic constitutional affection, due to an abnormal accumulation of uric acid in the blood and tissues, causing various symptoms, of which arthritis is the most distinctive and significant.

Historical.—With the exception of the classic work of Thomas Sydenham, “*Tractatus de podagrâ et hydrope*,” published in 1683, and based upon his own case, he having been himself a victim for forty years.—the history of our knowledge of gout is the history of the development of its pathology, which begins with Wollaston's discovery in 1797 that the deposits in the joints and vicinity in this disease are largely composed of uric acid. Previous to this time a humoral view of the nature of gout was accepted, though without tangible foundation. In 1784 Cullen promulgated the nervous theory of gout which was adopted from G. E. Stahl. Cullen's theory did not entirely exclude the humoralistic, since he allowed that a morbid substance appeared in the blood of some gouty persons after a time, but as the effect of the disease rather than as its cause. (See also Pathology.)

Etiology.—The tendency to gout is more frequently inherited, but is also acquired. Between 50 and 60 per cent. of all cases of gout can be traced to ancestry, parents or grandparents. More men are gouty than women, and it is the male line through which the tendency is most frequently transmitted. It is not usually manifested until after forty years of age, sometimes later, but the signs which are almost sure to eventuate in gout may show themselves before the twelfth year. While overeating, especially of meats, and intemperate drinking, associated with the luxurious habits which grow out of the possession of wealth, are the most frequent causes of acquired gout, these

last are by no means essential. Sir Dyce Duckworth's studies of gout in what is probably the richest field in the world, London, go to show that many of the peasantry of Ireland, among whom gout is unknown, became gouty after having lived for a time in London. On the other hand, not every person who inherits a tendency to gout becomes gouty, since the fostering causes previously mentioned may be wanting. In others this tendency is so great as not even to require the favoring condition.

While alcohol is an acknowledged cause of gout, it has been observed that something depends on the shape in which it is presented. Malt liquors, especially the "heavy" English ales and beers, strong in alcohol, are more active in the production of gout than the lighter beers consumed in Germany and this country. The same is true of the strong and the sweet wines, of which port and sherry are the type, while pure whisky is less harmful. The glyco-genic substances in the malts and sweet wines are probably responsible as sources of acid fermentation products in the stomach, which, after absorption, reduce the alkalinity of the blood and impair its solvent power over uric acid.

An interesting exciting cause of gout is lead-poisoning. This is seen particularly in England and especially in London, as pointed out by Sir Alfred Garrod in 1854. It is, however, rare in other parts of Great Britain and Ireland, and is growing more infrequent in London; for in 1870, according to Garrod, 33 per cent. of people who suffered from gout had been poisoned by lead, while Sir Dyce Duckworth, up to 1890, found only 18 per cent. in hospital cases. It is a rare cause also in France and Germany. It may be, as suggested by Alexander Haig, that the effect of plumbism is to diminish the alkalinity of the blood. In this country the combination is comparatively rare.

Injuries and blows on susceptible parts, and so slight a cause as pressure by a boot, are often predisposing causes.

Pathogeny.—It cannot be claimed that the pathology of gout is thoroughly established, although so many facts bearing on it are well determined. In this respect it resembles its sometimes congener, diabetes mellitus. It is commonly admitted that uric acid is in some way causative. Whether, however, the uric acid thus responsible is the result of increased formation or diminished excretion, or both, is not so generally acknowledged. As early as 1797 Wollaston showed that the deposits in the joints and vicinity were a compound of uric acid. About 1838 Sir Henry Holland suggested that the peccant material was uric acid in the blood. This was, indeed, suspected by others, but it was not until 1848 that Sir Alfred Garrod furnished the first demonstrative evidence of such accumulation by his well-known thread test.*

Alexander Haig † claims that there is "almost never" an excessive formation of uric acid at any time, and that its accumulation in the blood and body is generally due to retention or failure of excretion; that uric acid is, on the whole, continuously formed in the proportion of 1 to 33 of urea. In certain states of the blood, consisting essentially in increased alkalinity, uric acid is held in solution in larger quantity, constituting uric acidemia. At such times, too, it is eliminated in increased quantity in the urine, by which it is also readily held in solution because of the alkalinity of this secretion. In opposite states of the blood the uric acid is driven out of this fluid and depos-

* This is done as follows: To two drams (3 gm.) of serum from a blister add five or six minims (0.33 to 0.396 gm.) of acetic acid in a watch-glass. A thread immersed in this will in a few hours show an incrustation of uric acid. This reaction is not confined to gout. It occurs in chlorosis and leukemia.

† "Uric Acid as a Factor in the Causation of Disease," by Alexander Haig, London, 1892.

ited in the tissues of the joints. Haig holds, also, that these opposite conditions, which are fluctuations in secretion only, can be artificially produced by drugs, food, temperature, and other conditions influencing the reaction of the blood. Thus, alkalies, alkaline foods, and warm weather favor the former,—i. e., solution,—while acids and cold weather favor precipitation, and it is under influences like these that uric acid in the form of urates is stored up in the body. He further says that the blood never becomes loaded with uric acid except as the result of previous imperfect excretion, and such imperfect excretion or retention is sufficient to account for the largest quantities he has ever seen in the human body, and that it is not necessary to suppose excessive formation in explanation. Further, that he does not assert that such formation never occurs, only that he has never met any conclusive proof of its occurrence, while all the phenomena of disease can be explained without postulating the excessive formation of a single grain.

The ultimate result is, however, the same. Whether it be from diminished excretion or increased formation, or both, there is an accumulation of uric acid in the blood which is responsible, first, for certain premonitory symptoms of gout, and, second, for certain local symptoms. The latter are of an inflammatory nature, and consist essentially of pain, swelling, and redness of the joints, preferably of the smaller ones, and especially of the metatarsophalangeal articulation of the great toe: more frèquently, perhaps, of the left great toe.

As to the relation of the uric acid compounds to the local inflammation, it is scarcely necessary to say that uric acid does not exist in the blood in an uncombined state, even in pathological conditions. The normal urates, as originally shown by Bence Jones, and confirmed by Sir William Roberts, are quadri-urates. Such is the composition of the urate sediments in urine. In the pathological state these are converted into the less soluble biurates, which make up the local deposits. It has all along been considered that these deposits are the direct cause of the gouty inflammations. Haig, as the result of his recent researches, reasserts this view in the following graphic language:*

“Then I also noticed that in curing a headache by giving an acid to diminish the excretion of uric acid, I always produced a certain amount of pricking and shooting pain in my joints (generally in those which had been most used on the day in question), and it naturally occurred to me that the uric acid was held back in these joints and produced the pains. The uric acid which had failed to appear in the urine must have gone somewhere. What more natural than to suppose that it had been retained in the joints (where in gout it is found), and that the pricking pains were the evidence of its presence? Then, on turning to Sir Alfred Garrod, I find that he had described precisely similar joint pains as occurring in gouty subjects immediately after the ingestion of beer or wine, and a very little investigation sufficed to prove that all wines and beers are strongly acid, so that a very simple explanation could be given of the facts.

E. Pfeiffer holds that both gout and gravel are due to the fact that in these conditions uric acid is produced and excreted in a form difficult of solution. As such patients excrete on an average less uric acid, the blood becomes overcharged with it and the uric acid salts are deposited in different parts of the body unnoticed and without symptoms of irritation. Then, according to

* *Op. cit.*, p. 2.

Pfeiffer, the attacks of gout occur when from any cause the alkalinity of the blood becomes so great as to dissolve the deposited urates, which then give rise to irritation and inflammation. Not the precipitated uric acid, therefore, but the dissolved uric acid, according to this view, must be regarded as the irritating agent; while an acute attack is the result of a re-resolution in the blood of previously deposited uric acid, due to an increased alkalescence of the blood and body-juices, while a deposit is the result of diminished alkalescence. Pfeiffer, in further support of this view, calls attention to the fact that the most recent chemical analyses by Lecorché, Ebstein, and himself show that the excretion of uric acid *during* an attack of gout is increased and not diminished, as taught by Garrod. Pfeiffer further cites in support of this view the fact that acids, especially salicylic, in large doses promptly relieve the pain in gout, while it is increased by the administration of alkalis.

The most recent studies on this subject—those of Sir William Roberts *—reaffirm the older view, that the “mechanical theory offers a natural and complete explanation. The crystalline urate precipitated in the cartilaginous and fibrous structures of the joints necessarily act as foreign bodies; they excite irritation, clog the lymph channels, exercise pressure on the tissue elements, and impede their nutritive operations. These effects sufficiently account for the inflammation, pain, and swelling which ensue, and explain the remoter degenerative changes which follow.” While admitting that old tophaceous deposits are not always painful, my experience is that of Sir William Roberts, and, I believe, of most clinicians, that coincident with a fresh deposit of sodium biurates there is always pain, while the salicylates or alkalis are, in my experience, the promptest means to relieve the pain of gout.

Of modern authorities Ebstein † is the most eminent, who ascribes the excess of uric acid in the blood to an abnormal *formation* of this substance in the body, in parts also which do not normally produce it, as bone-marrow and cartilage. The lymph and blood becoming surcharged, a balance is commonly restored by increased renal excretion or perhaps by decomposition of the uric acid. When, however, from any cause the lymph moves slowly, the so-called premonitory *symptoms of gout occur,—viz., a “tired feeling,” vague pains, etc.* If an actual stasis occurs, the acute attack appears. This concentrated solution of uric acid acts like a chemical poison on certain tissues, giving rise to necrobiotic changes, and when these reach a certain stage, characterized by an acid reaction, the uric acid is deposited in them as sodium biurate. If this stage is not reached, the local symptoms disappear and the joints return to their natural state. So much of Ebstein’s view as makes a previously degenerated state of the tissues a necessary condition of the deposit of uric acid is commonly admitted by modern authorities, as represented by Ord and Sir Dyce Duckworth. The nervous theory of gout promulgated by Cullen in 1873 was to the effect that it is a mixed neurohumeral rather than a purely neural disease. Of modern authors, Sir Dyce Duckworth has taken the most pains to elaborate and establish the theory that gout is a neurohumeral disease. The sum of his conclusions may be stated as follows:

The diseased states recognized as of undoubted gouty nature are primarily dependent on a functional disorder of the nervous system, and thus gout is a primary neurosis. This, like others, may be inherited or acquired, modified, or even repressed, and may be associated with other neuroses. A

* “Uric Acid, Gravel, and Gout,” 1892, p. iii.

† “Beiträge zur Lehre von der Harnruhr-Diathese,” 1891.

large part of the symptoms known as gouty is due to perverted relations of uric acid and sodium salts *caused by* the neurosis.

Morbid Anatomy.—As will be further evident in treating the symptomatology of gout, there is scarcely a tissue which may not be affected by it, but the morbid conditions which are more distinctive are, first, the characteristic inflamed great toe of acute gout—the true *podagra*. The angry, swollen, dark-red or mottled appearance of such a toe once seen is not forgotten. Similar though less striking changes are sometimes seen in the metacarpophalangeal articulation of the thumb.

The superficial changes in chronic gout are less distinctive, and are often not different from those of chronic rheumatism. But wherever uratic deposits are present in the tissues, there, by universal consent, is gout. They are found most often in joints and in the parts around them: first, the cartilages of the movable joints, then the ligaments, tendons, bursæ, and, finally, the connective tissue and skin, this being the order of feebleness in vascularity and nutritive activity. Frequent situations are the digital joints and cartilages of the ear; more rarely the cartilages of the nose, the vocal cords, the cornea, kidneys, marrow of bone, and expectoration. Cartilages impregnated with urates present the appearance of being smeared with whitewash or white paint, and when preserved in pure alcohol, maintain it for a long time. Minutely examined, cartilages are infiltrated on the peripheral surface, more rarely beneath, with acicular crystals of sodium urate. Rarely they are found in the bone under the cartilage. The cartilage cells are for the most part free, and after the urates are dissolved out, the tissue appears natural or slightly granular. The tophaceous deposits are the best known and most characteristic lesion of gout. About the digital joints, especially the knuckles of the hands, they sometimes ulcerate through the skin, making the oft-repeated story of the gouty subject who chalked his games of whist with his knuckles a not unlikely one. The deposits are often associated with deflection of the fingers to the ulnar side—"seal-fin" type of hands—and of the toes outward, a late symptom not confined to gout—in fact, more common in rheumatoid arthritis. It is due to stronger action of the abductor muscles.

The nodular gouty tophi are not to be confounded with Heberden's nodosities, also characteristic of rheumatoid arthritis. Indeed, Heberden himself denied their gouty nature, though they do occur in gout also. Their gouty nature must be determined by other symptoms more essential to gout. They are irritable nodular outgrowths on the distal ends of the phalangeal bones. They vary in prominence and tenderness at different times, being worse in gout, especially after errors of diet, but on the whole they slowly increase with the age of the patient and the persistence of other symptoms.

Of undoubted gouty nature are the little vesicles over the nodosities, called "crab's-eye" cysts. To these are to be added certain exostoses and ecchondroses, or "lippings," beneath the synovial membrane, at the edges of the cartilages, and round the heads of the phalanges, and even of larger bones like the femur, patella, and tibia.

Changes in the *internal organs* are most often confined to the kidneys and vascular system. Uratic deposits have been referred to. They are not constant, and are found usually in the interlobular tissue toward the apices, but also more rarely in the tubules. Ultimately the gouty subject acquires an interstitial nephritis, the well-known gouty kidney; though the term "gouty kidney" has also been applied to kidneys the straight tubules of which are found filled with uratic sediments, as is the case sometimes at necropsy.

Arteriosclerosis is almost always present, and must now be ascribed to the xanthin bases, which are toxic while uric acid is not. The heart is hypertrophied in its left ventricle. There may be deposits of urate of sodium on its valves. Changes in the lungs are mainly confined to emphysema, which is found in many cases of long standing.

Symptoms.—*Of Typical Acute Gout.*—Persons subject to attacks of gout sometimes have *premonitory symptoms* suggesting the approach of an attack. These vary with the individual and are significant only in each case. They may be headache, neuralgia, any one of the numerous manifestations of deranged digestion, irregularity of the heart's action, palpitation, high tension of the pulse, depression of spirits, drowsiness, a disposition to yawn, a tired feeling—in fact, any symptom which the patient learns to associate with the attack. Attacks are apparently also invited or determined by anything which lowers the vitality of the patient. On the other hand, a supper with wine or a single glass of champagne will often produce an attack.

The first actual symptom of the typical attack is *articular pain, commonly in the great toe*, at the metacarpo-phalangeal joint, and with its appearance the premonitory symptoms usually pass away. The pain is extremely severe, sharp, shooting, and sudden, often arousing in the middle of the night a patient who has gone to bed apparently well and least expecting an attack. With this pain are the *swelling, heat, and discoloration* already described under morbid anatomy. Rarely, the attack begins with a *slight chill*. On the other hand, there may be pain without heat, redness, or swelling, and all the typical local anatomical features of an attack without pain. In some instances the attack develops more slowly. At times the first attack is so little distinctive that it is assumed to be something much more trifling, such as rheumatism or some slight injury, while the personal peculiarities, natural or acquired, always more or less influence the symptoms. After the outburst at night the extreme pain diminishes as morning advances, but it may recur the next night, and this goes on for four, five, or six days, when the attack terminates.

Some *fever* usually accompanies the onset of acute gout. The temperature promptly rises to 100° F. (37.8° C.), but does not far exceed it, 102° F. (38.9° C.) being the usual maximum attained. As in other acute diseases, the temperature is higher in the evening. The local temperature, notwithstanding the sensation of heat, is five or six degrees below that of the axilla at the same time. The attack terminates with *desquamation* of the epidermis over the inflamed joint.

Changes in the urine are almost distinctive. It is scanty, acid, highly colored, and of high specific gravity. It deposits uric acid and urates on standing, and often contains a small quantity of albumin. It sometimes contains sugar in small or even decided quantity, but I am certain that at other times the reaction of uric acid on copper oxid is mistaken for that of glucose. During or preceding an attack the uric acid excreted may be diminished; later it may be increased, but, as elsewhere stated, a relative increase in uric acid is often mistaken for an absolute increase in the twenty-four-hours' amount. The probabilities are that these changes are inconstant.

A recognized symptom of acute gout, and sometimes the only one, is *pharyngitis*, and now the term "gouty sore throat" is one in common use, though it is doubtless also often used carelessly. There seems no way of distinguishing it locally from other forms of sore throat in which there is no decided swelling.

Gout is said to be *retrocedent* or *metastatic* when it disappears suddenly from its external site and there are substituted for the outward symptoms derangements of some internal organ, especially the *heart* or *stomach* or *brain* or *urinary bladder*. In the first there appear cardiac symptoms of varying severity, including pain, shortness of breath, and irregularity in the heart's action; in the second, gastro-intestinal pain, a sinking sensation, vomiting or diarrhea, often associated with intense mental excitement or depression; in the third, meningeal symptoms; and in the fourth, cystitis and prostatitis. More rare events are gouty orchitis, parotitis, and urticaria, or other fugitive skin affections. Metastasis is more prone to occur in atonic cases. Sudden death has supervened in some instances, but postmortem lesions of a definite kind seem to be wanting, at least lesions which can be held responsible for the symptoms.

Of Irregular or Atypical Gout.—This includes a set of symptoms not so distinctive in themselves as peculiar in this, that they occur only in persons

Fig. 80.—Tophaceous Gout.

Both hands were symmetrically affected, man aged sixty (after Duckworth.)

who have had gout or who have a decided hereditary tendency thereto. These conditions being fulfilled, there is scarcely any superficial or visceral symptom which may not be of gouty origin, but among them may be named cutaneous eruptions, gastro-intestinal disorders, various forms of headache and neuralgia, hot and itching palms and soles, especially at night, a similar condition of the eyeballs, lumbago and other muscular pains, arteriocalillary fibrosis and its consequences, iritis, bronchitis, pericarditis, cystitis with hemorrhage into the bladder, and others.

Some affections of the *teeth* occurring under the same conditions may be regarded as gouty. Such are the so-called *pyorrhœa alveolaris* and "dental erosion."

All that was said of the general physical and chemical characteristics of urine in acute and chronic gout may be true of it in irregular gout.

Among other organs the *eye* in its blood-vessels, retina and optic nerve falls heir to changes which are ascribable to gout, but the same law as to their necessary relation holds, by which I mean that identical conditions occur

which are not due to gout, and the conclusion that they are thus related depends upon a definite knowledge of the previous existence of gout in the patient. An exception to this exists in the rare cases of actual uratic deposits in certain situations, as the cornea, the crystalline lens, vitreous humor, and even the retina.

Many conditions are called gouty on insufficient foundation.

Of Chronic Gout.—As repeated attacks of gout occur and the patient grows older, there gradually accumulate the morbid changes described under morbid anatomy as more or less characteristic—the joints deformed by tophaceous and other deposits, the lipping, the seal-fin hand, the renal and arterio-vascular changes, interstitial nephritis, etc. The urine now is increased, lighter hued, and contains albumin and a few hyaline and granular casts.

Some further allusion should be made to the deformities thus resulting as symptoms of chronic gout. They appear especially in connection with the toes and fingers, causing swellings, deflections, and torsions which produce the most fantastic shapes. Among these are deflected and abducted toes. Heberden's nodosities, the seal-fin hand, and the deformities caused by tophaceous deposits. It is important to remember that any of these except the tophaceous deposits may be due to rheumatoid arthritis as well as gout. Bursal cysts or crabs' eyes on Heberden's nodosities are said to point to their gouty origin. The appended cut from Duckworth illustrates the appearance of enormous tophaceous deposits undoubtedly of gouty origin as contrasted with Heberden's nodosities.

Treatment.—The treatment of gout easily divides itself into two parts: *first*, that of the gouty diathesis; *second*, treatment of the paroxysm or of the acute attack.

I. *Treatment of the gouty diathesis.*—It is plain that we may diminish the quantity of uric acid in two ways: first, by confining the gouty person to such food as produces a minimum of uric acid; second, by administering such medicines as will promote its solution and elimination. The first of these constitutes, in the main, the *dietetic* treatment, the second the *medicinal*.

I. *The Dietetic Treatment.*—This is by far the most efficient of the treatments of gout, without which all else is only palliation. It consists essentially in the elimination, from the dietary, as far as possible, of all *nitrogenous or albuminous* principles, the complete combustion of which results in urea, and the incomplete, in uric acid. I say as far as possible, for it is practically impossible to eliminate them altogether. The foods which are the type of this class should, however, be altogether omitted. Such are the meats of the butcher-shops, the albumen of eggs, and the cheeses. The first include beef, veal, mutton, lamb, and pork, whether salt or fresh, and for the most part fish. As to cheese, as one-half pound of this contains almost as much nitrogenous matter as a pound of beef,—27 per cent. when made of the whole milk, and 28 per cent. when made of skimmed milk,—it is plainly contra-indicated. If we consider only the edible parts of beef,—*i. e.*, meat deprived of the refuse represented by bones, skin, etc.,—it contains according to its source, from 17 to 23 per cent. of proteids; mutton, from 15 to 18 per cent. Of fish, flounder contains 13.8 per cent.; mackerel, 18 per cent.; halibut, 15 per cent.; and salmon, 21 per cent., or quite as much as beef and more than mutton. Salt codfish contains 15 per cent.; smoked her-

ring, 20 per cent.; and canned sardines, 24 per cent. Poultry contains from 14 to 15 per cent. of albuminates, and game 22 per cent. The hen's egg, including albumen and yolk, contains 13.7 per cent. of proteid, whence it is plain that it is a less objectionable food than meat.

On the other hand, milk contains but from 3 per cent. to 4 per cent. of protein; butter, 1 per cent.; and oleomargarine, 0.6 per cent. The fat oyster contains 8 per cent., the lean, 4.2 per cent., and the lobster, 5.5 per cent.; fish other than those previously mentioned, from 5 to 10 per cent.

Of vegetable foods, wheat bread contains 8.9 per cent. of protein; wheat flour, 11 per cent., and Graham flour, 11.7 per cent.; rye bread, 6.7 per cent.; buckwheat flour, the same; corn (maize), 9 per cent.; rice, 7.4 per cent.; sugar, 0.3 per cent.; potatoes, 2 per cent.; sweet potatoes, 1.5 per cent.; turnips and carrots, 1 per cent.; cabbage, 1.9 per cent.; melons, 1 per cent.; apples and pears, 0.4 per cent.; and bananas, 2 per cent. Again, beans contain 23.2 per cent. and oatmeal from 12 to 15 per cent., large proportions of proteids.

Thus, the typical foods permissible from the standpoint of composition are milk, butter, fruits, and succulent vegetables, except beans, and oatmeal. To these oysters and lobster may be added, moderately; fish, except that containing a large amount of protein, and, when extreme rigidity is not required, poultry in moderate amount; but all butcher's meat should be strictly forbidden.

It is usual, also, to inderdict the use of *carbohydrates*,—*i. e.* starches and sugars,—as well as the *hydrocarbons*,—fats and oils,—but I have never been able to see any reason for this. There is absolutely none from the standpoint of chemical composition, since they are totally without nitrogen, and, so far as my own experience goes, none from the clinical standpoint. Only in the event of their producing indigestion and fermentation, with the generation of acids, can they become a cause of gout, and then only, I should say, an exciting cause. I am in the habit, therefore, of permitting the use of rice, potatoes, and other farinacea, and, to a reasonable extent, sugar. I am glad to be able to say that I am sustained in this view by Sir William Roberts, who, in the brochure quoted on page 771, says also: "The most trustworthy experiments indicate that fat, starch, and sugar have not the least direct influence on the production of uric acid, but as the free consumption of these articles naturally operates to restrict the intake of nitrogenous food, their use has indirectly the effect of diminishing the average production of uric acid." Basing his conclusions upon experiments with solutions of blood-serum impregnated with common salt (0.1 per cent.), in which he found the precipitation of crystalline biurate always appreciably hastened, Sir William Roberts for some years past has directed the gouty to restrict, as far as possible, the use of common salt at meals. On the other hand, he recommends that the subjects of uric acid gravel should be advised to take habitually with their meals as much culinary salt as their palates will tolerate.

There are, however, other sorts of ingesta, also entirely or almost free from nitrogen, acknowledged to be both a predisposing and an exciting cause of gout—namely, *malt liquors* and *wines*. These are composed of water, alcohol, carbohydrates, and a trace of mineral matters, but no nitrogen. It is not easy at first to understand why these substances should be harmful. Experience, however, shows that the stronger wines, such as port, Madeira, and sherry, by their continued use, are very likely to produce gout, while the lighter wines,—the clarets, hocks, and Moselle wines,—if taken in modera-

tion, rarely produce it. After these, stout, porter, and the strong ales induce gout. Even lager beer, which contains but 3 per cent. of alcohol, is capable of acting similarly, and I know many men who have been forced to give up this beverage because of this effect. Cider and perry least of all beverages predispose to gout. On the other hand, distilled spirits, especially whisky, are almost entirely without effect in producing gout. Why is this? Apparently, the amount of alcohol is not the measure of the effect, for whisky, gin, brandy, and rum all contain more alcohol than any of the wines named. If reference is made to the wines most likely to produce gout, it will be found that they are those which contain a considerable quantity of both sugar and alcohol. Such are port, sherry, and Madeira, all of which contain more than 15 per cent. of alcohol and much sugar; also sweet champagnes containing 11 per cent. of alcohol. On the other hand, some very sweet wines, as Tokay, Malaga, and the higher Sauternes, which contain much sugar, are said to produce gout less rapidly. It would seem that those liquors which contain alcohol in combination with other substances, especially sugar, are potent in producing gout, particularly when they excite indigestion, *probably by restricting elimination* rather than producing more uric acid.

As to the *acidity* of alcoholic drinks, their influence is pretty clear as exciting causes. In this way act the beers, in which both alcohol and sugar are present in small amount, but which are highly acid. An explanation of this fact is less ready from the standpoint that the acute attack of gout is due to a reabsorption of the deposited uric acid by alkaline blood, than on the supposition that the attack is due to the irritative effect of uric acid deposited in the joints, because of the diminished alkalinity of the blood induced by the absorbed acid. Whatever be the explanation, few facts in the clinical history of gout are better established than that the ingestion of acid may be an exciting cause of attacks.

In the same way act *acid fruits*, such as strawberries, acid oranges, and lemons. On the other hand, to such influence I have known the most divergent response. Thus, a gouty patient of my own could bring on an attack by drinking a single glass of lemonade, while a gouty friend would drink a pitcher of lemonade at dinner without any ill effect whatever. It is to be remembered that the otherwise harmful effects of the strong distilled spirits, such as are well borne in gout, are no less serious in gouty subjects than in others, and are often induced by the careless prescription of whisky because less harmful than wines in gout.

A most valuable adjuvant to the dietetic treatment are the *natural mineral waters*. The waters which have heretofore received almost universal approval are the alkaline and alkaline-saline waters, although those possessing purgative properties also enjoy a good reputation. In America, however, few alkaline waters are native, while those which are, are so far inferior to the foreign waters that they do not serve the purpose. On the other hand the costliness of the foreign waters constitutes a very serious obstacle to their general use. Most of the native waters which have been employed and highly vaunted by their owners are of the kind known as negative waters—that is, they have no mineral ingredients in any quantity to justify their classification in any of the five principal varieties of mineral waters—viz., the alkaline, the saline, alkaline-saline, the purgative and sulphurous—or on which to base any therapeutic results except by their diluent effect. At the same time it has been noticed that these waters are not without effect in relieving gouty symptoms. Reasoning from these facts, we may prescribe such native nega-

tive waters as are accessible to the patient, or distilled water, with this end in view—the simple diluent and solvent effect which comes from an increased proportion of water ingested. The further propriety of such a course is found in the fact that gouty and lithemic patients are often moderate water-drinkers, never drinking water between meals and very little at meals. To such, eight ounces of water ordered on rising, between meals, and at bedtime, will often clear off a dark-hued urine of high specific gravity and substitute a light-hued, clear urine, without any sediment.

The mineral waters which have actually acquired the greatest reputation in the treatment of gout are those of which sodium bicarbonate is the chief ingredient, to which the calcium bicarbonate is regarded a valuable adjuvant. Such are the alkaline waters of Vals and Vichy in France, Evian-les-Bains in Switzerland, Neuenahr and Fachingen in Prussia, Contrexville and Vittel in the Vosges (France), and Dax in France. Other waters possessed of reputation in the treatment of gout, in which the quantity of alkaline bicarbonate is smaller, owe it to their combined alkaline and aperient properties, chiefly due to sodium sulphate and magnesium sulphate, and belong in the second category of remedies for the treatment of gout. Such are the alkaline and saline waters of Carlsbad and Marienbad in Bohemia, Kronthal in Nassau, and Brides-les-Bains in Savoy. Then there are the saline waters represented by Baden Baden, Ems, Homburg, Kissingen, Wiesbaden, and our own Saratoga waters. In saline waters we are much more fortunate in this country, the Saratoga waters furnishing all that can be desired. Finally, there are the bitter acidulated and bitter purgative waters—Hunyadi János, Friedrichshalle and Rakoczy in Hungary, Pülna in Bohemia, and Rubinat in Spain—rarely resorted to for gout, but useful as eliminating agents. Among the weaker aperient waters are those of Bedford Springs, Pa., in this country.

The use of these mineral waters is especially indicated in a continuous manner between the attacks, with a view to averting them. Especially useful are the thermal waters in the chronic arthritic complications, in which their internal use is combined with bathing. In this connection may be mentioned Calrsbad and Marienbad (at both of which the mud-baths are employed). Baden Baden, Ems, Wiesbaden, Hammon R'Irha in Algeria, available in winter, Plombières in the Vosges, and Dax in France. Homburg and Kissingen are also resorted to for their baths, although the waters are cold.

Sulphurous waters also have some reputation in gout. Especially is this the case with the waters of Aix-la-Chapelle in Rhenish Prussia and Aix-les-Bains in Savoy, Harrogate in England, Richfield Springs, Sharon, and St. Catherine's in Canada and Mt. Clemens in Michigan, U. S. A. In all these places the bath treatment is an important adjuvant. America is also more fortunate in sulphur waters.

The remedies in the second category—the aperients—are decidedly useful in gout, both as eliminators of toxic substances, and to prepare the way for the absorption and prompt action of the alkaline bicarbonates. They are not, however, used at the present day so freely as they were a century ago, and they are commonly reserved for the acute attack.

Hygienic measures are also of importance in the treatment of gout. The patient should bathe daily, using the cool bath in the morning or the warm in the evening on retiring, as experience may determine to be the best. The skin should be thoroughly groomed, and daily exercise should be practiced, an open-air, outdoor life being desirable whenever possible.

II. *The Medicinal Treatment and the Treatment of the Acute Attack.*—

As a rule, the use of medicines is reserved for the acute attack. From the earliest history of the disease practice has recognized two classes of remedies in the treatment of gout,—alkalies and purgatives,—the object of both being to eliminate the offender, the first by producing soluble combinations which pass off readily by the kidneys, and the second to carry it off by the bowels. It is plain that a combination of the two principles might be expected to be more efficient than either one alone.

First, as to alkalies and alkaline combinations. My experience places the salicylate of sodium easily at the top, and while it is not so rapid in its effect in relieving the pain of an acute attack of gout as it is in rheumatism, it is nevertheless an invaluable remedy, excelling all others. During an attack it should be given in doses as large as can be borne. As a rule, adult men easily bear fifteen grains (1 gm.) four times a day, or ten grains (0.65 gm.) may be administered every two hours. Even larger doses may be given with advantage, if borne by the stomach. With relief to the acute symptoms the dose should be reduced; but, as in rheumatism, the remedy should not be discontinued, and between attacks smaller doses should be kept up for some time. These, however, may be substituted by the natural mineral waters to be presently alluded to. The efficiency of the salicylates is explained by the fact that their prolonged internal use is attended with an increased elimination of uric acid.

After the salicylates, the alkaine carbonates have always held a high position in the treatment of gout. Half an ounce (15 gm.) a day in divided doses should be the initial treatment, continued, but in smaller doses, when relief comes to the acute symptoms. It may be combined with a little lemon-juice to improve the flavor, or the citrate of potassium may be given in the same doses.

Among the eliminating remedies is the time-honored colchicum, a drug which is of undoubted value in gout, but which, in my experience, must yield the palm to salicylic acid. For a long time its action was inexplicable, and it came to be known as a specific in gout as quinin is in chills and mercury in syphilis. Modern studies have, apparently, solved this problem. Professor Rutherford has shown that it is one of the most powerful cholagogues known. This, taken in connection with what we now know of the office of the liver in urea formation, simplifies very much the solution of the problem. It explains, too, why colchicum produces its sedative and anesthetic effect without necessarily causing purgation. Indeed, some, as Sir Alfred Garrod, consider that its effects are best attained without purgation, and Garrod says that if cathartic action is required, it is better to combine some aperient with the colchicum, as when much purging and vomiting results from colchicum, nervous and vascular depression follows. I confess I like to see a mild action on the bowels by increasing the dose gradually, and it is not necessary to produce either violent purging or vomiting. Whatever its mode of action, it sometimes operates in the most magical manner in relieving pain. The preparation commonly used is the wine. In this country the wine of the seeds is no longer official, so that if the wine is ordered, that of the root is dispensed. This is more powerful than the wine of the seeds. The dose of the latter is from 1-2 to 1 1-2 drams (2 to 6 c. c.) every three hours during the attack, but of the root from fifteen to thirty minims (1 to 2 c. c.), reducing the dose when nausea or purgation ensues. The acetic extract of colchicum was a favorite preparation of the older physicians, especially Scudamore, who introduced it, and who considered its action milder than

that of any other form. It is still sometimes used, and has the advantage that it may be put into pill form. Its dose is from one to two grains (0.065 to 0.13 gm.). Scudamore's gout remedy consisted of magnesium sulphate, four drams (15 gm.); magnesia, eighty grains (5 gm.); vinegar of colchicum, four fluid drams (15 c. c.); syrup of crocus, four fluid drams (15 c. c.); mint water, five fluid ounces (150 c. c.). From one to three tablespoonfuls are given every two hours until from four to six evacuations are produced in twenty-four hours. The fluid extract of colchicum may be administered in doses of from two to six minims (0.12 to 0.30 c. c.).

Colchicin, the active principle of colchicum, is also employed. Its dose is 1-50 grain (0.0013 gm.). The same dose may be employed hypodermically. A favorite modern remedy is the salicylate of colchicin in doses of 5 minims (0.31 c. c.), given in pearls or capsules. The other aperients commonly used in gout are the sulphates, of which magnesium sulphate is the favorite. Sodium sulphate is also used, and it is the constituent of the most actively purgative mineral waters already mentioned, viz., the Hunyadi János, Rakoczy, and Friedrichshalle, now largely used instead of the pure salt. It is also the largest constituent of the Carlsbad waters. A favorite combination of the older physicians was magnesium sulphate two drams, magnesium carbonate a scruple suspended in an ounce of cinnamon water, given two or three times a day until active purgation resulted. These two substances may be combined with colchicum, and with it make one of the forms of Scudamore's mixture, alluded to. Another of the older remedies, also purgative should not be lost sight of. It is Warner's gout cordial, essentially the tincture of rhubarb and senna of the pharmacopeia of the present day.

Colocynth is also employed as an aperient in gout, and advantage has been taken of this fact in the preparation of the secret remedy known as Laville's tincture, which is very largely used by the laity, and which undoubtedly has a very prompt effect in many cases of acute gout. The following has been published* as the composition of Laville's remedy, as determined by analysis:

Quinin,	5	parts.
Cinchonin,	5.	"
Colocynthin,	2.5	"
Lime salts,	5.	"
Water,	82.5	"
Alcohol,	100	"
Port wine,	800	"

The lithium compounds—the carbonate and citrate—have not proved so useful as to cause me to prefer them to salicylic acid. Indeed, the early results of Garrod with them cannot be said to have been realized in modern therapeutics. Sir Dyce Duckworth says of lithia that it is a remedy better adapted to the chronic than to the acute phases of gout, and so I have been using it. Five grains (0.3 gm.) four times a day, freely diluted, is the dose usually administered, and with this the potassium salts are sometimes combined.

Another modern remedy asserted to be efficient in the treatment of gout is *piperazin*. I regret to say that I have been disappointed in it. In my early trials I thought it useful, but soon learned that it was less efficient than the salicylates and colchicum. While an acknowledged solvent for uric acid

* "Druggist's Circular," October, 1889.

when dissolved in water, it seems to be incapable of dissolving uric acid in the system. It still has some stanch adherents, and may be tried. From fifteen to thirty grains (1 to 2 gm.) daily are advised, dissolved in water or in some one of the numerous mineral waters.

Local Applications.—For the relief of the acute attack of gout, leeches, blisters, and cold have all been discontinued of late years, not only because they are useless, but also because their use has been followed by fatal attacks of the so-called internal gout. Warmth and moisture do, however, have a mollifying effect, which is increased if the liquid preparations of opium be associated. Cocain, which might be expected to be useful, operates only through surfaces whence the epiderm is removed. Should such be present, a five per cent. solution may be applied on lint.

It often happens that the pain in a paroxysm of gout is so severe that it is impossible to wait until the effect of the foregoing remedies is secured, and a hypodermic injection of morphin is absolutely necessary to relieve the sufferings of the patient. I must remind the reader, however, that as many old subjects of gout have contracted kidneys, the use of morphin under these circumstances is attended with some danger, and the drug should be used with great caution.

All pressure by boots on joints disposed to gout should be carefully avoided, as well as injuries, as such influences undoubtedly act as predisposing causes. Muscular and mental fatigue are exciting causes of acute attacks, and should be avoided by the gouty.

Treatment of Retrocedent Gout.—The true nature of a metastatic attack having been determined, it must be relieved symptomatically, while efforts to stimulate a true external attack may be made by the hot mustard foot-baths, sinapisms, and the like. It has even been suggested that a pint of champagne may be advised, this being the wine most frequently responsible for acute attacks.

LITHEMIA.

SYNONYMS.—*Uricacidemia; Uricemia; American Gout.*

Definition.—A condition of imperfectly determined anatomical and chemical nature, but probably the result of an accumulation in the blood of partly oxidized products of food metamorphosis, of which uric acid is the type. It differs from gout chiefly in the absence of joint deposits and joint inflammation. In England the name of Murchison is inseparably associated with lithemia, and in this country that of J. M. Da Costa. The former ascribed the accumulation to inactivity of the liver. It has been called American gout, because it has been thought to take in this country the place that gout occupies in England.

Etiology.—The accumulation referred to is the result of intemperate eating and drinking, especially if associated with the lack of exercise sufficient to oxidize the food ingested. In either event the income is greater than the output, accumulation results, and morbid phenomena follow. Heredity also plays a part at times.

Symptoms.—Among symptoms, tolerably constant are manifestations of *indigestion*, including fullness and discomfort after meals, an unpleasant taste, at times nausea, and at others acidity; a tendency to constipation and absence of bile from the discharges; also a tendency to aphthous ulcers in

the cheeks and lips, with punctiform ulcers on the end and sides of the tongue. Extreme *nervous irritability* is also often associated or may be the most striking symptom, while *vertigo* and *headache* are among the most conspicuous and annoying. While vertigo is often associated with a fullness and throbbing, the vertigo and severe headache are rarely associated. A further characteristic is the *slow pulse*, which may beat at the rate of but fifty or sixty times a minute and even less, and exhibits a correspondingly increased tension, with sharp accentuation of the aortic second sound. On the other hand, if the patient be an alcoholic or addicted to tobacco, the first sound of the heart may be feeble. Curious *paresthesias* are also often present, of which *tingling* and a *sense of numbness* are conspicuous. There may be *anesthesia*. In contrast to this *muscular pain*, shooting or aching may occur anywhere in the body. Last, but by no means least, is *depression of spirits*, most inveterate and unpleasant, the patient imagining he is the subject of every known disease, while suicide is sometimes sought for relief.

There is almost invariably *alteration* in the *quality* and *quantity* of the *urine*. It is *scanty*, *highly colored*, of *high specific gravity*, depositing on standing, especially at a slightly lower temperature, a large bulky sediment composed of mixed urates or uric acid or both. In this sediment also are sometimes included oxalate of lime crystals. Yet though almost invariably present, this state of the urine cannot be regarded as essential, and cases occur with the *tout ensemble* of symptoms while the urine is in a natural condition.

Diagnosis.—This hinges very largely upon the condition of the urine, as described, and upon the habits of the patient. It has already been stated that lithemia differs from *gout* in the absence of joint symptoms, but it cannot be denied that the two conditions often occur conjointly. Less frequently, if at all, is lithemia the result of heredity, and it demands as an essential condition the overeating and drinking with defective oxidation referred to, which, while exciting causes of gout, are by no means always necessary to its production, especially when there is a decided hereditary tendency to the same. As intimated in the definition, uricacidemia is rather a condition inferred than actually demonstrated—inferred from the disproportionate amount of uric acid excreted as compared with urea.

Prognosis.—It may be said, too, of lithemia, as distinguished from irregular gout and from gout, that the prognosis is, on the whole, more favorable, and a cure may be generally promised the patient if he comply with the physician's instructions.

Treatment.—The indications are evident. The overeating and overdrinking must be reduced, and active outdoor exercise must be practiced in order to burn up the remnant of unoxidized food. The restriction which would be required depends somewhat upon the severity of the case, but in all instances may be covered by the injunction to the patient to become a vegetarian rather than carnivore. The juicy green vegetables, such as peas, beans, spinach, asparagus, cauliflower, celery, onions, cabbage, lettuce, and an abundance of milk, are allowed. The free use of water, preferably the alkaline mineral waters referred to in treating of gout, and the omission of all alcoholic drinks should be enjoined. A quart (a liter) of Vichy or Vals daily, or in their absence any one of the indifferent mineral waters, with the addition of lithium or sodium carbonate, should be drunk. When urgency is required, a diet of diluted milk or of milk and Vichy may be insisted upon until such symptoms pass away.

Of meats which may be permitted in moderate quantity along with vegetable food are oysters, fish, the white meat of chicken, and game. The question of the carbohydrates is a mooted one. I have never seen such food as rice and potatoes do harm, nor bread—if of good quality and not too freshly baked. Sugar is best restricted, because of its tendency to produce acid fermentations and acidity. There is no chemical contra-indication. Hydrocarbons, on the other hand, are not well borne, and all fats should be forbidden, including butter, as well as the fat of meat.

As to medicines, the most important are the alkalies, which may be added to the negative mineral waters if they are used instead of the more truly alkaline waters. Aperients, and of these again the salines, are especially indicated, and above all the natural mineral purgative waters, such as Saratoga waters in this country, Hunyadi, Friedrichshalle, and the like. Phosphate of sodium is a favorite aperient in these conditions on account of its supposed action upon the liver. The usual dose is one dram (4 gm.) in the morning, on rising, dissolved in hot water. The lithium salts may be used, and while I have not been able to trace any very direct results to their action, they serve as an excuse for the administration of liquids, since they are usually given dissolved in water—say five grains (0.3 gm.) of the carbonate or citrate in a glass of water before meals. Pleasant effervescent tablets containing these doses are now made by many manufacturing chemists. The stomachics and bitter tonics, of which nuxvomica and strychnin are the types, may form useful adjuvants, and pepsin with hydrochloric acid after meals is often useful. The salicylates, if well borne, are useful remedies to hold in solution the uric acid and favor its elimination. Extremely painful attacks may require the use of opiates, but the doses should be as small as possible, and their use should be discouraged under all circumstances excepting in extreme urgency.

DIABETES MELLITUS.

Definition.—A condition characterized by copious secretion of a urine charged with glucose and due to some as yet imperfectly understood derangement of the glycogenic and glyco-destructive functions of the organism.

Historical.—Diabetes is one of the oldest diseases known, being referred to by the Roman Celsus and the Greek Aretæus, both of whom lived in the first century of the Christian era; also by the early East Indian physicians as a condition characterized by copious secretion of urine, extreme thirst, and emaciation. Little, if anything, was, however, added to the subject until the latter part of the seventeenth century, when Thomas Willis (1622-75) in England first inferred from its sweetness the presence of sugar in the urine. Moreover, it was not until a century later, 1775, that Matthew Dobson, also an Englishman, actually obtained sugar from urine. Among other early students of this subject were Cowley (1788), Frank (1794), John Rollo (1797), W. Prout (1825) in England, and Bouchardat and Mialhe in France. Inseparably associated with the subject is Claude Bernard, who first discovered that glycosuria could be produced by puncturing the floor of the fourth ventricle. Since that time there is perhaps no subject in medicine to which has been contributed so much knowledge from an experimental side as this one, and yet no subject as to the true pathology and etiology of which we possess proportionately less accurate information.

Other names associated with the clinical and experimental investigation of diabetes are Brücke, Cantani, Dickinson, Pavy, Ebstein, Frerichs, Külz, Lécorché, von Mehring, Minkowski, Naunyn, Seegen, C. C. von Voiht, Senator, F. Voit, and Carl von Noorden.

Geographical and Racial Distribution.—Diabetes is not a common disease anywhere, and it is variously frequent in different countries and races.

Thus it is less common in the United States than in Europe, where there are said to be from five to nine cases among 100,000 inhabitants, while according to the last United States Census there are but 2.8 in 100,000. According to Dickinson, the disease is more widely prevalent in the agricultural counties of England than in the cities. It is common in Sweden, on the one hand, and in southern Italy and India, especially in Ceylon, on the other, while especially rare statistically in Holland, Russia, and Brazil.

It is much more frequent among Hebrews than among Christians in the experience of almost everyone, yet for what reason I have been unable to discover. One of my Hebrew friends suggested that it is due to the intensification of hereditation by intermarriage. It is rare in the negro race, though I have met several cases. It is a disease especially frequent among the rich and well-to-do, though the poor are not exempt. It is also a disease of adults, yet it has occurred in infants at the breast. In the reports of the Registrar-General of England for the years 1851-60, ten deaths are registered under the age of one year and thirty-two under the age of three. The youngest patient I ever had was a little girl aged twenty-two months, who was delivered prematurely because of nephritis in the mother, though the child was healthy up to one year. Albuminuria was associated with the diabetes. The disease is most frequent between the ages of thirty and sixty. It is more serious in the young, recovery in very young subjects being almost unknown. It is much more frequent in males than in females, in the proportion of nearly three to one, though Senator's* statistics show that under the age of twenty more females are affected than males. This has been my own experience. Little is known of the effect of occupation, though it is thought that occupations taxing the mind favor it. It has happened to me to treat a number of physicians and farmers. Heredity has in my experience been less conspicuous than European writers find it. From 10 to 25 per cent. are thus traced by different Continental observers. On the other hand, it may occur in several members of a family. It is not unusual to find diabetes mellitus in some members of a family and gout in others.

Pathology and Pathogenesis.—The etiology of diabetes is so intimately united with its pathology that it is scarcely possible to separate their consideration. What is known, therefore, of its immediate causation will be developed in connection with the pathology, while its more remote causes will be briefly considered in the ensuing paragraph. Inseparably connected, also, with the pathology of diabetes are the phenomena of sugar formation in the economy. A brief statement of the latter seems, therefore, justifiable. During life there is constantly being produced and stored in the liver of man and the lower animals an amyloid substance, which was named by its discoverer, Claude Bernard, *glycogen*.† Its formula is C_6, H_{10}, O_5 , that of starch, and the term *zoamylin*, or animal starch, was at one time suggested for it. The glycogen formation takes place whether animal or vegetable food be taken, but it is much larger upon a vegetable diet. It is commonly held that it does not occur at all with a diet of pure fats, but Salomon‡ claims that it is produced in the livers of rabbits fed on olive oil. C. von Noorden also considers that fat is converted into sugar in the liver.§ All physiologists agree that this amyloid substance is derived mainly from the

§ Article "Diabetes Mellitus," in "Twentieth Century Practice of Medicine," New York, 1895, vol. ii. p. 42.

starchy and saccharine principles of food, but partly also by a splitting up and rearrangement of the elements of nitrogenous food. This possibly takes place in the liver, resulting in the production of urea and glycogen, the latter being stored in the liver-cells. The muscles are also favorite reservoirs for glycogen storage. The most important property of glycogen is its ready convertibility at the temperature of the body into glucose, or grape-sugar; for this a glycolytic ferment is probably required. By means of these storage reservoirs the blood is kept supplied with 0.12 to 0.18 per cent. of grape-sugar in health, the oxidation of which contributes to the forces of the economy.

In diabetes mellitus some derangement of this balance takes place, as the result of which more or less of the glucose delivered to the blood is not utilized, in a word, is wasted. This may be brought about in several ways: (1) It may be that the glucose arising by a reconversion of the glycogen stored in the liver is contributed to the blood too rapidly to be oxidized; (2) It may be that, although the glucose is delivered in normal quantity, it is still not consumed because of some defect in the oxidizing mechanism, some deficiency in the glycolytic ferment; (3) It may be that the glucose arising from sugar and starch digestion in the intestine is not first converted into glycogen as in health, but passes directly through that organ to the vena cava too rapidly or in too large quantity to be utilized, or lacking some molecular quality which permits its oxidation. One or the other of these alternates will explain all cases of glycosuria when the non-utilized glucose is derived only from the carbohydrates of the food. These are the milder cases and include also those cases of glycosuria clearly traceable to overingestion of sugars and starches. Those bad cases of diabetes, however, which Dr. Pavy calls "composite diabetes," in which the glucose arising from proteid foods, and finally even from proteid tissues, is not utilized, are less easy of explanation. For it would seem that not only is the glucose normally arising unconsumed, but that there is also an increased formation of glucose from these sources, and it may be even from the "fixed proteids" of the body. Whichever of these it is, the excess of sugar thus resulting in the blood is eliminated by the kidneys, and thus glycosuria becomes an essential symptom of diabetes mellitus.

Etiology.—What causes this deranged mechanism? I have already said that there is no disease concerning which so much accurate knowledge has been arrived at and of the true pathology of which we are so thoroughly in the dark. It is not a kidney disease, as was once supposed in its early history, although this impression still prevails among the laity, and naturally so, because the essential evidence of its existence is found in the urine. We know, further, that diabetes occurs under very different circumstances. We can produce diabetes in an animal by irritating the floor of the fourth ventricle, as was originally done by Claude Bernard in his celebrated *piqûre* experiment. There are, however, also other parts of the nervous system, the irritation of which will produce diabetes, from the cerebellum down to the point of emergence of the sympathetic nerves to the viscera. It is commonly admitted that this experimental glycosuria is caused by a centrifugal stimulus from the nervous centers to the liver, through the vasomotor system. We know, also, that tumors impinging on the floor of the fourth ventricle, and lesions of this part of the brain, including abscesses, are attended by diabetes mellitus; also injuries to the spinal cord.

Relatively remote from the nervous centers is an organ, the pancreas,

the diseases of which are often associated with diabetes mellitus, and whose extirpation is followed by glycosuria. On the other hand, we know that in a large number of the gravest forms of diabetes autopsies have failed to disclose any lesion whatever; in fact, the most unmanageable and serious cases are those in which we find no lesion. Therefore, while we must admit that both the nervous system and the pancreas have something to do with the causation of diabetes, we are not able to trace a nervous or pancreatic lesion in every case. It is further likely that the sympathetic nerve is an important channel for nervous influence, regulating as it does the opening and the closing of the blood-vessels.

A word more as to the relation of the pancreas to diabetes. I have said such relation is proved from the experimental as well as from the clinical side, and I myself, in a few cases at autopsies, have found a pancreatic lesion. Hanseman claim pancreatic lesions in 50 per cent. of cases. From the experimental side it is found by von Mehring and Minkowski that extirpation of the pancreas is immediately followed by diabetes; and, although there are some differences in results, it is one of the best determined facts that glycosuria follows such extirpation. Sometimes such a diabetes has been transient, but then it has been found also that a fragment of the pancreas was left behind. I repeat that while we must admit that the pancreas has something to do with a large number of cases of diabetes, we cannot say so of all, as there are some in which no lesion is found.

The rationale of this relation of the pancreas is not settled. It has been alleged that the absence of the pancreatic secretion is responsible, but it has been shown that simply cutting off the secretion from the intestine does not cause diabetes. It has been suggested that extirpation of the pancreas really operates by disturbing the sympathetic nerves in the vicinity; but this has also been experimentally refuted, and, with this, the view of Klebs, accepted by Senator, that the coexistence of diabetes mellitus and disease of the pancreas is primarily or secondarily due to lesions of the celiac plexus. The researches of Lepine, which have been confirmed, ascribe the glycosuria to the absence of a glycolytic ferment furnished in health by the pancreas to the blood. This explanation certainly accounts for the facts. It is evident that it is impossible to explain all cases of diabetes from any one standpoint to the exclusion of another.

An important relation has recently been established between the suprarenal gland and glycosuria, by the studies of Blum,* Herter, and Croftan. The first showed that glycosuria ensued upon the subcutaneous injections of animals with freshly prepared suprarenal extract, even when the diet was free of carbohydrates. This was confirmed by G. Suelzer † and A. C. Croftan.‡ Reasoning thence Croftan announced that the suprarenal capsules contain a substance which either causes the formations of sugar or inhibits the normal destruction of sugar.

Herter § does not accept Croftan's conclusion, but concludes rather that many and perhaps most forms of glycosuria and diabetes are due to the action of substances or conditions which interfere with normal oxidation in the cells of the pancreas. He adduces in proof, the fact shown by himself that

§ With A. N. Richards, "Preliminary Communication," *Med. News.* February 1, 1902. Also "Experimental Glycosuria from Adrenalin Chlorid and its Relations to other Forms of Glycosuria, Dependent on the Action of Reducing Substances on the Cells of the Pancreas," *Trans. Assoc. Amer. Physicians.*, 1902.

glycosuria results from subcutaneous injection of adrenalin chlorid, and moreover that painting the pancreas with the same solution is followed by a transitory glycosuria with corresponding glycemia, while no such effect follows a similar application to the liver or spleen; while after adrenalin chlorid undergoes oxidation it loses its ability, when thus applied, to cause glycosuria. Thus is laid at the door of the suprarenal capsule interference with the cell activities in the pancreas which are concerned with the production of an oxidizing enzyme whose function it is to oxidize glucose. Closer than this we have been unable to come. Deranged suprarenal function is of course not the only cause which interferes with the normal function of the pancreas.

Any agency, direct or reflected, which is capable of influencing normal cell activity of the pancreas may become a cause of diabetes. Hence a variety of causes, some of which seem but remotely connected with the disease, may operate to cause diabetes. In illustrations of traumatic agency by which the pancreas is indirectly affected I may refer to cases of movable kidney causing pancreatic diabetes, cured by nephropexie reported by Sherman Thompson Brown.* As instances of such influence may be mentioned the rare instances of diabetes associated with pregnancy. Operating through the nervous system, in addition to nervous lesions already named, may be worry, gastro-intestinal derangements, disorders of the liver, sexual excesses and the like. Among more remote causes recently suggested are toxic agencies introduced from without or originating in the alimentary canal, such, as instanced by Williamson,† may be the explanation of many cases otherwise unaccountable.

Morbid Anatomy.—Diabetes can hardly be said to have an essential morbid anatomy, for, except in the instances mentioned, the morbid lesions which are found after postmortem examination to have been associated with diabetes are, in the main, such as are the consequence of the continued presence of the condition, rather than such as cause the symptoms. Sometimes there are absolutely no alterations discoverable, either by the unaided eye or with the microscope.

To begin with the organ which has so much to do with the glycogenic function of the body,—*the liver*,—it frequently presents the appearances of a hyperemic organ—that is, it is darker and harder than the normal organ, while it is also enlarged, sometimes considerably, at other times only slightly. Corresponding to this, the microscope, by very moderate amplification, shows enlarged and distinct acini, with capillaries dilated and distended in various degree with blood. Higher magnifying powers—300 to 400 diameters—show the liver-cells to be enlarged, distinctly nucleated, rounded, and disposed to fuse. If a weak solution of iodine is added, they may strike a wine-red color, which, according to Rindfleisch, is confined to the nucleus; but, according to Senator, may extend to the whole of the cell. Klebs ascribes this reaction to postmortem changes in the glycogenic substance. The minute changes described are said by Rindfleisch to be more striking in the peripheral zone of the lobule than in that of the portal vein, while the intermediate zone, or that of the hepatic artery, is fatty, and the central part, including the rootlets of the hepatic vein, is nearly normal. Incidental morbid states are hypertrophic cirrhosis and atrophic cirrhosis. An interesting fact in this connection is that the most serious organic disease of the liver appears never to cause glycosuria.

* "Philadelphia Medical Journal," April 4, 1902.

† "The Practitioner," July, 1900.

As to the *pancreas*, about which so much has already been said, it may be well to mention the changes found at different times. They include calculi found in the pancreas of a diabetic as early as 1778 by T. Cowley, cancer by Bright at a comparatively early date and atrophy by Griesinger, who had found the pancreas atrophied in one of the five diabetics whose bodies he examined after death, yet believed that this lesion was of no significance whatever. But the observations which have been published in great numbers (Hartsen, Fles, von Recklinghausen, Frerichs, Klebs, Harnock, Külz, Schaper, Lancereaux, Senator, and others) allow us to assume that diseases of the pancreas are present in about one-half of all the cases of diabetes. The statement of Senator* that this organ "is found diseased with surprising frequency, in particular either atrophied or, in addition, degenerated," is in the main correct. Among nine cases Frerichs saw atrophy or fatty degeneration of the gland five times, and in the Vienna dead-house the pancreas was found strikingly small, soft, and anemic in thirteen out of thirty diabetics (Seegen). Other coincident diseases of the pancreas already mentioned are cancer and impacted calculus. Reference should not be omitted to the important work of Eugene L. Opie, who has shown minute changes in the island of Langerhaus in certain cases of diabetes mellitus.†

The kidneys, primarily unaffected, are in many cases sooner or later influenced by the constant hyperemia to which they are subjected in eliminating the sugar. The appearances commonly met are those of hyperemia and overgrowth of epithelium—in a word, those of catarrhal nephritis. Occasionally the changes are more advanced, and the epithelium is fatty. More rarely granular contracted kidney is present, contributing a more serious significance to the albuminuria. These changes are not necessarily attended by albuminuria previous to death. In most other cases I believe nephritis to be an accidental coincidence. There occurs also sometimes a vesicular swelling of the epithelium in the straight tubes, hyaline changes in the descending limb of Henle's loop, as well as a hyaline change in the vessels of the Malpighian tubes. As to the proportion of cases in which the kidneys reveal morbid alterations, it is a decided majority.

The *lungs* are often the seat of tubercular deposits and cavities resulting from their softening; also of bronchopneumonia and croupous pneumonia, which may terminate in gangrene. The *heart* is sometimes hypertrophied.

Symptoms.—Almost invariably the earliest symptoms noticed by the diabetic are *thirst* and *polyuria*. One or the other of the two may be noticed first, or the patient's attention may be called to both simultaneously. It occasionally happens that a *dryness of the fauces* and a glutinous *viscid* character of the *saliva* attract attention before any other symptom. Sometimes it is observed that a drop of urine falling upon the boots or clothing and evaporating there, leaves a persistent white or yellowish spot due to sugar. *Dryness and harshness of the skin*, due to absence of perspiration, soon make their appearance and early attract the attention of those who ordinarily perspire freely, and occasion varying amounts of discomfort. *Itching of the skin* is also sometimes present. The *temperature* of the body is not increased, at this stage scarcely altered, although later in the disease it may be decidedly lowered. If the further progress of the disease is not arrested, a *voracious*

* Senator, *loc. cit.*, p. 837.

appetite becomes the next symptom, notwithstanding which the patient observes that he slowly *loses in weight* and grows daily *weaker*. Extreme *languor* and *weakness* are characteristic. The rapidity with which these symptoms succeed one another varies. Sometimes the course is very rapid, constituting an acute form; at other times the successive stages are exceedingly slow in developing chronic diabetes.

Boils and *carbuncles* in the skin are also of frequent occurrence, favored by the malnutrition growing out of diabetes, and the former are occasionally the first symptoms recognized. The latter never occur early, but, when present, are frequently the immediate cause of death.

Gangrene of various parts of the body is another of this class of symptoms. It is sometimes spontaneous, but more frequently is immediately caused by some trifling injury which, under other circumstances, would be without result. It has been known to start from a blister and from the cutting of a corn. Beginning most frequently in those parts of the body most remote from the center of the circulation, as the toes, its progress and appearances are like those of senile gangrene. Sometimes, however, the gangrene is moist.

Eczema, with itching and burning of the labia and vicinity, is a frequent and troublesome symptom in women incident to the extremely frequent micturition. In the male the meatus urinarius is sometimes the seat of a similar irritation. Eczema elsewhere, as on the palms of the hands, is also a symptom.

The early *loss of sexual desire* is characteristic.

Dyspeptic symptoms may appear at various stages, seldom very early. Acid eructations, flatulence, and epigastric pain, or an indescribable sensation described as "sinking" of the epigastrium, are among them. *Constipation* is sometimes a very troublesome symptom, and adds, in my experience, to the seriousness of the case; on the other hand, diarrhea is occasionally present.

The foregoing category includes all the symptoms which present themselves in the milder form of the disease. But unless averted, all these symptoms become intensified. The patient complains of constant burning thirst, is continually urinating, and as constantly drinking water to quench his thirst, and, while often eating enormously, grows emaciated, although at the onset of the disease he may have been a robust, vigorous man.

As the disease advances there is a peculiar vinous or *acetous* odor of the breath, which has been compared to that of stale beer, and by Sir Thomas Watson to the odor of a place in which apples are kept. This is believed to be due to acetone and diacetic acid, both of which exist in the blood of severe cases of diabetes.

Later, cough often sets in, owing to bronchitis and tubercular phthisis, and, with the copious expectoration incident to them, adds to the debilitating agencies already at work. Roberts thinks phthisis occurs in one-half the cases. I am sure not so many die of it in this country. C. von Noorden says one-fourth of all diabetic subjects in Germany have the disease, and Lancereaux, that victims of pancreatic diabetes are especially prone to tuberculosis. The consumption thus induced sometimes rapidly hastens the fatal termination, while at other times it appears to have but a trifling influence in this respect. The other symptoms characteristic of pulmonary consumption are also present, not excepting hectic sweats. The perspiration thus arising may contain sugar.

Diabetic coma, first described by Kussmaul in 1874, is a form of coma which often comes on in advanced stages of diabetes and almost as often ter-

minates in death. The condition is one of suddenly or gradually supervening unconsciousness, with or without previous irritability or uneasiness, anxiety, vertigo, or symptoms resembling alcoholic intoxication. Sometimes it is preceded by obstinate constipation or intestinal catarrh or severe colicky and muscular pain. Convulsions do not occur, but the eyes are half open, the pupils dilated, and the eyeballs wandering. In addition to coma there are frequent and feeble pulse, deep inspiration, with short expiration, more or less frequent than in health, and gradually invading cyanosis. The temperature, at first slightly elevated, is subsequently subnormal. The condition lasts for from twenty-four to forty-eight hours, when death usually supervenes. Over one-half of all deaths in diabetes are ascribed to diabetic coma by Frerichs, but others assign a much smaller number to it. The odor of acetone may issue with the breath. The coma has been variously ascribed to acetone and diacetic acid, to oxybutyric acid, and by Professor Saunders and D. J. Hamilton * to slow carbonic acid poisoning due to fat embolism of the pulmonary vessels, the result of lipemia. All views are speculative. Acetone and diacetic acid are very often present for a long time, and yet no diabetic coma supervenes. There would seem to be better reason for ascribing the condition to "acid intoxication," as held by Stadelmann and Minkowski, since the continued presence of oxybutyric acid is always followed, sooner or later, by coma unless the patient dies from some other cause. Diabetic coma must not be confounded with other forms of coma which may occur in diabetes, as true apoplexy and uremia.

More Unusual Symptoms.—The previously recorded symptoms occur sooner or later in most cases, the thirst and saccharine polyuria being essential. There are many others which occur more or less frequently, but not constantly. Among the rarer symptoms is *cataract*, the association of which with diabetes was long ago noticed by Prout. It develops rapidly and is nearly always symmetrical, involving both eyes simultaneously, but not to the same degree. It is sometimes a very nice point to determine whether cataract is due to diabetes or to the usual causes. The earlier the age at which it occurs, the more probably is it due to diabetes.

Other visual defects may occur. Among these are myopia, amblyopia, presbyopia, and loss of accommodating power from defect of the ciliary muscle. George E. de Schweinitz informs me that a sudden development of myopia between the fortieth and sixtieth years without apparent lesion is characteristic of diabetes. It may be due to a fine edema of the choroid, or a choroiditis which in turn determines an elongation of the axis of the eyeball and thus produces myopia.

The ophthalmoscope may reveal dilatation of the *retinal* vessels. The late Albert G. Heyl † described a condition which he called *intra-ocular lipemia*, in which the light salmon color of the blood contained in the branches of the retinal vein and artery contrasted with the cinnabar-red of the vein and yellow-red of the artery, also by the greater width of these vessels and the lighter yellow of the fundus. Finally, *atrophy of the retina* and hemorrhagic and inflammatory affections of the eye have been described, and total blindness has been ascribed to the first named.‡ *Derangements* of other *special senses* said to attend diabetes are impairment of hearing, roaring in the ears, and derangement of smell and taste.

A *spongy* state of the *gums*, with recession and excavation, is an occa-

‡ Dufresne, "De l' Amblyopie Diabétique," "Gaz. Heb.," November, 1861.

sional symptom, resulting in extreme cases in absorption of the alveolar processes and falling-out of the teeth.

Severe *neuritis* in the brachial and crural nerves is not infrequent. In grave cases the *tendon reflexes* are diminished or absent. *Unilateral sweating* has been observed. Senator refers to three cases—two of the left half of the face and one of the right. *Edema* sometimes appears late in the disease, and is not necessarily the result of renal complication.

Alterations in the Blood.—It has already been mentioned that in diabetes the blood becomes highly charged with glucose, which increases from a normal of 0.05 to 0.15 per cent. to 0.2, and in extreme cases to 0.57, per cent. and from this abnormal glycemia comes glycosuria. From the presence of the first we should naturally expect a higher specific gravity of the blood-serum, which has been found as high as 1033, as contrasted with the normal 1028. On the other hand, the serum has been found thinner than normal, containing, according to different analyses, from 80.2 to 84.8 of water instead of the normal 78 to 79 per cent. The red blood discs are often diminished, and the alkalinity of the blood is also lowered. As such diminution is at a maximum when oxybutyric acid is being excreted, it has been ascribed to this substance.

An abnormal amount of fat in the blood, producing the technical lipemia, was observed by the earliest students of diabetes, and is attested by many analyses, as well as by the milky appearance of the serum and the intra-ocular appearances described by Albert G. Heyl. The analyses of Simon show from 2 to 2.4 per cent. instead of the normal 1.6 to 1.9 per cent.

Changes in the Urine.—The peculiarity of diabetic urine most noticeable to the patient is its enormous quantity, which has been known to exceed seventy pounds (31.78 kilos) in twenty-four hours, while apocryhal accounts of larger amounts are extant. Frank records 52 pounds (23.6 kilos); Bardsley* 36 pints (20.4 liters) and 32 pints (18.6 liters); Bence Jones found 56 pints (31.78 liters); Sir Thomas Watson and Dr. Dickinson 26 pints (14.77 liters), and Dr. Pavy 32 pints (18.16 liters). From 70 to 100 ounces (2100 to 3000 c. c.) are frequent quantities. The quantity of urine passed is limited by the amount of fluid ingested, for while it is possible that the amount of the former secreted may exceed for a very short period the quantity of the latter ingested, it is evident that this cannot continue for any length of time, and, in point of fact, it is found to be almost invariably a little less, the remainder being removed by the lungs, skin, and bowels. It is said that in health the lungs exhale fully one-fourth as much water as the kidneys secrete. Should it be proven that cases do occur in which the amount of water secreted exceeds that ingested by the mouth for any considerable period, it must then be admitted that absorption of water from the air by the skin is possible. On the other hand, it was early observed by Th. Cowley † (1788) that the quantity of water occasionally is not at all or but slightly increased. To this condition Frank, ‡ another old author, gave the name of *diabetes decipiens*. It is well known, also, that intercurrent diseases, especially febrile affections, sometimes diminish the quantity of urine as well as the amount of sugar excreted; while the same diminution of urine and sugar also occasionally occurs toward the fatal termination of the disease.

* Bardsley, article on "Diabetes" in the "Cyclopedia of Prac. Med.," Philadelphia, 1845, p. 607.

‡ J. P. Frank, "De Curandis Hom. Morbis Epitome," lib. v., "De Profluviis," Pars 1, Manheimii,

But the most important change is, of course, the presence of *glucose*. Of this, the quantity varies greatly in different cases and at different times in the same case. Every case of trifling and temporary glycosuria should not, however, be considered a case of diabetes. The sugar should be easily recognizable by the ordinary tests and should be constant. From what may be indicated as "evident traces" the proportion of sugar may reach, it is said, as much as 15 per cent. I have never found more than 10 per cent., though I often hear reports of the finding of larger quantities which I can scarcely credit. The twenty-four-hours' quantity varies similarly. The maximum quantity secreted in this time appears to be that reported by Dickinson, wherein a man twenty-five years of age voided 50 ounces (1500 gm.) of glucose in twenty-four hours. But the more usual quantity is from 10 to 80 milligrams to the cubic centimeter, or from 20 to 25 gm. in twenty-four hours; this corresponds nearly to from 5 to 30 grains to the fluid ounce of the English system, or from 300 to 3800 grains in the twenty-four hours.

The effect of muscular exercise in diminishing the quantity of sugar in the urine of diabetics was early confirmed by K ulz and others, while it is scarcely necessary to say that accidental as well as intentional changes in diet are followed by consequent variations. So, too, urine passed after fasting, as on rising in the morning, contains generally less sugar than that passed after a meal, and in the clinical study of cases of diabetes, where a part of the twenty-four hours' urine is not obtainable, it is important to bear this in mind. As the difficulties in obtaining a part of the twenty-four hours' urine regularly are very great, it is often preferable, in my experience, to take for examination two samples, one passed in the morning on rising, and representing the fasting urine, and another on going to bed, representing the day urine.

Consistently with the increased solid matter thus added, the *specific gravity* of diabetic urine is, as a rule, high, 1040 being very common, while Bouchardat found it as high as 1074 in one instance. The well-known disposition of diabetic urine to become *frothy* on shaking, and to maintain this frothy condition, is a natural physical result of its increased density. Urine may, however, have a low specific gravity and yet contain sugar. I have found it as low as 1010 and lower. Such low specific gravities of glucose, if present in any decided degree, must depend on the low proportion of other normal ingredients. Sugar sometimes disappears very rapidly from urine by fermentation, thus reducing also the specific gravity.

Concurrent with the increase in quantity of urine is an *absence of color*, which in extreme degrees is almost total, so that the urine may be as clear as spring-water. Almost all diabetic urine, sooner or later after exposure at a moderate temperature, becomes *cloudy* from the development of fungi coincident with fermentation. The *odor* of the urine is usually normal when first passed, but sooner or later, in consequence of fermentation setting up, it may acquire an acetous odor. The latter change also increases the degree of the normal acid reaction and maintains it much longer after exposure to the air than is the case with normal urine. This acetous odor is ascribed to acetone and diacetic acid. The urine may have a sweetish odor when passed, which has been compared to "sweet brier." Diabetic urine is sometimes quite free from *sediment*. At other times there is a copious sediment of uric acid. In the sediment may also be included the *penicillium* fungus, common to acid urine, as well as the more characteristic yeast or sugar fungus, or the *torula cervisiae*. This also sometimes appears as a *mold* on the surface of the urine.

Of the normal chemical constituents of the urine, *urea* is almost invari-

ably increased. This is contributed to by two causes. The first is the ingestion of large amounts of nitrogenous food, whether to appease the appetite or by the physician's advice. The second cause is the destruction of the tissues themselves which characterizes the severest cases in the last stages in spite of the enormous food consumption. In such event the nitrogenous tissues are split up into urea and sugar.

As regards *uric acid*, it is either normal or slightly increased. Of the other constituents of the urine, creatinin is increased; sulphuric acid is subject to its normal variations; chlorin, phosphoric acid, lime, and magnesia are said to be increased; phosphoric acid and lime especially so. Ammonia is sometimes largely increased.

Of *abnormal* constituents, albumin is often present—perhaps in one-third of all cases; some make it a larger proportion, some less. The albuminuria is not generally larger and, in my experience, is not often a serious symptom. Albuminuria does not necessarily imply renal change. It is scarcely necessary to say that the urine may become albuminous from any of the causes of albuminuria independent of diabetes, as pus from pyelitis, cystitis, etc.

Inosit, or muscle-sugar, occasionally replaces the grape-sugar in diabetes, but more frequently accompanies it. Gallois* found it in five out of thirty-five diabetics.

Finally, *acetone*, *diacetic acid*, and *beta-oxybutyric acid* are all frequently met in diabetic urine. It is now conceded that the source of these substances is albumin either of the food or body tissues, diacetic or acetoacetic acid being probably first formed and rapidly transformed into acetone. When but little diacetic acid is produced, it is all converted into acetone; when much is formed, both substances appear in the urine. The conversion takes place mainly in the urine, but doubtless also in the tissues or the blood, since acetone may be present in the expired air. To acetone is ascribed the vinous odor sometimes present in the urine. Acetone is produced in health in a slight amount in the normal decomposition of albumin, freely in certain diseases other than diabetes. According to von Noorden, these substances are formed in the disintegration of the albumin of the body and not of the food—in a word, when the patient is “consuming his own proteids.”

Beta-oxybutyric acid is believed by many to be the first stage in the formation of diacetic acid. Von Noorden also thinks this possible, but he claims for it a certain “clinical independence,” and considers it probable that oxybutyric acid, on the one hand, and aceto-acetic acid, on the other, arise from qualitatively different disintegration processes. While acetone in the urine does not add to the seriousness of diabetes, the presence of oxybutyric acid is of the gravest prognostic significance. It is said never to disappear permanently after being once present, and to be almost always followed in a few days or weeks by diabetic coma and death. Diacetic acid has an intermediate significance between acetone and beta-oxybutyric acid.

Of the other secretions, the *perspiration*, when present, frequently contains sugar, at times a notable amount, as much as 6 1-2 grains (0.42 gm.) having been extracted by Fletcher from a piece of flannel, three inches square, which had lain upon the skin of a diabetic patient for forty-eight hours. The *saliva* has rarely been found to contain sugar independently of that which it acquires from the food. That the *gastric juice* ever contains it

* Gallois, “Comptes Rendues,” 1, p. 533; also “De l'Inosurie,” Paris, 1864.

under similar conditions is disputed, but it has been found in effusions and exudations, as might be expected.

Duration.—Though the course of a few cases of diabetes is so rapid as to justify the name acute, the number of these cases is not sufficient to justify a classification into acute and chronic. In such rapid cases death has taken place at periods ranging from two days to six weeks, yet in no instance can it be averred that the disease was of as short duration as it seemed, since it may have existed some time before it was discovered, while in several it was evidently of longer duration. It is true, therefore, that diabetes mellitus is a disease almost invariably of long duration. Cases of fifteen, eighteen, and twenty years' duration are reported. I have had a number of cases under my care for more than ten years. The younger the subject, the shorter the duration and the more promptly fatal the result, while after middle age, under treatment, the duration may be indefinite.

Diabetes mellitus is sometimes distinctly intermittent for a time, regardless of treatment. I was for a long time incredulous on this subject, but recent experience has taught me that such a form of diabetes occurs, in which both polyuria and glycosuria may disappear without treatment, to recur again. Such cases are, however, easily controlled by treatment when discovered, while they are as certain to pass over into the permanent form if neglected.

Complications.—The diabetic is characteristically subject to complications, which may be accounted for in a word by his diminished power of resistance to all disease-causing agencies and to the toxic influences incident to the disease itself. Most of these have already been considered among symptoms. Such are the numerous skin affections, gastro-intestinal disturbances, pancreatic and renal affections, functional cardiac and nervous symptoms, including neuritis and diabetic coma. *Tuberculosis* has also been mentioned. It is especially apt to attack young subjects and to cause their death. *Arteriosclerosis* is prone to occur in diabetics, with its full train of consequences, and to appear earlier in life among them. *Jaundice* sometimes occurs, and having presented itself twice in the history of a case under my observation, can hardly be considered accidental. Senator says that, when not an accidental complication due to a catarrh of the duodenum, it may result from compression of the biliary capillaries by the overloaded blood-vessels or enlarged gland-cells of the liver.*

Gout and diabetes are sometimes associated, and an interesting and important fact has been learned from this association, viz.: that cases of diabetes complicated with gout are always mild cases and easily controlled. Sometimes the symptoms of gout and diabetes alternate. That is, when the glycosuria appears the gouty symptoms subside and *vice versa*. These cases are apt to be associated with arteriosclerosis and death from apoplexy may ensue.

Diagnosis.—The diagnosis of diabetes mellitus is very easy, yet I have known it to be long overlooked by the practitioner. Unnatural thirst and copious diuresis should always suggest a chemical examination of the urine, and although there are sources of error in testing for small quantities of sugar, the quantities thus overlooked are not usually of clinical significance. In fact, in my observation, glucose is more frequently declared present by inexpert examiners when absent than the reverse. Almost any one of the

* Senator, *loc. cit.*, p. 912.

tests, therefore, which are found in the various manuals for the examination of urine, applied with ordinary care, will respond readily to quantities which are of clinical significance.

Tests for Sugar.—For provisional purposes Trommer's method of using the copper test answers very well. Its ingredients are easily attainable, and there is no risk of error from changes during keeping, to which Fehling's and Pavy's solutions are subject.

(1) Trommer's test is used as follows:

To a small quantity of urine, say five c. c. (80 minims), add half as much liquor potassæ or sodæ, then drop by drop a 5 or 10 per cent. solution of cupric sulphate. On first adding the copper, a blue precipitate of hydrated cupric protoxid takes place, *which, if sugar is present, is redissolved on shaking*, producing a clear blue liquid. The copper solution should be thus added until the precipitate is no longer dissolved on shaking. Then heat the mixture to boiling, and if sugar is present, a copious yellow precipitate of hydrated cuprous oxid or of red cuprous oxid occurs. Either is conclusive evidence. Occasionally the precipitate of earthy phosphates is so copious as decidedly to obscure the reaction, and by beginners is sometimes mistaken for the suboxid. In this event the earthy phosphates may be removed by filtration after *slightly* warming the mixture. The reaction should take place as soon as the boiling-point is reached—indeed, it sometimes occurs before this point is reached. Prolonged boiling should be avoided.

(2) In Fehling's solution * the constituents of Trommer's test are united in definite proportions in order that a quantitative estimation may be made. It is also used for qualitative testing, while a rough quantitative estimation may be made at the same time by what is known as the *clinical method* at the University of Pennsylvania Clinic.

A given quantity, say one c. c., of Fehling's solution is placed in a test-tube, diluted with about four times its bulk of water, and boiled for a few seconds. If the solution remains clear, add immediately the suspected urine, drop by drop. If sugar is abundant, the first few drops will usually cause the red or yellow precipitate, but if the reaction does not occur, the dropping may be continued, followed each time by heating until an equal volume has been added. If no red or yellow precipitate occurs, sugar is absent. Now, Fehling's solution is so composed that if an equal volume is exactly reduced by an equal volume of urine, that urine contains 1-2 of 1 per cent. of glucose; if by half bulk, 1 per cent.; if twice the bulk, 1-4 per cent., and so on, whence one can easily estimate roughly the percentage. Should the urine contain more than 1 per cent. of sugar, it should be diluted one to ten and the result multiplied by ten.

If a reduction takes place on boiling the test fluid alone, a new supply may be obtained, or a little more soda or potash may be added, the fluid filtered, and it is again ready for use. Such spontaneous reduction of the cuprous oxid often occurs when Fehling's solution is kept for some time.

In judging the progress of a case of diabetes under treatment it is not sufficient to test the urine qualitatively, but a quantitative determination of

* *Fehling's solution.*—Dissolve 34.652 gm. of pure crystallized sulphate of copper in 200 gm. of distilled water; 175 gm. of chemically pure crystallized neutral sodic tartrate in 480 gm. solution of caustic soda of specific gravity 1.14, and into this basic solution the copper solution is poured, a little at a time. The clear mixed fluid is diluted to one liter, or 1000 c. c.

Ten c. c. of this solution will be reduced by 0.05 gm., or 50 milligrams, of diabetical sugar. If Fehling's solution is to be kept some time, it is absolutely essential that it should be placed in smaller bottles holding from 40 to 80 gm., sealed, and kept in a cellar.

Still greater security may be obtained by dissolving the cupric sulphate in 500 c. c. and the tartrate salt and potash in 500 c. c., keeping the two solutions separate in rubber-stoppered bottles. Equal volumes of the two solutions are united when needed for use.

sugar must be made. This may be done by the clinical method just described or by volumetric processes described in the manuals for the examination of urine, but the simplest process is the (3) *fermentation method* of Dr. Roberts. In this the specific gravity of the urine is taken before and after fermentation, and the difference in the two results indicates the number of grains of sugar in each fluid ounce of urine. Suppose, then, the specific gravity before fermentation to be 1045, and after fermentation 1035: the quantity of sugar is ten grains to the fluid ounce, or 0.65 gm. in thirty c. c. These figures can be reduced to percentage by multiplying by 0.23.

Mention should be made of those rare instances in which the sugar does not reduce cupric oxid. I have had a case under my care. The urine had a specific gravity of 1050 when the patient came under observation, but there was no response whatever to the copper or bismuth test; yet by the fermentation test a large amount of sugar was shown to be present.

(4) Polarimetry is a very convenient method of analysis if an instrument is at hand, though the costliness of a good instrument will probably always be in the way of its general use.

Tests for Acetone, Diacetic Acid, and Oxybutyric Acid.—Of the numerous tests for acetone, most of which require the distillate for their successful application, Legal's nitroprussid of sodium test is the most satisfactory for the practitioner, because it does not require the distillate.

Legal's Test for Acetone.—A fresh, rather strong solution of sodium nitroprussid is made by dissolving a few fragments in a little water in a test-tube. To three or four c. c. of the suspected urine add enough liquor sodæ or potassæ to secure a distinct alkaline reaction. To the mixture then add a *few drops* of the nitroprussid solution, when the whole quickly assumes a red color, whether acetone is present or not, said to be produced by creatinin even more rapidly than by acetone. In any event the red color disappears; but if acetone is present, the addition of a few drops of concentrated acetic acid causes a purple or violet-red color. If there is no acetone, this final change does not occur, while the purple color also fades in a little while, even if caused by acetone.

To test for *diacetic acid* add a few drops of a solution of ferric chlorid to a small quantity of the urine, when a beautiful Burgundy-red reaction occurs. A precipitate of phosphates succeeds the adding of the first few drops, but this is redissolved by a further addition of the chlorid. The test is confirmed if, after heating the original fluid, there is no response on application of the chlorid of iron—the effect of heat being to dissipate the diacetic acid. A more brilliant reaction is obtained if the urine be first treated with a solution of acetate of lead, filtering out the white precipitate and testing the filtrate. Urine passed after the administration of salicylic acid, antipyrin, carbolic acid, salol, phenocol, kairin, and other drugs furnishes a similar reaction.

The reaction for diacetic acid being obtained, it is scarcely necessary to test for *beta-oxybutyric acid*, as the significance is the same. The test is a complicated one, but beta-oxybutyric acid is presumably present when a quantitative estimation indicates a larger quantity of glucose than does polarization, since beta-oxybutyric acid rotates polarized light to the left, as contrasted with the dextrorotatory power of grape-sugar. Again, if after complete fermentation with yeast or precipitation with basic acetate of lead and ammonia the urine is found levorotatory, beta-oxybutyric acid is presumably present.

Prognosis.—The prognosis of diabetes varies with the age at which the disease makes its appearance, the time which has been allowed to elapse before treatment is instituted, and the treatment itself. Once thoroughly established early in life, or before twenty-five years of age, recovery is rarely possible, but even at this age, if treatment is instituted sufficiently early, much may often be done to avert the end. Diabetes is a disease in which the expectant plan of treatment is disastrous. It is a disease which never gets well of itself, and always gets worse if not properly treated. At the same time the mild cases amenable to treatment are in a decided majority. When the disease appears after middle life in fat persons or those disposed to gout, and is early recognized and promptly treated, it is usually easily controlled; and although it is almost never safe to declare a case of diabetes absolutely cured, it does occasionally happen that recovery is so complete that the patient may be left to his own mode of living. As a rule, however, even those who have apparently recovered must keep a watch upon their diet, and should at intervals have their urine examined with a view to sounding, as it were, their condition. We are entirely justified in saying to a diabetic patient, "As long as your urine remains free of sugar you are practically as well as if you had no tendency to diabetes." On the other hand, for spare, nervous, and hard-worked persons, especially mentally overworked, under forty, there is a much more unfavorable outlook. Even here, if the co-operation of the patient can be secured, much may be done. Every intermediate degree of seriousness may occur. When diabetes depends upon recognized nervous lesions, the prognosis is altogether that of the lesion itself. The cause of death is very frequently some intercurrent or consequent disease, as phthisis or diabetic coma. The syphilitic origin of the disease and obesity are favorable prognostic factors; a spare habit and habitual constipation are unfavorable.

Treatment.—This resolves itself easily into the dietetic, the hygienic, and the medicinal.

1. *Dietetic Treatment.*—This is by far the most efficient, and no permanent results have ever been obtained without it. It consists essentially in the elimination from the diet of such articles as are readily convertible into glucose—viz., the carbohydrates. It is acknowledged that in the early stage of the disease only the saccharine and amylaceous foods fail to be consumed in the economy in the usual way and appear in the urine as glucose. Hence, if these be excluded from the diet and their place supplied by other assimilable articles, the symptom disappears, and the disappearance of this symptom seems to be, for the time being at least, the cure of the disease.

If it were necessary to select a diet absolutely free from sugar and starch, it would indeed be restricted, as there are comparatively few articles of food thus constituted. Such are, however, meats of every kind, fresh or salted, including tripe, tongue, ham, bacon, and sausage; soups made from meat and without flour; game, poultry, fish, oysters, lobsters, crabs, eggs in every form; butter and new cheese, oils and fats. Happily, however, it is not necessary to use articles absolutely free from the two baneful principles, and in this manner quite a variety of palatable articles may be added to the dietary. Among these are cream, curds, milk, and buttermilk, and all green vegetables, including spinach, endive, lettuce, dandelion, cabbage in various forms including coleslaw, Brussels sprouts, cauliflower, broccoli, string-beans, tomato, watercress, celery tops, asparagus tops, turnip tops, young onions, cucumbers, pickles, and olives. To these may be added unsweetened jellies (preparations of gelatin) and especially a variety of nuts, including almonds, walnuts,

butternuts, filberts, pecan nuts, Brazil nuts, but not chestnuts; also, all acid fruits, as apples, lemons, strawberries, etc. Tea and coffee, with cream and without sugar, cocoa-nibs, but not chocolate, are permitted; also all wines which contain little or no sugar, including claret, Burgundy, Rhine, and still Moselle wines, together with very dry sherry, unsweetened brandy, whisky, and gin when required. The carbonated waters, natural or artificial (the so-called soda-water of the shops), are pre-eminently suitable. Water is to be allowed *ad libitum*, for water is the medium by which the sugar is carried out of the blood and tissues. Its supply should therefore be liberal, and with the diminished sugar formation comes diminished thirst. Better still are the alkaline mineral waters, especially those of Vals, Vichy, Carlsbad, and the Saratoga Vichy.

Beer, ale, porter, cider, and the fermented liquors generally are not allowable because of the sugar and carbohydrates they contain. They are less objectionable when fermentation is carried to a high degree, resulting in a more complete destruction of the sugar. This is the case with certain bottled lager beers and English ales.

It is not simply the small quantity of sugar and starch contained in them which renders the vegetable substances named admissible, for many of them contain a great deal of sugar; but these sugars, unlike grape-sugar, are more easily assimilable. Such are pre-eminently mannite, the sugar of manna; lactin, or sugar of milk; levulose, or fruit-sugar, and probably, also, inosit, or the sugar of muscle. Such is also inulin, a hydrocarbon and starchy principle found in the *inula helenium*, or elecampane, but especially in Iceland moss. Hence, too, the impunity with which milk can often be taken by diabetics, although it contains from 3 to 6 per cent of lactin. On this account, too, levulose may be cautiously used for sweetening tea and coffee in mild cases. Glycerin is also sometimes substituted for sugar, but though less objectionable, both theory and experience go to show that it is not a safe substitute. Levulose and even mannite are much to be preferred to glycerin, both for sweetening and as a substitute for sugar in force production. But none of these sugars can be used with safety for sweetening purposes, and if sweetening is indispensable for the patient, it should be done with saccharin.

It will be noticed that not only all saccharine substances of animal or vegetable origin and all vegetables largely composed of starch, as potatoes, rice, and corn, are omitted from the category of admissible articles, but that *bread*, and all preparations made of wheat, rye, rice, or corn-flour, are conspicuous by their absence. This is found to be a very important omission from the dietary of most persons, and numerous, indeed, have been the attempts to devise substitutes for it, with varying success. The best known and most popular of these is gluten bread, made of the so-called gluten flour, whence the starch is partially removed by washing. Unfortunately, the gluten flour made in this country contains nearly as much starch as the white flours, with perhaps a single exception—a meal made by the Battle Creek Sanitarium Co., of Battle Creek, Mich.* In England and France diabetic patients are much more fortunate, gluten flours of sufficient purity being there obtainable. Flour of the soya bean (*soya hispida*), containing only 4 per cent. of starch and a large amount of nitrogenous matter and oil, is also used for making griddle-cakes and biscuit. These, if freshly made, are very

* This is known as gluten meal No. 1. A biscuit is made of this known as No. 1 gluten biscuit. No. 2 meal and biscuit contain more starch.

palatable; but biscuits made for some time become rapidly rancid from decomposition of the oil.

Another substitute is bran flour or unbolted wheat flour, which contains relatively less starch. The pure bran itself is not wholly innutritious. Dr. Prout very early recommended, as a substitute for bread, a compound of bran, milk, and eggs, which he declared not unpalatable.*

Still another substitute for wheaten bread is the almond food suggested by Dr. Pavy. The almond is composed of 54 per cent. of oil, 24 per cent. of nitrogenized matter known as emulsin, 6 per cent. of sugar, 3 per cent. of gum, and *no starch*. Chemically speaking, it is therefore admirably adapted for diabetic food, and when the sugar and gum have been extracted, it leaves nothing to be desired. The sugar and gum are removed by treating the powdered almonds with boiling water slightly acidulated with tartaric acid, or by soaking the almonds in a boiling acidulated liquid, which may form part of the process for blanching. The boiling and the acid fluid are necessary in order to precipitate the *emulsin*, which would otherwise emulsify the oil of the almond. Biscuits made of almond-flour † and eggs are palatable, and may be eaten with a little dry sherry or whisky and water.

Biscuits made of *inulin*, the starchy principle already referred to on page 810, were suggested by Kütz.‡ Lichenin, or moss-starch, abundant in Iceland moss, is a variety of inulin, and would be the material used for the purpose. Being very cheap, it is suitable on this account. Though a starch, it is, according to Kütz, one of the assimilable starches already mentioned, of which small quantities, at least, do not increase the excretion of sugar. The biscuits are made with the addition of milk, eggs, and salt.

The best of these substitutes is unsatisfactory, as patients soon tire of them and want the real bread. Aleuronat § bread is regarded by von Noorden as the only one at all satisfactory, since it retains the bread taste. Although containing some carbohydrate, I have lately commenced to use it for my patients, and it promises to be fairly satisfactory.

The following classified summary of articles of food admissible for diabetics will be found convenient for reference:

Shell-fish.—Oysters, mussels, and clams, raw or cooked in any way, *without* the addition of flour.

Fish of all kinds, fresh or salted, including lobsters, crabs, sardines, and other fish in oil; fish roe, caviare.

* The following are Dr. Camplin's directions for making biscuit of the bran flour: To one-quarter of a pound of flour add three or four fresh eggs, one and a half ounces of butter, and half a pint of milk; mix the eggs with a little of the milk, and warm the butter with the other portion; then stir the whole well together; add a little nutmeg or ginger or other agreeable flavoring, and bake in small forms or patty-pans. The cake, when baked, should be about the thickness of an ordinary captain's biscuit. The pans must be well buttered. Bake in rather a quick oven for half an hour.

These cakes or biscuits may be eaten by the diabetic with meat or cheese for breakfast, dinner, or supper; at tea they require rather a free allowance of butter, or they may be eaten with curd or any of the soft cheeses.

† Seegen recommends an almond food made as follows: Beat a quarter of a pound of blanched sweet almonds in a stone mortar for about three-quarters of an hour, as fine as possible; put the flour thus produced into a linen bag, which is then immersed for an hour and a quarter in boiling water acidulated with a few drops of vinegar. The mass is then thoroughly mixed with three ounces of butter and two eggs; the yolks of three eggs and a little salt are added, and the whole is to be stirred briskly for a long time. A fine froth made by beating the whites of the three eggs is then added. The whole paste is now put into a form, smeared with melted butter, and baked by a gentle fire.

‡ Kütz, "Beiträge zur Path. und Therapie des Diabetes Mellitus," Marburg, 1874, Bd. 1, p. 145.

§ Aleuronat bread is made by R. Williamson as follows: Mix two ounces (62 gm.) of desiccated cocoanut powder with a little water containing a small quantity of German yeast. Make the mass into a sort of paste, and put in a warm place for half an hour or longer. The small amount of sugar contained in the cocoanut is almost entirely decomposed by the fermentation produced by the yeast, and the cocoanut paste becomes spongy. Add two ounces (62 gm.) of aleuronat, one beaten egg, and a small quantity of water in which a little saccharin has been dissolved, and mix well until a dough is formed. Divide into cakes and bake in a moderate oven for twenty or thirty minutes.

Aleuronat is a yellowish powder containing from 80 to 90 per cent. of vegetable albumin and only 7 per cent. of carbohydrates. I have found much difficulty in securing properly desiccated cocoanut powder.

Meats of every variety except livers, including beef, mutton, chipped dried beef, tripe, ham, tongue, bacon, and sausages. Also poultry and game of all kinds, with which, however, sweetened jellies and sauces should not be used.

Soups.—Clear bouillon and other soups, beef-tea and broth made without flour, rice, vermicelli, or other starchy substances; and without the vegetables named below as inadmissible.

Vegetables.—Cabbage, cauliflower, Brussels sprouts, broccoli, green string-beans, the green ends of asparagus, spinach, dandelion, mushrooms, tomatoes, lettuce, endive, coleslaw, olives, cucumber (fresh or pickled), radishes, sorrel, young onions, watercresses, mustard and cress, turnip tops, celery tops, artichokes, gherkins, okra, parsley, or any other green vegetables.

Bread and cakes made of pure gluten, bran, aleuronat, soya, peanut- or almond flour, inulin, with or without eggs and butter. Griddle-cakes, pan-cakes, biscuit, porridges, etc., made of these flours. Oatmeal porridge with cream. Where especial stringency is required, the last should be altogether omitted.

Eggs in any quantity and prepared in all possible ways, without sugar or ordinary flours.

Butter and Cheese.

Nuts.—All except chestnuts, including almonds, walnuts, Brazil nuts, hazelnuts, filberts, pecan nuts, butternuts, cocoanuts.

Condiments.—Salt, vinegar, and pepper in moderate quantities.

Fruits.—Cranberries, plums, cherries, gooseberries, red currants, strawberries, acid apples, lemons, oranges sparingly—all without sugar. Acid fruits may be stewed, with the addition of bicarbonate of sodium instead of sugar.

Jellies.—None except those not sweetened with sugar. Saccharin may be used for sweetening instead of sugar. Jellies may be made of calf's foot or gelatin and flavored with wine.

Drinks.—Coffee, tea, and cocoa-nibs, with milk or cream, but without sugar. Also, milk, cream, soda- (carbonated) water, and all mineral waters freely; lemonade without sugar, acid wines, including clarets, Bordeaux, Rhine, and still Moselle wines, and very dry sherry. Unsweetened brandy, whisky, and gin. No malt liquors except those ales and beers which have been long bottled and in which the sugar has all been converted into carbonic acid and alcohol. Saccharin may be used for sweetening tea and coffee.

To be Especially Avoided.—Cantaloupes, watermelons, peaches, grapes, and all other sweet melons and fruits; potatoes (white and sweet), rice, beets, carrots, turnips, parsnips, peas, and beans; all vegetables containing starch or sugar in any quantity; sweet wines, including sherry, Madeira, port, and champagne.

In mild cases the dietetic measures previously indicated are usually followed by the most prompt and decided results, in some instances by the permanent removal of all symptoms, in others by a continued absence of them so long as a watchfulness over diet is maintained. In a more advanced stage of the disease, in which more rapid emaciation and loss of strength show themselves, such a regimen is followed by a decided diminution in the amount of sugar excreted, but it fails to disappear altogether, and a more rigid elimination of saccharin and amylaceous articles must be attempted. Sooner or later, however, a stage is reached when not only albuminous food breaks up into urea and sugar and urea and water, but the albumin of the tissues under-

goes the same metabolism and excretion, while emaciation, starting first with the disappearance of fats, invades even the muscular tissue. Fatty foods longest resist this breaking up, but, ultimately, in progressive cases, even they increase the elimination of sugar.

Each case should be thoroughly studied as to its own peculiarities and demands. I do not pursue the same plan in every case. Sometimes I place the patient at the onset on a strict nitrogenous diet of broths, meat, and eggs, with a view to determining what can be accomplished. This done, successive articles of food are added and their effect upon the urine is watched. In other cases, especially when the quantity of sugar is not large, I first take away from the diet all sweets, and the purest starch foods, including bread. Too great stringency must not be insisted upon, and the presence of one per cent. or a maximum of two per cent. of glucose in urine may be permitted for a time; but semi-occasionally, say once a month, a return should be made to the strict diet, with a view to taking soundings, and if it is found that all the glucose disappears, we may be encouraged to permit for a time a more liberal diet.

In many cases of diabetes of long standing there comes a time when it becomes necessary for the welfare of the patient that a rigid diet must be suspended for a time. So settled is this truth that some physicians erred on the other side and have been led to decry altogether the dietetic treatment. A question of great practical importance asks what shall guide us to such a change of diet? It has occurred to me that it is the continued presence of diacetic acid in the urine. For this informs us that not only the proteid elements of food, but even the fixed proteids of the body, are splitting up to supply the demand for glucose which is still wasted because it cannot be oxidized. The carbohydrate at least meets this demand and thus conserves the fixed proteids for other uses.

2. *Hygienic Treatment.*—Next in importance to the dietetic is the hygienic treatment of diabetes. This consists in bathing, and attention to the skin, together with outdoor muscular exercise and perfect ventilation within doors.

The diabetic should breathe the freshest and purest air. While the cases are not numerous in which embarrassed respiration results in glycosuria, there are undoubted instances in which this has occurred, as in croup and whooping-cough; and it is well known that asphyxiated lower animals are likely to have glycosuria. Although the glycosuria thus resulting is probably reflex, it can hardly be expected that the diabetic should improve under unfavorable respiratory conditions. He should not, therefore, live, work, or sleep in a confined atmosphere, but secure the most perfect ventilation, spending much of his time out of doors, and sleeping in large, well-ventilated chambers, with windows open, etc. Especially should he avoid inhalation of irrespirable gases. Attention to the skin, or skin culture, is most important to the diabetic. He should bathe at least twice a week in tepid or hot water on going to bed in winter, and on rising take a cool sponge-bath daily. In summer he may take a cool bath on rising and on retiring. He should groom his skin thoroughly daily, either after the bath or independent of it on the days on which he does not bathe. Two tablespoonfuls of sodium carbonate to an ordinary bath is a suitable addition to the latter, softening the skin and facilitating its action by removing the effete epithelium.

Muscular exercise should be taken daily by the diabetic, both by walking and gymnastics. Glycogen is undoubtedly consumed in the muscles during

their action, and it is quite certain that in diabetes there is an undue accumulation of sugar in the muscles. Exercise should be sustained regularly day by day, even in wet weather, care being taken to keep the feet dry, while it should never be carried to the point of fatigue.

Attention to other secretions, particularly to that of the bowels, is of the greatest importance. Diabetics who are constipated are always more difficult to relieve. It is probably partly on account of their action in this respect that the alkaline and alkaline-saline aperient waters, as those of Vichy, Vals, and Carlsbad, are so useful. To those who visit these springs, a part of the benefit is ascribable to the other favorable hygienic influences, such as rest, fresh air, and exercise, by which they are surrounded. Independently of these influences, however, there is reason to believe that the alkaline waters are of service to diabetics, and when their cost is not a consideration, a quart of Vichy or Vals and half as much Carlsbad may be taken during the day, beginning before breakfast. The Vichy is a more alkaline water, containing thirty-five grains (2.3 gm.) of carbonates to a pint (0.5 liter), while Carlsbad contains but eleven grains (0.51 gm.), but twice the proportion of chlorids, eight grains (0.7 gm.) to a pint (0.5 liter), and nearly ten times as much sodium sulphate, or nineteen grains (1.25 gm.); hence its more purgative quality. Since Carlsbad has the highest reputation, it is more likely that it is through the action of the sulphates and chlorids on the liver rather than that of the alkalines they contain that these waters are efficient. This is the more likely, as other alkaline waters nearly as rich as those of Vichy and richer than Carlsbad waters in sodium carbonate, but without sulphate of sodium, are without reputation. The alkalies may, however, increase the effect, and are especially of service when there is acidity.

The waters of the celebrated Saratoga Springs in this country have an undoubted action on the liver, probably through the chlorids they contain, which are in very large proportion, reaching in the Geyser Spring seventy grains (4.6 gm.) to the pint (0.5 liter), and in the Empire and Hathorn, sixty-three grains (4.19 gm.) to the pint (0.5 liter). They contain no sulphates, but the carbonates are present in considerable proportion, though much less than in the Vichy waters. Saratoga Vichy, which, of the Saratoga waters, contains most sodium carbonate, has ten grains (0.6 gm.) to the pint; the Geyser, nine grains (0.58 gm.). In the absence of the Carlsbad and Vichy waters I would use the purgative Saratoga waters, especially the Vichy and Geyser.

3. *The Medicinal Treatment.*—Like all diseases in which treatment by drugs is relatively inefficient, diabetes has its full share of reputed remedies, most of which are useless. This dare not, however, be said of all.

The only drug that can be relied upon to produce an effect in diminishing glycosuria is opium. It seems that it was used for diabetes as early as the second century by Archigenes. It was also used by Ætius the physician, in the fourth century, and in the latter part of the eighteenth century and beginning of the nineteenth by Rollo, Frank, Tommasson, and especially the English physician, Pelham Warren, in 1812. It is certainly a useful agent in diabetes, but its use is united with disadvantages in the locking-up of the secretions which attends it. On account of its comparative freedom from these effects, codein has come to be the favorite alkaloid of opium in diabetes. It may be given in 1-4-grain (0.016 gm.) doses three times a day, or 1-2 grain (0.032 gm.) twice a day, increasing 1-4 grain (0.016 gm.) daily until the desired effect is produced or it proves useless. If the sugar dis-

appears, the drugs should be gradually withdrawn. If constipation is caused by it, aperient remedies should be associated, and very suitable are the natural aperient waters, including the bitter waters, Friedrichshalle, Hunyadi János, Racokzy, Püllna, etc. I have seen a patient entirely relieved under its use, and it alone, with no return of the sugar after its omission. I rarely give as much as ten grains (0.65 gm.) a day, and usually defer its use until I find other measures insufficient.

After opium, arsenic has longest maintained its reputation as a remedy in diabetes, and I use it in all mild cases, preferring Fowler's solution. It seems to me there is something more than a simple tonic action in it. Possibly it acts partly on the gastro-intestinal tract and partly on the red blood discs, increasing their oxidizing power over glucose. The plan I have adopted, after many years' experience, is to give small doses long continued rather than to attempt to bring about its physiological action. Hence three drops twice a day, continued indefinitely, is now my favorite method.

The bromid of potassium is sometimes efficient in diabetes accompanying functional nervous disorders due to mental overwork or psychic disturbance. Bromin and arsenic are combined in the shape of Clemens' solution of bromid of arsenic, of which the dose is from three to five minims (0.184 to 0.3 c. c.).

Substances which possess the power of oxidizing sugar in the blood have long been sought. The alkalies, and especially the alkaline carbonates, at one time enjoyed considerable reputation in the treatment of diabetes, after Mialhe claimed for them the power of destroying the sugar in the blood, and of neutralizing the volatile acids retained within the organism in consequence of the defective action of the skin. Whatever their mode of action, the carbonates continue to be used by many physicians, both in Germany and in England, with results which justify the practice. Potassium or sodium bicarbonate, in ten-, fifteen-, or twenty-grain doses (0.6, 1, or 1.3 gm.), may be administered. The efficiency of the alkaline mineral waters is thus explained. Much was hoped of pancreas preparations, especially since the brilliant results that followed the use of thyroid extract in myxedema. They have proved disappointing. The glycolytic ferment isolated by Lepine from the pancreas and from malt diastase has not been any more satisfactory. Suprarenal extract has also been employed.

The coal-tar derivatives, antipyrin, antifebrin, and phenacetin have been highly recommended by the French physicians, and I have found them of service in mild cases, giving from ten to fifteen grains (0.6 to 1 gm.) three times a day on an empty stomach, beginning with the smaller dose in the case of the first two. Their efficacy is said to be increased when combined with an equal bulk of sodium bicarbonate. Salicylate of sodium has warm advocates, and in gouty cases it may be useful. According to von Noorden, it is especially in neurogenous diabetes that the last of the remedies just named is useful, quieting the irritability of the central nervous system.

Jambul is a remedy with some reputation. I have been so much disappointed in its effects that I rarely use it. It is given in the shape of powder or fluid extract, in doses of 5 to 30 grains (0.3 to 2 gm.) of the former and a half to 2 drams (1.8 to 7 c. c.) of the latter.

Iodid of potassium has produced some striking results in the case of diabetes due to syphilitic lesions of the brain.

Lactic acid was strongly advocated by the Italian physicians. Cantani recommends that from 75 to 150 grains (5 to 10 gm.) of the acid should be

taken daily in from eight to ten fluid ounces (240 to 300 c. c.) of water. Whence buttermilk or Zoolak (a fermented milk in which the sugar of milk is converted into lactic acid by a ferment) becomes a suitable food at least.

Cod-liver oil becomes a useful remedy in cases in which the carbohydrates are totally converted into sugar and excreted, the albuminoids for the most part, while the body albumin is being encroached upon as a source of energy. Especially useful does it become when associated with alcohol in the shape of whisky or brandy, which always helps the assimilation of fat. In the same category as cod-liver oil must be placed butter, cream, bacon, and the like as foods.

Treatment of Complications.

Eczema and Pruritus.—These sometimes intensely annoying symptoms commonly abate with the reduction of the glycosuria, but require also other measures. In the first place scrupulous cleanliness is necessary, accomplished by warm, tepid bathing. In addition, we may use solutions of boric acid 2 drams (8 gms.) to the quart (1 liter) or sodium hypophosphite, one ounce (30 gm.) to a quart (1 liter) of water; also zinc ointment, ointment of acetate of lead; solutions of corrosive sublimate, very weak,—1 to 3000,—and tumenol-sulphonic acid in 10 per cent. alcohol solutions. Carbolic acid 5 to 10 minims (.3 to .6 gm.) glycerin ʒss (8 c. c.) and water an ounce (30 c. c.) make a soothing preparation. As a last resort in pruritis nitrate of silver may be used in the strength of twenty grains (1.3 gm.) to the ounce (30 c. c.), making daily applications, which though sometimes painful, are ultimately effectual.

Diabetic Coma.—Treatment is usually futile here. The alkalies and alkaline mineral waters should be pushed. Intravenous injections of alkaline solutions have been disappointing. More hopeful is the intravenous injection of a 0.8 per cent. salt solution, as recommended by von Noorden, using a liter in four doses at intervals of four hours. A teaspoonful of common salt to a gallon of sterilized water affords a strength sufficiently near the percentage named. Hypodermoclysis, which is much easier, will accomplish the same result, as I can attest from personal experience. Copious diuresis follows, and may be expected to carry out noxious substances.

More hopeful is a *prophylactic* treatment of diabetic coma, called for when diacetic acid or oxybutyric acid and large amounts of acetone are found in the urine. Under these circumstances it seems certain that whatever be the form of diet in use at the time, it must be changed, and if it be remembered that these substances are now conceded to arise from the disintegration of body albumin and not from food, as formerly supposed, diet would at least seem a matter of indifference under the circumstances, while a change alone seems desirable. The patient should be immediately placed upon alkaline treatment, associated with the free use of alkaline mineral waters. Thus, twenty grains (1.3 gm.) of sodium bicarbonate may be given every three hours, dissolved in eight ounces (250 c. c.) of Vals or Vichy water. The bowels should be kept open, and alcohol in the shape of whisky or brandy freely given.

DIABETES INSIPIDUS.

Definition.—Any excessive secretion of non-saccharine and non-albuminous urine which has continued for a long time.

Etiology.—The condition, unlike diabetes mellitus, affects more frequently younger persons, being rare in those over fifty years of age, relatively frequent in infancy, and most common between the ages of twenty and thirty.

As to sex, it is said to be much more frequent in males than in females, two to three times as many of the former as of the latter. In my own experience I have found the disease nearly equally frequent in both sexes.

As to causes, the same uncertainty prevails as with diabetes mellitus. An examination of cases shows an association with a certain number of conditions, such as cerebral disease, including tumor of the brain, meningitis, paralysis of the sixth nerve, sunstroke, cerebrospinal fever, falls and blows on the head, exposure to cold and the drinking of cold fluids, drunkenness, pregnancy, hysteria, emotion, especially fright, hereditary influence, syphilis, and previous disease, etc., but this does not show causation. The proportion, however, of cases in which the condition is associated with brain diseases and injuries to the head, taken in connection with the fact of Bernard's discovery that puncture of the floor of the fourth ventricle above the diabetic center produces polyuria without glycosuria, makes it very likely that central nervous irritation, however induced, is at the bottom of the symptom. It is reasonable to suppose, too, that diabetes insipidus may be the result of some irritation, direct or reflex, of this center in the medulla oblongata, or of the sympathetic ganglia in the abdomen. The latter explanation also applies to cases of polyuria attending the presence of abdominal diseases, such as tumor, aneurysm, or peritonitis, though it is doubtful whether these should be regarded as cases of diabetes insipidus.

Morbid Anatomy.—The essential morbid anatomy of diabetes insipidus would be the lesions of the nerve centers or sympathetic ganglia which may underlie the symptoms. But as these are often undiscoverable, or at least indefinite, it is impossible to describe them. Notably is this the case with lesions of the third and sixth nerves. Associated central nervous lesions, when present, are found more frequently in the vicinity of the base of the brain.

Symptoms.—The *enormous secretion of urine* of almost spring-water-like clearness, and of specific gravity often as low as 1003, is the most conspicuous symptom, but more annoying, probably, is the *extreme thirst* which always attends it. These may be said to be the essential symptoms, others which may or may not be present being rather their consequence. Very constant among the latter are *dryness of the skin* and *absence of perspiration*. The health may be otherwise perfect, though *emaciation* and *weakness* are often present. The debility is sometimes extreme. Occasionally there are derangements of digestion, and sometimes also the appetite is ravenous, as in diabetes mellitus, though less frequently so.

These symptoms may occur suddenly in the midst of apparent health, or they may supervene upon others or be substituted for them, chiefly those of a nervous character, which may be the result of the nervous lesion causing the polyuria. Such symptoms are headache, restless, irritability,

sleeplessness, what is commonly called *nervousness*, more rarely convulsions, delirium, paralyzes—indeed, any one or more of the great variety of symptoms which result from organic or functional nervous disease. Sometimes these symptoms succeed upon the polyuria or are increased by it. It is certain that the milder nervous symptoms are sometimes the result simply of the inconvenience and annoyance caused by the two cardinal symptoms, polyuria and thirst. The patient is kept busy, as it were, night and day, in passing water. It is not surprising that such a patient should be fretful and irritable, and that sooner or later his health should be broken if the symptoms are not relieved.

In addition to the symptoms detailed, there are said to occur at times dryness of the tongue, epigastric and lumbar pains, diarrhea, and impairment of mental faculties and of the sexual function. In some instances there is the most extraordinary tolerance of alcoholic drinks, while in others there is an exaggerated susceptibility to their influence. A very slight lowering of the *body-temperature* has been observed, amounting, however, to but a few tenths of a degree, and it is never below 97° F. (36.1° C.). In advanced stages of the disease *edema* of the lower extremities sometimes occurs.

The *duration* of the condition varies greatly. Sometimes it continues through life with no inconvenience except that from the constant diuresis and thirst. Dr. Willis records a case lasting fifty years. On the other hand, it is seldom of brief duration; indeed, there is needed a certain chronicity in order to admit it in the category of diseases. One case is reported as terminating fatally in seven weeks. Under prognosis will be found some further information as to duration, but it may be said, in general, that most cases which terminate unfavorably and most which recover completely do so within a year. I have now under my care a lad of seventeen who has been under treatment for eleven years. He is able to work quite hard much of the time.

No complications arise except such as cause the disease or results from it. Among the latter is occasionally dilatation of the pelvis of the kidney, and atrophy of this organ is mentioned, due to pressure of the accumulated urine and resulting in a sacculated condition. The symptoms of the malady are almost always influenced, and sometimes even cut short, by intercurrent disease, especially of a febrile character, or even by a profound physical impression, as long-continued suppuration after a blister. The boy referred to was an aggravated choreic before he became diabetic.

Physical and Chemical Characters of the Urine.—As to the quantity of urine passed, it is enormous, exceeding often the amount passed in saccharine diabetes. As many as forty-three liters (90 pints) are recorded by Trousseau, and one-fourth this quantity is common. It has been said, even, that the quantity secreted sometimes exceeds the amount of fluid ingested, but this is impossible for any length of time, unless water is absorbed from the atmosphere, which is not impossible. In point of fact, the water excreted is always a little less than that ingested, either as drink or in the solid food. As the quantity of urine excreted increases or its normal acidity diminishes, its color disappears and its specific gravity declines. In one case under my care the specific gravity was scarcely 1001, while the urine in moderate bulk was absolutely colorless. Again, a faint greenish tinge is exhibited by the urine in bulk.

As to the other constituents of the urine, it may be said in general that they are all increased, except possibly uric acid. Thus, the *urea* is increased

to three and even four times its normal amount. In a case reported by J. M. Da Costa* the urea was diminished.

Sulphuric and *phosphoric* acids are both increased, and especially, according to Dickinson, the combination of phosphoric acid with the earths, lime, and magnesia. The same is true of the *chlorids*.

Of abnormal constituents, *inosit* has been found, and *albumin* very rarely, but care should be taken not to confound the polyuria with the slight albuminuria of a contracted kidney or with an albuminous polyuria in which there is no organic disease of the kidney.

Some of the accounts published as to the quantity of water consumed and excreted are almost incredible, yet they seem well authenticated. In illustration may be mentioned the following instances from Dr. Willis' work on "Urinary Diseases": † An artisan, fifty-five years old, had had constant thirst with commensurate diuresis since he was five years of age. From the age of sixteen he had drunk, on an average, no less than two pailfuls daily. While in the Hôtel Dieu, to which he was admitted for an injury of the knee, he drank on an average thirty-three pints of water every day, often swallowing two liters, or about two quarts, at a draught. He passed daily about thirty-four pounds of urine and one pound of feces. He otherwise enjoyed good health, and was the father of several children. The long duration of this case and the otherwise excellent health enjoyed by him are by no means exceptional. Very little serious disturbance seems to result so long as water is supplied to quench the resulting thirst. In extreme cases patients have been known to drink their own urine.

An extraordinary flow of *saliva* was observed in one instance by Kütz, ‡ along with polyuria, in a hysterical girl of eighteen years, from whom as much as 18.72 ounces (525 c. c.) were collected in twenty-four hours, while the quantity ranged during four months from 360 c. c. to the former amount. The quantity of urine passed during this time ranged from 200 to 260 ounces (6000 to 7800 c. c.). The increased flow of saliva may be explained by the fact that in some of the experiments of Eckhard, § Loeb, || and Gruetzner ¶ puncture of the medulla oblongata was followed by ptyalism.

Diagnosis.—The diagnosis of diabetes insipidus is very easy. The persistent thirst, polyuria, and absence of sugar from the urine are pathognomonic. The only possible error is mistaking the polyuria of chronically contracted kidney of *interstitial nephritis* for that of diabetes insipidus. In addition, however, to the fact that a careful examination for albumin will disclose it in the urine of contracted kidney, the quantity is never so large, nor is the thirst so extreme; so that it would seem only necessary to mention the possibility of such an error in order to avoid it.

Prognosis.—It is extremely unusual for a case of diabetes insipidus to terminate unfavorably unless there have been also present symptoms pointing to serious nervous lesion. Recovery is not infrequent. According to Roberts, of 67 cases collected, 16 are reported as complete recoveries and 14 ended fatally, nearly an equal proportion. The remaining 37 were still in progress. In cases of recovery or death the duration is comparatively short. Of the 16 recoveries, in 9 the duration was less than a year; in 1, four years; in 2, eighteen and nineteen years, and in the remainder, some years. Of the

14 fatal cases, 9 terminated in less than a year, 1 in *seven weeks*, and 2 in two months; the other two survived eighteen months and twenty years respectively. Of the 37 cases in progress, only 5 continued for a year or less. The remainder had continued for periods ranging from something over a year to fifty-nine years.

These results seem to be tolerably independent of treatment. It may be said, therefore, that, as a rule, cases that last more than a year are apt to continue, but ordinarily only require to be furnished with an abundance of water to keep them tolerably comfortable. According to Dickinson, cases due to drunkenness are more likely to run a severe and rapid course, usually terminating fatally within a few months, and one terminated thus in two months.

The disease appears to me altogether less serious than diabetes mellitus, and I quite concur with Senator, who says "it is rather a troublesome than a dangerous complaint." But Trousseau and Da Costa were inclined to consider it more serious than diabetes mellitus.

Treatment.—The treatment of diabetes insipidus would naturally resolve itself into the treatment for the disease of which it is the symptom rather than of the symptom itself; but as the former is very frequently undiscoverable, it must consist mainly of efforts to diminish the secretion of urine, and with it the thirst.

First, it is generally conceded that there should be no restriction in the drinking of water or other harmless fluids, for the diuresis is not so much caused by the great ingestion of water as the thirst is caused by the diuresis. It should be mentioned, however, that one or two instances are reported wherein improvement seems to have resulted from such restriction; and if, as in some cases, a habit of drinking has been the initial event, moderate restriction may be reasonable. Caution should be used in the administration of drugs, though my experience is not that of Dickinson, who says that "remedies designed to restrain the urinary secretion seldom fail to do harm." The older remedies are ergot, opium, gallic acid, and valerian; of all, the doses ultimately used are usually large. In one of my patients the symptoms subsided under the use of gallic acid after I had failed with full doses of ergot. In another, probably due to syphilis, the effect of the iodid of potassium was shown in an aggravation of the symptom whenever it was discontinued and an amelioration when it was resumed. Of all drugs, I have found the iodid of potassium most frequently followed by improvement.

Trousseau and Rayer claimed extraordinary results from the use of valerian, the former using the fluid extract in enormous doses—2 1-2 drams (6 c. c.) a day, which was increased to one ounce (30 c. c.) daily in one instance. Rayer used the powdered valerian and the valerianate of zinc, giving the latter in pills in gradually increasing doses until twenty grains (1.25 gm.) a day were given. At the present day the more palatable elixir of valerianate of ammonia, combined with bromid of potassium, is to be preferred.

Reasoning from the effect of intercurrent disease and powerful physical and nervous impressions, Roberts suggests a large *blister* at the nape of the neck or epigastrium, according as the associated symptoms and the anamnesis point to the nervous or the digestive system, a suggestion which may be acted upon with advantage.

The constant galvanic current has been recommended, and in cases of spinal lesion may be expected to be of advantage. Both Seidel and Külz have used it with good results. The former applied one pole of a "strong

battery" over the loins near the spine, and the other as deeply as possible over the hypochondrium, upon each side daily for five minutes. In eight days the urine fell from 195.9 ounces (5957 c. c.) to 153.3 ounces (4600 c. c.) per diem, in three weeks to 76.6 ounces (2300 c. c.), and the next month 63.5 ounces (1904 c. c.), while the weight of the body increased nine pounds. Külz applied one pole of a battery of from thirty to forty cells as high as possible in the nape of the neck, and the other to the loins or epigastrium, the best results being apparently obtained with the positive pole to the nape of the neck, and the negative first to the loins for four minutes and then to the pit of the stomach for four minutes.

Tonics and nervines, such as strychnin, iron, arsenic, salts of quinin, cod-liver oil, etc., are appropriately added to the treatment with a view to sustaining the strength of the patient, which is apt to fail. To these are to be added fresh air, sea air, exercise, and all possible favorable hygienic influences.

Hygiene is even more important than in diabetes mellitus, and should include a careful attention to the skin, warm clothing, warm baths, frictions, etc., in order to divert a portion of the circulation from the kidneys to the skin. The thirst should also be quenched when possible by bits of ice and acidulous fluids.

OBESITY.

SYNONYMS.—*Adipositas universalis; Polysarcia adiposa; Corpulence.*

Definition.—Obesity may be defined as an inconvenient accumulation of adipose tissue in the body.

Etiology.—The most usual cause of an excessive accumulation of fat doubtless is overeating associated with an inactive life; and though it may be true of some fat persons that they are really moderate eaters, careful examination will generally prove that they are not. Heredity exerts an undoubted influence, and we find corpulence running in families. Commonly it does not make its appearance until after thirty-five years of age, but in this country particularly it is often seen earlier, in boys and girls of ten years and upward.

Of foods, each one of the representative varieties, albuminoids, carbohydrates, and fats, is capable of contributing fat, deposited in fat vesicles in the body, and it has even been said that albuminoids furnish more of the fatty tissues of the body than the carbohydrates. Certain it is that a person may become corpulent who eats very little fat. In most cases, however, corpulent persons are found to be liberal consumers of all three of the food elements. While the carbohydrates are direct sources of fat production, it is generally conceded that they act largely by sparing the fats derived from other sources. They decompose and oxidize so rapidly, and thus give themselves up so readily to force production, that the stored fats are not called upon. Thus it is that sugars and starches indirectly favor corpulence. To this class belong also alcohol, and especially beer, which contains over five per cent. of carbohydrates, in addition to from 3 to 4 per cent. of alcohol, and it is well known that liberal beer-drinkers furnish a large quota of fat men. A second method in which large quantities of alcohol contribute to adiposis is by hastening albuminous metamorphosis, setting free non-nitrogenous substances readily

converted into fat, which are deposited, among other situations, in the liver, giving rise to the fatty liver so constantly found in drunkards.

Another cause of corpulency is muscular inactivity. Fat is consumed by muscular contraction, and its absence must contribute to fat accumulation, and one need not go far to see its evidence in many who lead lives of idleness. Oertel has especially called attention to the fact that a simple diminished ingestion of fluids, without other changes in the diet, will reduce the amount of fat. The effect may be brought about in two ways; first, by diminishing the work of the heart and thereby favoring oxidation; second, by an effect which is not so much the diminution of fat as a withdrawal of water—a sort of “desiccation,” it is called by Strümpell.

The subjects of anemia and chlorosis often become fat, probably because of defective oxidation, growing out of a diminished supply of oxygen, which the crippled corpuscles are unable to carry in sufficient quantity.

Sexual continence probably contributes to corpulence, since eunuchs are well known to grow fat, and both women and men are disposed to grow fat when the sexual function begins to abate. Finally, corpulence itself favors the further accumulation of fat, first by interfering with the muscular activity of its subject, and therefore with the oxidation of fat, and, again, diminishing combustion by reason of a reduced demand for heat, the fat itself conserving heat by preventing its radiation.

Symptoms.—A description is scarcely needed of the anatomical condition which constitutes obesity. The round, plump face, the double chin and hanging cheeks, the enormous girth of body, the pendulous belly and elephantine arms, legs, and thighs need no further description. The labored, waddling gait is often conspicuous. The first evident indication of harmfulness due to corpulence is an increased frequency in the breathing-rate, at first on slight exertion and later independently of it. This is in part a true cardiac asthma—due, first, to the fact that the heart cannot push the blood through the lungs rapidly enough to permit its aëration at the ordinary breathing-rate; and, second, to the fact that the motion of the lungs is also restricted. The latter is due to the accumulation of fat over the thorax and in the mediastinum, and to the accumulated intra-abdominal fat and probably enlarged liver, which interfere with the proper descent of the diaphragm. This leads at first to cardiac hypertrophy, further stimulated by the extra work demanded of the heart in propelling the increased bulk of the blood; further augmented by resulting arteriosclerosis, and impeded venous circulation. Later the fatty infiltration of the muscular walls of the heart leads to further embarrassment in its action and to impairment of its nutrition, whence come cardiac weakness and ultimate failure, with edema, pericardial and pleuritic effusion, and sometimes sudden death.

The pulse, hard to find, is usually frequent, but may be slow and irregular. The heart can be examined only with difficulty, on account of the large accumulation of fat, and the normal sounds are feeble and distant. The situation of the apex can be found only by the aid of the stethoscope. Intertrigo is often an annoying symptom, and great care is required to avert it. Interstitial nephritis may be superadded. By no means all corpulent persons run this course. Many lead lives of considerable comfort.

Treatment.—This consists in acting upon two principles: first, furnishing less food to oxidize, and, second, increasing the oxidation of the fat in the body.

The first is accomplished by cutting down the quantity of all kinds of

food, but especially carbohydrates. Sugar should be prohibited altogether, and saccharin substituted, if sweetening is desired. Bread may be taken in small amounts, say two ounces, well toasted and with it a thin layer of butter; or hard biscuit may be substituted. A cup of tea or coffee with a little milk may be allowed; also a single egg at breakfast or luncheon; meat once a day. The latter may be of any kind, and with it may be taken green vegetables, such as peas, string-beans, tomatoes, cabbage, spinach, Brussels sprouts, lettuce, celery, and the like, omitting altogether rice, potatoes, and the farinacea in general. A little cheese may be allowed.

Only small quantities of fluid should be permitted at meals—just enough to aid in the solution and digestion of food. This may be tea, coffee, water, or skimmed milk, the first two without sugar or cream. Beer, porter, and sweet wines should be prohibited, but a glass or two of hock or claret with an alkaline mineral water may be allowed.

A diet of skimmed milk only is a sure way of reducing fat, and a start may be made with it, commencing with two ounces every two hours and increasing until from six to eight ounces are attained. Unfortunately, very few persons will bear this treatment for any length of time, but, as stated, a beginning may be made with it, and when the patient tires, the other treatment just described may be instituted.

The second indication to promote oxidation is accomplished by exercise, gymnastics, walking, mountain-climbing, or cycling. The last has been effective in reducing the weight of the corpulent, and if combined with a proper diet, may be expected to do more. Massage is also useful, especially in co-operation with the Turkish bath and steam bath. These last help in the "desiccation" of the body, which in turn facilitates oxidation. Great difficulty is experienced in getting the patient to carry out the dietary and to exercise assiduously.

Certain health resorts have much reputation for their efficiency in reducing corpulence. Homburg, Marienbad, and Carlsbad are among the most celebrated of these, and I have seen many patients return thence after a cure of four to six weeks markedly improved in all the symptoms which come from obesity. The effect is probably altogether due to the strict diet, the systematic exercise, and the bathing, the massage, and the laxative effect of the waters, although the physicians at the various spas which have a reputation for reducing obesity claim also that the effect of the sulphate of soda, which is a constituent of most of these waters, is to stimulate oxidation in the direction of the fatty structures, while limiting the metamorphosis of the nitrogenous substances. This intermittent method of treating obesity, by recourse to baths and springs once a year while the intervening period is spent in free eating, is not to be recommended. It is much better to adopt a continuous method which may not be as rapid, but is persistent.

Thyroid extract has been administered with reputed advantage in obesity in doses of from three to five grains (0.2 to 0.35 gm.) three times daily, which may be gradually increased to twenty grains (1.3 gm.), with the same precautions as advised in the treatment of myxedema. Under this treatment the loss of weight is sometimes quite rapid, going to show that defective thyroid secretion may be a factor in causing obesity.

Mention should perhaps be made of the so-called systems of diet for reducing corpulency, a number of which have been suggested. Those especially deserving of notice are the Banting system, Ebstein's method, the method of Dancel-Oertel, in addition to the mineral water cures. It is, of

course, impossible in the limited space of a text-book to give these methods in full. The principles of their application will alone be considered and the student is referred to special sources for their detailed description.*

(1) The Banting system consists in the administration of a large amount of albuminous food, especially lean meat to the exclusion of fats and carbohydrates; green vegetables being allowed *ad libitum*; (2) Ebstein's method demands moderation and restriction in the quantity of foods generally, and for the fat-forming carbohydrates substitutes the albumin-saving, but not fat-forming fats; (3) the Dancel-Oertel method reduces especially the quantity of water and other liquids, only a minimum of 800 grams (about 1 1-2 pints) of water mixed with wine, and twice a day a cup of coffee or tea; of solid foods, nitrogenous alimentary substances and vegetables, especially such as contain little water, with fat only in such quantity as to render the dishes palatable. Oertel emphasizes the mechanical advantages of restriction in the use of water upon derangements of the vascular system; (4) the mineral water cures, as might be expected, are based chiefly upon the use of such waters, especially those containing sulphate of sodium and chlorid of sodium, the cold springs being preferred. The springs are thus classified: (a) cold waters containing sulphate of soda—Marienbad, Tarasp, Schuiz, Frazensbad, Elster, Cudowa, and Rolitsch—carbonic acid waters; (b) hot springs containing sulphate of sodium—Carlsbad, Bértrich; (c) cold waters containing chlorid of sodium—Homburg, Kissengen, Nauheim, Neuhaus and Oeynhaus; in America the Saratoga springs; (d) springs containing iodine—Hall, Krankenheil, Salzschlirf, Kreuznach, Münster am Stein. The drinking of waters at these places is combined with the use of saline, carbonated, mud, and steam baths.

RICKETS.

SYNONYM.—*Rachitis*.

Definition.—“There is a disease of infants called the rickets, wherein the head waxeth too great, while the legs and lower parts wane too little” (Thomas Fuller, 1608-61). This quaint description of the celebrated English chaplain, written over two hundred and fifty years ago, remains so nearly correct at the present day that I cannot forbear adopting it. It is further defined as a constitutional disease characterized by deformity in bones, due to cell overgrowth and deficiency in lime salts.

“The rickets” was evidently known for some time by the laity before it received its description by F. Glisson in 1650, who suggested the change of name to rachitis from the Greek *ῥάχις*, the spine. The term rickets is derived from the old English word *wrickken*, to twist.

Etiology.—Rickets rarely begins before the child is six months old or after it has attained the age of eighteen months, though a form is described by Sir William Jenner coming on as late as the ninth or even the twelfth year; on the other hand, it may begin earlier, and the child may even be rickety in the womb. Yet it cannot be admitted that rickets is hereditary, in the usual sense of the term. The child may become rickety in the womb if the mother is feeble, underfed, and overworked, and if the father is weak at its conception, but not because the father and mother were rickety when children.

* “Dietetic and Therapeutic Hints to the Visitors of Bad Homburg.” By Heinrich Will, M. D., 1893.

Again, certain races tend to be rickety, especially the negro and the Italian. Foul air and bad food, absence of sunlight and exposure to dampness and cold, are more potent factors, and it is likely that a defective composition of the breast milk, including a deficiency in the phosphates, is the strongest. Prolonged lactation may contribute to such deficiency. It is a disease of the city rather than of the country, and of the Continent of Europe rather than of America. Vienna, London, and Paris are prolific fields. In the first-

Fig. 81.—Deformed Skeleton from a Case of Rachitis—(from *Atlas du Musée Dupuytren*).

named cities from 50 to 70 per cent. of all children brought to the clinics are said to be rickety. Parrot held that congenital rickets was a form of syphilis, basing this view on studies in the French capital. On the other hand, there is reason to believe that the changes in prenatal rickets are not identical with those of the postnatal form. The subjects of the former are usually still-born, are short of limb, and though the curves of the bones are exaggerated, there is no proliferating zone of cartilage between the epiphysis and apophysis, whence the term *achondroplasy*, suggested by Parrot, and *chondrodystrophia*

fatalis, by Kaufmann. Boys and girls are equally liable to rickets. The syphilitic origin of congenital rickets is not, however, conceded by others.

Minute examination recognizes numerous cells in the spongy spaces in the bone. The studies of Kassowitz lead him to believe that a hyperemia of the periosteum, the marrow, the cartilage, and the bone itself is the fundamental condition responsible for the abnormal development. His views may be regarded as a refinement and development of those originally suggested in 1650 by F. Glisson, who held that an excessive vascularity was at the bottom of the changes.

Morbid Anatomy.—This shades somewhat into symptomatology, and the two can scarcely be separated. The changes are mainly in the bones of the skull, the long bones, and the ribs. The first may escape if the disease sets in after the middle or end of the second year. The frontal and parietal eminences are exaggerated, while the top of the head and the occiput are flattened, the whole effect being toward making the head square or “box-shaped.” The fontanels remain open some time,—until the second or third year of life,—while the edges of the bones where they come together to form the sutures are thickened, though soft and yielding. In addition to these changes, or instead of them, there may be large areas of delayed ossification

Fig. 82.—Rickety Chest—(after Gee).

Dotted line indicates the shape of the chest of a healthy infant about the same age.

in the parieto-occipital regions, producing yielding spots, constituting the so-called craniotabes of Elsässer; but as craniotabes occurs in connection with syphilis and other wasting diseases of young infants exhibiting no other sign of rickets, and even in new-born infants, it cannot be regarded as pathognomonic.

In the long bones, such as the radius and ulna, swelling of the cartilage between the epiphysis and shaft is apparent. Owing to the rapid proliferation of cartilage cells, resulting in a broad band of jelly-like material between the cartilage and the bone, a spongy structure is rapidly built up, deficient in strength and stiffness. Beneath the periosteum the same gelatinous material is deposited, and a spongy tissue is formed instead of normal bone. The process of bone formation does not proceed further. There is no deposit of lime salts. The periosteum is loosely attached. The long bones bend easily, especially the tibia, producing the characteristic bow-leg, which may occur even before the child walks, when it is caused by sitting cross-legged. The thighs may also become bowed, the inner ends of the condyles prolonged downward and the tibia set outward, producing the “knock-knee.” This does not, however, appear until the child begins to walk. In extreme cases the long bones may fracture. Sometimes both the femora and tibiæ are bowed forward.

Quite as characteristic are the changes in the chondral ends of the ribs and in the shape of the chest. The former are enlarged and nodular at the junction with the bone, producing the well-known beaded appearance, which may often be recognized at a glance. The altered shape of the chest-walls, most marked in children who have had much cough, is due to the yielding of the soft costal ends of the cartilages and to a falling-in of the ribs at these points, while the sternum and cartilages are pushed forward, as seen in Figure 82.

This is especially the case in the region between the fourth and eighth ribs, which may be so bent in as to form a vertical groove, increased during inspiration. Associated with this is sometimes a transverse groove, known as Harrison's groove, starting at the ensiform cartilage and passing transversely outward toward the axilla. At the same time the arch of the ribs below may be widened and the belly thrown forward by the arching inward of the vertebræ. Extreme degrees of this chest deformity produce the prominent sternum constituting the "chicken-breast" or "keel-shaped" thorax. Other changes in the bones are an exaggeration of the normal double curve in the clavicle; a bending of the humerus, usually at the insertion of the deltoid, sometimes produced by lifting the child by the arms; the radius and ulna may be curved and twisted, the articulations knotted and bulbous, loose and mobile, because of relaxed ligaments. The spine is also often altered, the change being for the most part an increase in the normal curve outward in the cervico-thoracic portion and inward at the lumbo-sacral. In other cases there is a lateral curvature. The scapula is often thickened. The pelvis is distorted and twisted, and the antero-posterior diameter is markedly lessened. The rickety pelvis is one of the well-recognized causes of dystocia. These changes are all the result of mechanical causes, such as the weight of the body or muscular traction.

Chemical analysis of rickety bones approximately reverses the normal proportion of organic and mineral constituents (calcium salts), reducing the latter to 35 per cent., while the gelatinous or organic matters amount to 65 per cent.

An *enlarged liver* and *spleen* are usually present, and sometimes also the mesenteric glands are enlarged.

Symptoms.—(See also Morbid Anatomy.) The earliest symptoms noticed are not invariably the same. There is usually *profuse sweating*, especially about the head and neck, and a mild degree of fever, as the result of which the child is inclined to throw off the bed-clothing. There is evident discomfort in being handled. The last symptom is apparently due to a *tenderness* of the skeleton, causing pain when the child is raised or danced up and down after the manner of amusing children. Along with these are the less distinctive symptoms of indigestion, indicated by nausea and vomiting, offensive stools containing partly digested milk, and flatulent distention, causing the belly to be prominent. Among other less essential symptoms may be mentioned *nervousness*, *restlessness*, *peevishness*, and *infantile convulsions*, the relationship of which to rickets is not accidental and was pointed out by Jenner. Tetany and laryngismus stridulus are also often symptoms.

Concurrently it is noticed that teething is delayed, and we have the authority of Sir William Jenner that if there are no teeth at nine months there is something rickety about the child. But I am confident that I have seen dentition delayed after this time in children who were not and who did not become rickety. In rickety children the teeth which are cut soon decay.

Muscular weakness is characteristic, so that the child cannot sit up and makes but a feeble or no effort to walk. Such muscular weakness has been mistaken for paralysis, whence it has been called the *pseudoparesis* of rickets. Close upon these symptoms, or at least within two or three weeks of the first symptom, follow the *skeletal changes* described under morbid anatomy, page 826. The head is large in comparison with the face, the skin is pale and thin, and the child has often an old and a wise look quite beyond its years. The appearance of the beaded ribs, the bowed legs or "knock-knees," prominent belly, and curved spine often serve to make the diagnosis easy at a glance. The prominent belly requires some further description, as it varies somewhat at different periods. Before the child walks the normal cervical anterior curve may be increased and a posterior curve present from the first dorsal to the last lumbar vertebra, which may be recognized by holding the child up. After it begins to walk, however, the dorsal spine continues curved backward while the lumbar projects forward. The latter, therefore, contributes also to the prominent belly produced in part by flatulent distention, and partly at times by an enlarged liver and spleen.

Complications.—These include especially bronchial catarrh and bronchopneumonia, the effects of which are aggravated by the conformity of the chest, the weakness of the ribs, and the feebleness of the respiratory muscles. Collapse of the lung is often a consequence of lung affections. Chronic hydrocephalus is a complication, while many of the conditions mentioned under symptomatology—viz., diarrhea, convulsions, laryngismus stridulus, and the like—may also be so regarded. The rickety child is weak and is vulnerable to all the illnesses of childhood.

Diagnosis.—This is usually easy, although, of course, all the symptoms detailed are not always present in their typical expression. The various spinal curvatures may be somewhat confusing. Thus, the question of *caries* may arise. But the rickety spine differs from that of *caries* by the wide curve, the absence of angularity, the flexibility of the spine, and the fact that by laying the child flat on its face the curve disappears. The other symptoms of rickets are also present. The lordosis of rickets produces a deformity resembling that of *congenital dislocation of the hip* and of *hip disease*, but here again other signs of rickets are present, while the distinctive signs of the disease in question are absent.

Prognosis.—Rickets is never in itself fatal, and the course is toward recovery. But the child is always in danger from the complications. Such are bronchitis, bronchopneumonia, laryngeal spasm, and convulsions. Walking is always delayed, and the child may be still unable to walk at the end of the second or third year. Mention has been made of the fact that the rickety pelvis in women is one of the most frequent causes of difficult labor.

Treatment.—We should seek to avert rickets by a judicious prophylaxis, which consists in keeping the health of the mother at the highest point at all times; this, not by organic food only, but by a judicious admixture of salts such as are contained in the whole cereal grain, especially in wheat and barley. Frequent pregnancies and prolonged nursing, being acknowledged causes, should be interdicted.

The treatment of the child should be *dietetic, medicinal, hygienic, and operative or mechanical*. As the condition depends often upon the lack of ordinary good food, the simple addition of such food in lieu of the mother's milk, if this be found defective, may be all that is required, especially if it be possible to secure that rarely attainable article, a healthy wet-nurse. In the

absence of this beef-juice, the yolk of eggs, peptonized milk, and beef peptonoids may be substituted. Due consideration must, however, be paid to digestion in the selection of food, the stools should be examined daily, and if undigested residue is found, the food should be changed. Pepsin and hydrochloric acid in doses adapted to the age of the child should be given, while the predigested foods are often highly useful. Cod-liver oil inunctions are invaluable, and though in some respects unpleasant, I have seen so many children seemingly wrested from death by their use that I value nothing more highly. Saccharine and starchy foods should not be allowed, except in very moderate quantities. The flours of the whole cereals, well baked and cooked as thin gruels and strained, make a suitable addition to the food, while the fruit-juices of orange and lemon may be given in small quantities. Medicines should be cautiously given. Among them are lime salts, as the hypophosphite of calcium or lactophosphate of calcium, ten grains (0.65 gm.) of either three times a day, or lime-water, or the official syrups containing the salts mentioned. Doses should be carefully regulated, as digestion is feeble. Minute doses of iron, preferably the citrate or malate, may be given. Phosphorus was recommended by Kassowitz, and is indorsed by Wegener, Jacobi, and Strümpell, in doses of from 1-200 to 1-100 grain (0.00033 to 0.00066 gm.) two or three times a day dissolved in olive oil or cod-liver oil. The principle of the administration of these two drugs is different. The salts previously mentioned are convenient modes of administering calcium, while phosphorus is supposed to stimulate *bone growth*.

The hygienic treatment is more important than the medicinal. Fresh air and outdoor life are indispensable. If the child is warmly clothed and well protected, it may be taken out even in cold weather. *It should not be allowed to walk or even to sit up unless properly supported*—in fact, should be handled as little as possible.

Mechanical appliances may be employed with advantage, especially in lateral bowing, before the bone is hardened. Forcible manual straightening may also be employed in moderate grades of deformity, but should be relegated to the experienced orthopedic surgeon. After ossification is complete, deformities may be corrected by the orthopedic surgeon, by osteotomy, chiefly of the bones of the lower extremities, though the radius and ulna are sometimes operated on. Osteotomy of the pelvis has been suggested by Macewen in parturient women in whom delivery is impossible, but a recently revived operation, symphysiotomy, has made it unnecessary.

OSTEOMALACIA.

Definition.—A softening which takes place in the bones by a solution of lime salts subsequent to their complete development.

Etiology.—The precise cause is unknown. A geographical distribution, however, exists, in accordance with which it is common on the Rhine, in Westphalia, in Eastern Belgium, and in Northern Italy. In this respect it is similar to goiter, which prevails in special localities, and it has been suggested on this account that it may be due to some local cause. It is for the most part a disease of adults between thirty and forty years old, and of women more than of men. It is favored by unhygienic surroundings, such as damp and badly ventilated dwellings. Frequent pregnancy is supposed to be an exciting cause.

Pathogeny.—There is, primarily, *increased vascularity*. To this succeed a *solution* and disappearance of the *lime salts* of the bone. These take place from within outward, from the marrow cavity, dissolving out first the lime salts and then melting away the matrix, enlarging the central cavity until the cortical portion acquires a paper-like thinness. The whole bone has been compared to an “inflated and dried intestine.” The product of the solution at first is a mucoid matter that mixes with the marrow. The latter soon loses its vascularity and gradually acquires a thinner but still viscid character and a yellow color. The periosteum is likewise hyperemic and at first thickened. The process is compared to the artificial solution of the earthy salts from bone by hydrochloric acid, and it is supposed that the solvent agent exerts its effect from the medullary spaces and Haversian canals. It has been suggested that lactic acid is the solvent, as it has been found in the medullary canal and in the urine of subjects of osteomalacia. The process extends unevenly. *It differs from rickets in being a degeneration of fully formed bone, while the latter is a degeneration of developing bone.*

Morbid Anatomy.—The favorite seats of the process are the vertebræ and the bones of the pelvis and thorax. The result in the former is an S-like curve of the spinal column, due to a kyphoscoliosis or backward curvature of the dorsal and a lordoscoliosis or forward curvature of the lumbar part, while the cervical portion in connection with the upper dorsal portion protrudes anteriorly. The thorax is distorted and compressed laterally, while the sternum is prominent and bent. The pelvis is also compressed laterally, the symphysis projects like the prow of a ship, and the sacrum projects forward producing a deformity of the pelvis often discoverable only by internal examination.

Symptoms.—The first symptom is usually *pain*, deep seated and severe, oftenest in the sacral region, nape of the neck, back, and thighs, and this pain is persistent and increased by motion, giving rise to a hobbling gait. There is also *tenderness*. *Walking*, therefore, becomes more and more *difficult* and finally impossible, and the patient takes to bed. But this affords no relief, the pain being kept up by the pressure of the bed-clothing and the weight of the body. In the meantime the deformities described under morbid anatomy take place, though those of the pelvis are less obvious externally. *Difficult labor* is an inevitable consequence should the patient conceive, just as it is in rickets. *Dyspnea* is a frequent consequence of compression of the lung by the distorted thorax. *Fractures*, complete and incomplete, are frequent events, even of the ribs as well as of the extremities. In this respect osteomalacia differs from rickets, in which the bones bend but do not break. Such fractures repair imperfectly. Sometimes, on the other hand, the limbs are soft and yielding, and may be bent like lead pipe. The bones of the head and face are for the most part exempt, though the head is much bent toward the chest, making the stature lower.

The *general condition* of the patient often remains for a long time unaltered. There is little or no fever. The organic functions are normally maintained. The presence of lactic acid in the urine has been mentioned. It is said that phosphoric acid is diminished. Albumin is also sometimes present. Calcareous concretions have been found in the kidneys and bladder.

Diagnosis.—At first there may be doubt as to the nature of the disease, but as the characteristic symptoms present themselves, its real nature becomes evident. *Disease of the vertebræ and cord* has been confounded with it, but the hobbling gait peculiar to it does not usually resemble any of the gaits of

spinal disease. Being a disease of adults, it is not likely to be mistaken for *rickets*. Moreover, it is a disease which affects the shafts of bones rather than the epiphyses.

Prognosis.—The disease is usually ultimately fatal, although death is often long deferred and the course is chronic—from two to ten years. Arrest sometimes occurs, but is only temporary. The disease again starts, and its course is generally irresistible. Death commonly takes place from exhaustion or from some complication like pneumonia. Recovery is not impossible. The so-called cystic degeneration of bone is said to be a consequence.

Treatment.—Theoretically, the indications are the same as for rickets—viz., to supply the blood with lime salts. Practically, they have not proved of much value. They may, however, be prescribed in the shape of the syrup of the lactophosphate of lime in the dose of from one to two fluid drams (4 to 8 c. c.) or the syrup of the hypophosphites in the same dose or the latter in combination with iron or with cod-liver oil. Proper hygiene and good food are of the utmost importance. Phosphorus itself is a drug highly commended. (See Rickets.) Strümpell gives the following prescription for it:

℞ Phosphori,	0.01 gm (3-20 grain
Olei amyg. express,	10.00 (150 grains)
Misce, deinde adde,		
Pulv. acaciæ,	} aa	5.00 gm. (75 “
Syrupi, simplicis,		
Aquæ dest.,	80.00 gm. (1200 “
M. Sig.—Two to four teaspoonfuls a day.		

Women who are subjects of osteomalacia should be warned against marriage.

PURPURA.

SYNONYMS.—*Morbus maculosus*; *Peliosis*.

Definition.—A name given to several dyscrasic states, all attended by subcutaneous or submucous extravasations of blood. Such extravasations do not disappear on pressure, and vary in size from that of a pin-point to areas a centimeter or more in extent. When minute or punctiform, they are called petechiæ; when larger than this, ecchymoses. An indisposition on the part of the blood to coagulate is commensurate with the tendency to extravasation. Purpura is always a symptom rather than a disease, but in certain conditions it forms the most conspicuous symptom of a group which scarcely admits of any other classification. In this event an adjective term derived from some more conspicuous one of these symptoms, or from the name of some investigator who has described the condition, is added to give precision. In other instances it is so purely a symptom and plays so minor a rôle in the disease that it is called symptomatic. Under any circumstances it is not always easy to keep the varieties distinct.

SYMPTOMATIC PURPURA.

This includes the forms of purpura in which the petechiæ and ecchymoses are usually of minor importance. In a few instances in which the dyscrasia is very great they become by their number and extent indices of the degree of such dyscrasia. Such are:

1. The purpura which often invades the extremities of the old (senile purpura).

2. The purpura of the infectious diseases (infectious symptomatic purpura), especially typhus fever, smallpox, scarlet fever, measles, pyemia, mycotic endocarditis.

3. The purpura of poisons (toxic symptomatic purpura)—as, for example, that which occurs in connection with venomous snake-bites, or with overdoses of certain medicines, such as ergot, mercury, copaiba, quinin, iodid of potassium, and others. Certain persons possessed of idiosyncrasies acquire purpura on the administration of much smaller doses. In these the extravasations may occur anywhere on the body.

4. The purpura attending certain diseases which, though not infectious, induce cachectic states—viz. (cachectic symptomatic purpura), cancer, tuberculosis, Bright's disease.

5. Certain nervous diseases (neurotic symptomatic purpura), including locomotor ataxia, myelitis, rarely neuralgia, and hysterical states associated with the bleeding points known as *stigmata*.

6. Mechanical symptomatic purpura, when induced by some cause resisting the onward movement of the blood, as a paroxysm of whooping-cough, croup, or an epileptoid fit.

The diagnosis of these conditions is a purely etiological one, and the prognosis and treatment are those of the diseases causing them.

SCURVY.

SYNONYM.—*Scorbutic Purpura*.

Definition.—A disease characterized by a dyscrasic state of the blood, which favors subcutaneous or submucous hemorrhage, by a peculiar spongy state of the gums, and extreme general weakness.

Etiology.—Less than half a century ago the idea of scurvy was always associated with the seafaring life, since sailors were its chief victims, though almshouses and prisons also held their complement. In the food of these persons fresh vegetables and vegetable juices and organic salts were wanting. So it came to be acknowledged that such privation was responsible for scurvy, and proof of this belief was thought to exist in the fact that with the quicker voyages of ships and a supply of suitable food, scurvy had almost vanished from the nosology. It appears, however, that, after all, the effect of such causes is predisposing and the disease may be really infectious, being due to some as yet undetected organism. Especially firm in this belief are those who have, by reason of its distribution, had the best opportunities for its study—as, for example, in Russia, where the disease is endemic, sometimes epidemic. Finally, it turns out that not only sporadic cases, but even epidemics, occur quite independently of the dietetic causes named.

At the present day scurvy has become a rare disease, but is still met in camps, prisons, almshouses, and situations where the food causes named exist along with dampness, foul air, and depressing influences generally, among which nostalgia is supposed to be especially potent. The effect of the food causes has been held by Garrod and by Ralfe to be the deficiency of the potassium salts, more especially of the alkaline carbonates derived from the conversion of the organic salts of the vegetable and fruit juices—viz., the malates, tartrates, citrates, and lactates. Experimental proof of the latter is adduced

by feeding animals upon acid salts, the effect of which is to impair their nutrition and to produce dyscrasic states of the blood similar to those of scurvy and followed by like extravasations.

The disease attacks the old and young of either sex, though the old are more susceptible, and it happens, probably from accidental circumstances, that more males are affected than females.

Reference should be made to the observations of my colleague J. P. C. Griffith,* who has shown that scurvy has appeared in children who have been too long fed on certain artificial infant foods.

Morbid Anatomy.—This consists in (1) alterations of the blood; (2) the extravasations of blood, which may be anywhere,—subcutaneous, submucous, intermuscular, and interstitial. The blood changes are not distinctive. The blood is dark and fluid, the blood-corpuscles and hemoglobin are concurrently reduced, and there is no leukocytosis. Rarely there is even sloughing of the skin and mucous membrane, leaving ulcerated patches in the skin and bowels. The spleen is soft and enlarged, and there may be degenerative changes as well as hemorrhages in the kidneys, liver, and muscles.

Symptoms.—The more evident symptoms are the *changes in the gums*, and the *deep-seated and superficial hemorrhages*.

The *gums* are swollen, soft, and spongy, with disposition to bleed easily. In the more severe cases there is ulceration, with loosening and falling out of the teeth, the tongue is swollen, and the breath excessively foul. The gums of young children and of the aged are more often uninvaded. In rare cases only is there *necrosis* of the jaw.

The *hemorrhages*, always petechial, appear usually first in the lower extremities, then on the arms and trunk, but they occur anywhere as roundish, dark-red spots which may assume larger size. They are rare in the face and scalp, and are less common under the mucous membranes and in deep-seated tissues. Subperiosteal hemorrhages may occur. Nasal hemorrhages may be frequent, melena and hematuria rare, hematemesis and hemoptysis still rarer. The extravasations are slow to disappear, even when recovery takes place. The occasional sloughing has been referred to. A residual, slowly healing ulcer results.

Other symptoms are *debility*, extreme in severe cases, and *anemia*. The *pulse* is small, feeble, and frequent, and corresponds to the heart's action, which is sometimes irregular; more rarely is it slower than in health. The *temperature* is normal, rarely somewhat elevated. *Sore throat* is mentioned as a premonitory symptom. In bad cases *nephritis* and *endocarditis* occur. Articular swelling is an occasional symptom: it is one of the results of the dyscrasia; so are *wheals* and *vesicles*.

Diagnosis.—This depends, as stated, on the etiology, the gingival changes, and the hemorrhages. It is these which chiefly distinguish it from the other forms of purpura.

Prognosis.—Sporadic cases always get well, and epidemic cases usually, unless too far advanced before coming under treatment.

Treatment.—This is usually most satisfactory when the necessary conditions are fulfilled—a restored wholesome hygiene and suitable food. Good ventilation and outdoor life in healthy localities, with plenty of fresh vegetables, fruits, and fresh meats, ordinarily suffice to accomplish a prompt cure. It is usual to give lemon and orange-juice as the types of the fruit-juices. Tonics and roborants, of which iron, quinin, and strychnin are the

* "The Relation of Scurvy to Recent Methods of Artificial Feeding," "N. Y. Med. Jour.," Feb. 23, 1901; Scurvy, Not Rheumatism," "Phila. Med. Jour.," Feb. 2, 1901; "American Pediatric Society's Collective Investigation on Infantile Scurvy," "Arch. of Ped.," July, 1898.

type, are the medicines needed. Calcium chlorid may be used in doses of from 5 to 15 grains (0.3 to 1 gm.). Antiseptic and astringent mouth-washes should be used, and ulcers should be stimulated by local applications, of which nitrate of silver in solution is the best.

INFANTILE SCURVY.

SYNONYMS.—*Barlow's Disease; Periosteal Cachexia.*

Definition.—A cachectic condition of infants, associated with subperiosteal hemorrhagic extravasations.

Historical.—In 1878 and again in 1882 Cheadle published in the "Lancet," and about the same time Gee published as occurring in England, cases of a cachexia in very young children, associated with hemorrhage, and due to imperfect food-supply. About the same time Barlow made an exhaustive study of the subject and gave his results in the "Medico-Chirurgical Transactions," volume xlvi., 1883, and in the Bradshaw Lecture for 1894. W. P. Northrup published a paper on "Scorbutus in Infants," describing cases in this country, in the "New York Medical Journal," December 12, 1891, and another with Crandall in the same journal, volume i., 1894.

Symptoms.—Barlow's account is graphic, almost sensational, but I gather that the condition exists essentially in a *hemorrhagic subperiosteal extravasation*, causing thickening and tenderness in the shafts of the bones beginning in the lower extremities, but invading also the forearm and arm, more rarely the scapula, vault of the cranium, and face. Rarely there is intermuscular extravasation. The resulting *tenderness* and *pain on motion* cause the child to keep quiet, with the legs drawn up, and to cry out when handled. The lesions are symmetrical. The *joints* remain *free*. The sternum and adjacent cartilages and a small portion of the contiguous ribs may be sunk bodily back as though subjected to violence. There may be a sudden prolapse of an eyeball. Along with these symptoms are profound *anemia* and *erratic temperature*, which may be subnormal, normal, or as high as 102° F. (38.9° C.).

The disease occurs at any period after four months, but it is most common from the ninth to the eighteenth month, and is of rapid development.

Treatment.—It has been ascribed to the use of the proprietary forms of condensed milk and preserved foods for infants. These should therefore be omitted, and fresh cow's milk substituted, with beef-juice and strained gruel made from whole-grain cereals only. Orange-juice or lemon-juice in water may also be given in moderate doses. Under this treatment the prognosis is favorable and recovery prompt.

ARTHRITIC PURPURA.

SYNONYM.—*Rheumatic Purpura.*

Definition.—The characteristic feature of arthritic purpura is a joint involvement. Hence it is also called rheumatic purpura, though its rheumatic nature cannot be said to be absolutely settled.

Symptoms.—Three varieties are distinguished:

1. *Simple Arthritic Purpura.*—This is a mild form, most frequent in children. The *articular pain* is very mild and attended with but slight fever. The *spots* are found for the most part on the *legs*, more rarely on the trunk and arms. There may be *digestive derangement*, manifested by loss of appe-

tite and diarrhea. The condition terminates favorably in a week or ten days. It may be associated with a mild degree of anemia.

2. *Peliosis Rheumatica*.—Schönlein's disease. This is a much more serious affection from every standpoint, occurring usually in young persons from fourteen to thirty. The *joint* symptoms are pronounced and multiple, and there are decided swelling, *pain*, and *fever*, with a temperature of 101° to 103° F. (38.3° to 39.4° C.). The *eruption* first appears on the legs near the affected joint, but I have seen it present extensively on the arm, distant from the joint, followed by sloughing; in the same case were retinal hemorrhages. *Sloughing* and *necrosis* of the skin even have occurred. It may be simply purpuric, or may be associated with urticarial wheals—exudative—or vesicles (pemphigoid purpura). When severe, it is often associated with hematuria and hemorrhagic nephritis with edema. I saw, with Agnew and Osler, a remarkable case in which the latter condition hastened a fatal termination by uremia. Endocarditis is also a complication.

3. *Henoch's Purpura*.—This is a variety occurring most often in children, but also in adults, characterized by *severe gastro-intestinal* disturbance in addition to the previously named symptoms. There are pain, vomiting, and diarrhea, rarely intestinal ulceration, and perforation with fatal peritonitis. Acute enlargement of the spleen has been observed.

Here, also, recovery is the rule.

Diagnosis.—The diagnosis is easy by reason of the associated joint symptoms, but the same doubt exists as to a true rheumatic nature in all forms.

Prognosis.—This is regarded as favorable, but fatal terminations do occur, especially in peliosis rheumatica in which there is nephritis. Relapses in this form may occur at the same time of year for several years in succession.

PURPURA HÆMORRHAGICA.

SYNONYM.—*Morbus maculosus Werlhofi*.

Symptoms.—This form of purpura is characterized by *hemorrhage* from the mucous membranes, including nose, mouth, palate, stomach, and intestinal canal, in *addition to extensive subcutaneous ecchymosis*. The brain and kidneys and serous membranes may also be seats of hemorrhage—apoplectic symptoms indicating the first. A *prodrome* of languor and weakness may precede for a couple of days, to be succeeded by a rapid succession of ecchymoses and hemorrhages. More decided constitutional disturbances follow, including typhoid symptoms and fever, though the latter is mild and may be altogether absent, even in severe cases.

In the *purpura fulminans* the hemorrhages are mainly confined to the skin, producing confluent ecchymoses and dense infiltrations covering large areas, with sanguineous blisters. The internal organs, on the other hand, remain free, while the urine and the bowel evacuations are natural. At times there is fever; at others, not. Hemorrhagic purpura has occurred after pneumonia and scarlet fever, and again in children apparently healthy.

Diagnosis.—As to diagnosis, *scurvy* is almost the only condition liable to be mistaken for purpura hæmorrhagica. In the latter the gums are intact, and there is an absence of the conditions favoring scurvy.

Prognosis.—The termination is usually favorable in from ten days to two weeks, although there may be fulminating cases, usually in children, terminating fatally in twenty-four hours. Severe cases recover more slowly.

Treatment of Arthritic Purpura and Purpura Hæmorrhagica.—

Treatment is best directed to improving the quality of the blood and to building up the general tone rather than to the control of the hemorrhage, though the latter must not be entirely ignored. Almost all that has been said of the treatment of scurvy is applicable to these forms of purpura. Iron and arsenic are the typical roborants and blood-builders, to which nutritious food, including vegetable juices, is to be added. Arsenic should be given in full doses, beginning with small ones and ascending rapidly.

In the articular forms the salicylates and salicin should be used in such doses as the stomach will tolerate.

Of the astringent remedies found serviceable may be mentioned ergot, in doses of from five to thirty minims (0.3 to 2 c. c.) of the fluid extract; persulphate of iron, in doses of from 1-4 to 1-2 grain (0.016 to 0.032 gm.); acetate of lead, one to three grains (0.0648 to 0.2 gm.); dilute or aromatic sulphuric acid, five to fifteen minims (0.33 to 1 c. c.).

HEMORRHAGIC DISEASES OF THE NEW-BORN.

Hemorrhagic Syphilis of the New-born.—Usually about from the *third* to the *fifth* day after birth hemorrhage is observed at the navel of the child, or it may occur earlier. Blood also flows from the mucous membranes of the mouth, the bowels, and the kidneys. The skin becomes jaundiced. The stomach rejects food, and though it may appear well nourished at birth, the child rapidly wastes, and dies at the end of a *week* or *ten* days. The autopsy discloses *syphilitic lesions* in the liver, lungs, nasal passages, and elsewhere.

Epidemic Hemoglobinuria of Infants, or Winckel's Disease.—As described by Winckel in 1879, in an epidemic at the Foundlings' Hospital, at Dresden, the first symptoms, noticed usually on the *fourth day after birth*, are a bluish tinge on the skin of the face, trunk, and limbs, with a more or less icteroid hue. There are *fever, rapid breathing*, and sometimes *cyanosis*. Occasionally there are *vomiting* and *diarrhea*. The *urine* is light brown, albuminous, contains methemoglobin, and deposits a sediment consisting of epithelium and tube-casts. The *blood* contains an excess of leukocytes and numerous granular bodies. The child lives, on an average, two days, though in one case death supervened in nine hours. The autopsy in this case disclosed yellow staining of the skin and internal organs; the spleen was large, hard, and darkened; the kidneys were dark brown in color, their tubules being filled with granular pigment; the liver and heart were fatty. There may be punctiform hemorrhages on the surface of the internal organs. There is no septic condition of the umbilical vessels. An infectious origin is not unlikely.

Acute Degeneration of the Internal Organs of the New-born, or Buhl's Disease.—How far this disease, described by Buhl in 1861, differs from Winckel's disease, or the latter from the former, remains to be settled, for, in the first place, fatty degeneration of the heart and liver is found in many cases of Winckel's disease, while in others there is found the general fatty degeneration of kidneys, liver, heart, etc., described by Buhl. In the second place, infants surviving the first few hours after birth in Buhl's disease have the same symptoms as those described under Winckel's disease, while the other symptoms, such as minute hemorrhages and bile staining of various internal organs, are not essentially different.

Morbus Maculosus Neonatorum.—Still another form of hemorrhage from one or more of the surfaces, and especially of the alimentary canal, in

the new-born is described under this title. The bleeding generally begins within the *first week*, but may be as late as the second or third week. *Hemorrhage from the bowels* (melæna neonatorum) is the most frequent form, but it may be from the stomach, mouth, nose and navel, or from the navel alone. It may be accompanied by hematogenous jaundice,—indeed, by any or all the symptoms described under Winckel's disease,—but differs in the occasional presence of fever and apparent absence of postmortem lesions, though ulcers of the esophagus, stomach, and duodenum have been found. It is generally fatal in from one to seven days. All these conditions can be appropriately considered as forms of purpura.

Treatment.—The treatment of hemorrhagic affections of the new-born often avails little, though recoveries sometimes take place, especially in the last-described form, in which C. W. Townsend reports nineteen recoveries out of fifty cases collected.

The treatment demands *absolute rest* with the head low. Even the exertion necessary in nursing at the breast should be interdicted, and the infant should be fed, while recumbent, with a teaspoon, using also the mother's milk if this be not condemned as worthless. The utmost care in providing *uniform warmth* should be taken. This can best be accomplished by means of an incubator. One may be improvised, as suggested by F. A. Hoffman, out of a box in the bottom of which hot bricks are placed. Over them is swung the infant's bed. A thermometer is so inserted as to be readily observable, and the temperature is kept at 90° F. (32° C.). To *control the hemorrhage* ergotin may be used hypodermically, one grain or minim (0.06 gm.) every six hours. Gallic acid may be given by the mouth in one grain (0.06 gm.) doses, but extreme care should be taken in using remedies by the mouth.

HEMOPHILIA.

Definition.—A hereditary vice of constitution, manifested by a tendency to uncontrollable hemorrhage, occurring either spontaneously or as the result of trifling injury.

Etiology.—No explanation has as yet been offered of hemophilia other than that it is usually hereditary, though rarely also sometimes acquired. While individual instances of fatal hemorrhage were observed centuries ago, "families of bleeders" were first described in this country. Of great importance because of its bearing on the marriage of these hemophilic subjects is the fact that the tendency is transmitted through the female line rather than through the male. Thus, if a man belonging to a bleeding family who is himself not a bleeder marries a woman who is healthy and not a bleeder, his offspring are usually exempt from the affliction. On the other hand, a woman a member of a bleeding family marries, and even if she be exempt herself, she may have offspring who are bleeders. These facts were pointed out by Grandidier. Not all the children of such persons are afflicted, while the male members are more frequently subject than females. The families of bleeders are apt to be large, and their appearance is that of health, as a rule. It is said that blondes predominate, with delicate, soft skin and distinct, distended veins.

Morbid Anatomy.—Two facts of importance have been recognized—viz., that in some instances the walls of the blood-vessels have been

found thin with a fatty degeneration of the intima, and in many there is deficient coagulability of the blood. A third fact, which adds nothing in explanation of the hemorrhagic tendency, is a superficial situation of the arteries. A striking case of this kind in a blonde woman, formerly a bleeder, was for a time under my observation. Beyond this we know nothing, notwithstanding the exhaustive studies of Wickham Legg, Grandidier, and Hössli.

Symptoms.—Attention is commonly called to a bleeder by the occurrence of a hemorrhage difficult to control, though induced by some trifling cause. The extraction of a tooth is one of the most frequent of these events. It may be the prick of a pin, or a scratch, or a slight cut, as in vaccination, or no cause may be discoverable. The tendency may manifest itself at the cutting of the umbilical cord at birth, or in Jewish children at the circumcision. On the other hand, the same accidents which are without result early in life may induce the hemorrhage later. Uncontrollable epistaxis is one of the most frequent manifestations, occurring in 169 out of 334 cases collected by Grandidier. It may be induced by simply blowing the nose. Other situations are the mouth, stomach, ear, and eyelids. On the other hand, hemorrhages rarely occur in the interstices of organs, and though interstitial hemorrhages do occur, they are usually the result of trifling blows, when the well-known "black-and-blue" appearance is produced. The absence of interstitial hemorrhages, except as the result of some cause, however trifling, may be said to distinguish hemophilia from the acquired hemorrhagic tendency.

Menstruation may be very copious in women, but not fatal, while the natural loss of blood in child-bearing is rarely augmented. In the case referred to on page 837 the hemophilia disappeared with the appearance of the menopause, soon after which it was substituted by a chronic nephritis.

The external hemorrhages, including those of the mouth and nose, may be profuse and even fatal. They often last twenty-four hours or longer. When checked, reaction from them is rapid, and the victims quickly resume their natural appearance, though repeated hemorrhages may engender a permanent anemia.

Joint affections may be associated with this as with the acquired hemorrhagic tendency. They involve usually the larger joints, and may include swelling and pain, with fever, producing a close resemblance to rheumatism, or there may only be pain.

Diagnosis.—This is apparent if the family tendency is known, and any alarming hemorrhage without sufficient cause should excite inquiry.

Prognosis.—Sooner or later hemophilia is apt to be fatal, though there may be many severe hemorrhages before the last one comes. The younger the subject, the more serious the outlook. It does, however, happen that the tendency is outgrown, subsequent attacks becoming milder and milder. In the majority of cases death takes place between the first and the eighth year, and adolescence once survived, the chances of outgrowing it are greatly increased.

Treatment.—This may be prophylactic. The children of bleeding families should be carefully guarded against traumatic causes, however slight, while they should be carefully looked after from the hygienic and nutritive standpoints. Fresh air, daily bathing, outdoor exercise, and judicious measures intended to harden the threatened subject should be practiced. Plain, wholesome, and nourishing food should be given, and due

attention should be paid to digestion. As a part of the prophylactic treatment, too, is discouragement from marriage, especially in the case of women.

During an attack absolute quiet must be enjoined. Styptics are to be employed locally, rather than internal medicines. Of styptics, the solution of the perchlorid or persulphate of iron is the best, beginning at first with dilute solutions and increasing to the full strength of the official solution if necessary. Tannic acid is another good styptic, and if at hand, may be dusted well upon the part or applied on cotton to cavities. In epistaxis the nose must be plugged if the ordinary methods of applying these agents fail.

Though little is to be expected from internal remedies, they may be tried. Wickham Legg recommends the tincture of the perchlorid of iron in half-dram (2 c. c.) doses every two hours. Ergotin and acetate of lead may also be used. Suprarenal extract and its active principle, adrenalin chlorid, have also been employed for hemophilia, the former in doses of five grains every three hours. Adrenalin chlorid is used in the shape of a one per cent. solution, of which a fluid dram (4 c. c.) may be added to a half-pint or pint (250 to 500 c. c.) of normal salt solution by hypodermoclysis, or intravenous injection. If urgent 15 minims (1 c. c.) may be used undiluted and the remainder in the diluted form.

The usual treatment for consequent anemia should be employed.

SECTION IX.

DISEASES OF THE NERVOUS SYSTEM.

GENERAL INTRODUCTION.

HISTOLOGY OF THE NERVOUS SYSTEM.

The difficulties in the diagnosis of diseases of the nervous system are gradually diminishing as the thread of its histology is being unraveled. The studies of Golgi, His, Forel, Waldeyer, Ramón y Cajal, Dejerine, Lenhossé, van Gehuchten, and others have considerably altered previously accepted views. A brief statement of the fundamental features of the newer histology seems, therefore, necessary.

The studies of these and other observers resolve the nervous system into an immense number of units, to which Waldeyer has given the name *neurons*—whence the name neuron theory. It is necessary to state that the neuron theory is now being vigorously attacked, but as it is of service in explaining nervous diseases, it may be employed until the evidence against it becomes so convincing that we are free to abandon it. Each *neuron* is made up of:

1. A nerve cell.
2. Protoplasmic processes, or dendrites.
3. An axis-cylinder or axon continuous with the nerve-fiber.
4. Terminal ramifications of the axis-cylinder.

The *axis-cylinder* of a *motor* spinal cell gives off at different intervals lateral branches known as collaterals. These *collaterals* or *paraxons*, and finally the axis-cylinder itself, break up into many fine fibers, known as *terminal ramifications*, or *end brushes*, or *branch tufts*. Each neuron has been believed to be independent of every other—that is, no protoplasmic process of one neuron is continuous with that of another, nervous communication being through simple contact or proximity. More recent investigations, however, throw some doubt on this. The protoplasmic processes conduct impulses to the cell, are *cellulipetal*, as named by Cajal; the axis-cylinders conduct impulses away from it and are *cellulifugal*. The nutrition of the neuron depends largely on the cell body. If the latter is intact, the processes are preserved. If it is injured they waste, or if they are cut off they degenerate; on the other hand, the cell body suffers when its processes become diseased.

The motor neurons, having their cell bodies in the gray matter of the brain, are called central neurons; those neurons having their cell bodies in the spinal cord and in the ganglia on the peripheral nerves, are called peripheral neurons. The end brushes or terminal ramifications of a central motor neuron surround the body and protoplasmic processes of a peripheral motor neuron, while those of the peripheral neuron are in connection with a motor plate. The axis-cylinders of the central and peripheral neurons traverse chiefly the white tracts of the brain and spinal cord and the per-

ipheral nerves. The cells of the anterior roots of the spinal nerves lie in the anterior cornua of the gray matter, and have the protoplasmic processes short and the axis-cylinders long. (See Fig. 83.)

The cells of the posterior roots are situated in the ganglia on those roots; the axis-cylinders of these cell bodies divide soon after leaving the cell body, one process passing to the periphery, the other to the spinal cord. Communication between different parts of the nervous system and with the rest of the body is thus rendered possible. The processes extending to the periphery receive impressions from the exterior and carry them cellulipetal to the ganglion cells on the posterior root of the spinal nerves, whence they are conveyed by the axis-cylinders cellulifugal to the cord. This impres-

Fig. 83.—Diagram of an Element of the Motor Path—(after Strumpell, modified).

sion may result in a reflex act without the co-operation or knowledge of the brain, or it may proceed to the brain and give rise to a volitional act through the motor tract.

A motor impulse starting from the brain cortex must pass through at least two sets of neurons before it can reach the muscles. In this course it is cellulifugal from the cell in the cortex, cellulipetal to the cells in the gray matter at different levels in the anterior cornua, and thence cellulifugal from the latter cells to the various muscles of the body, ending in the end-plates. Hence we speak of the motor tract as being composed of two segments, an upper end and a lower. The neurons of the upper motor segment have their cell bodies and protoplasmic processes in the cortex about the fissure of Ro-

lando. The axis-cylinder processes run through the internal capsule and the cerebral peduncles, through the pons, medulla oblongata, and cord, ending in terminal ramifications around the protoplasmic processes and cell bodies of the lower segment. The neurons of the lower segment are those having their cell bodies and protoplasmic processes in the anterior cornua of the gray matter, while their axis-cylinders leave the spinal cord by the anterior roots of the spinal nerves, to be distributed as described. The *upper segment*, in large at least, is a *crossed tract*—that is, the neurons composing it have their cell bodies and protoplasmic processes in the cortex, while their axis-cylinders cross the middle line to end about the cell bodies in the opposite half of the spinal cord; so that motor impulses starting in the left half of the brain produce contraction in the muscles of the right half of the body, and vice versa, although both sides of the brain probably innervate unequally each side of the body. (See Fig. 83.) The *lower motor segment is a direct tract*—that is, its neurons, and the muscles to which they are distributed, are all on the same side of the body.

The path for sensory conduction is also composed of segments, but the direct route of sensory conduction is more complicated and our knowledge is much less exact. The cell bodies of the lower neurons are in the ganglia of the posterior roots of the spinal nerves and in the ganglia of the sensory cranial nerves. These ganglion cells have a single process, which, after leaving the cell, divides in a T-shaped manner, one branch running into the central nervous system and the other toward the periphery. The process which connects with the periphery is regarded by some as a protoplasmic process, while that which passes to the center is known as the axis-cylinder. The former runs in the sensory nerves, starting from the various specialized sensory apparatus of the periphery. The axis-cylinder enters the cord by the posterior roots. After entering the cord it divides into an ascending and a descending limb, which traverse the posterior columns. The descending branch runs a short distance and ends in the gray matter of the same side of the cord, giving off a number of collaterals, which also end in the gray matter. The ascending branch may end in the gray matter soon after entering the cord, or it may run in the posterior columns as high as the medulla oblongata, ending in the nuclei of the posterior columns. Thus the *lower segment is also a direct tract* terminating in the gray matter of the posterior cornua at different levels, and in the gray matter of the medulla oblongata. (See also section on Spinal Cord.) The *upper segment* starting from these is a *crossed tract*, crossing at different levels, so that sensory impressions are ultimately lodged in the brain on the side opposite that whence they start in the periphery. The so-called muscular sense, perhaps better called the sense of position, is probably conducted upward on the same side in the columns of Burdach and Goll on each side of the posterior median fissure. The exact termination of the sensory processes in the cerebral hemisphere is not known, but they pass up in the tegmentum of the pons and possibly in the internal capsule. It is believed by many that these processes terminate in the optic thalamus, and that from here the impulses are conducted to the cortex by means of another set of neurons. The motor cortex is probably also sensory, although the sensory area may be more extensive than the motor.

Both motor and sensory spinal nerve roots come from definite segments of the spinal cord. They descend a short distance within the spinal canal, unite within the intervertebral foramen, but external to the point where the roots perforate the dura mater and pass through the foramina as spinal

nerves. But in their distribution they do not retain the same definiteness, the same sensory and motor areas being supplied with nerve fibers from different segments of the cord, and there is an overlapping, as it were, of parts supplied by different nerve fibers. At the same time, by the combined aid of experiment and morbid physiology, we have learned that movements in certain muscles are accomplished by motor nerves which emanate from corresponding segments of the spinal cord, and that from certain sensitive areas are gathered up impressions which are carried to corresponding sections of the spinal cord. Nay, more. By the same means we have learned that there are areas in the cortex of the brain that preside over certain motions, and areas which have to do with sensation; though with respect to the latter our knowledge is much less definite. We know more of the cortical localization of the *special* senses than of general sensibility and pain. These facts are the foundation of what is known as *topical diagnosis*, in the case of the brain as *cerebral localization*, by which is meant the inference, from the study of local derangements of sensation and motion, of the more or less exact site of lesions in the nervous centers. These will be considered with appropriate detail in our study of the diseases of different parts of the nervous system.

GENERAL SYMPTOMATOLOGY.

(INVESTIGATION OF A CASE OF NERVOUS DISEASE.)

The advantages of a careful method in the study of disease are perhaps more apparent in the case of the nervous system than in that of any other of the anatomical divisions of the human body. This is partly because of the number and variety of the affections to which the nervous system is subject, and partly because of the association of certain identical symptoms with widely different lesions.

The primary steps of family and personal history are the same as for other diseases, including age, sex, occupation, and whether married or single. We may therefore pass at once to the study of such symptoms as are special.

I. PHENOMENA OF MOTION.—It is immaterial whether we set out with sensory or motor phenomena, but it appears somewhat easier to begin with derangements of motion, and of these (1) *voluntary motion* is naturally first investigated. To this end, the patient is asked to move his limbs, while the strength of whatever motion he is capable is easiest measured by resisting it, and by testing the power of his hand-grasp. For more accurate measurement the dynamometer is used, an instrument devised to measure both compression and traction, although it is more commonly restricted to the former. Advantage may be taken of the fact, too, that the same motion requires different degrees of strength in different positions of the body. Thus it is easier to draw up the thigh when lying on the back than when on the side, and it may be possible in the former position when it is not in the latter. Both extensor and flexor muscles must be thus tested. By such an investigation we discover the presence of a complete *paralysis* or total loss of voluntary motion, and *paresis* or simple weakening of such power.

By a *monoplegia* is meant an isolated paralysis of one part of the body, as of an arm or a leg. By a *hemiplegia* is meant a paralysis of the entire

half of the body, including half of the face, one arm, and one leg, also known as unilateral paralysis. By a *paraplegia* is meant a simultaneous paralysis of corresponding halves of the body. Paralysis of the two arms is known as a *superior, or brachial, paraplegia*, of the two legs as an *inferior, or crural paraplegia*, while the word paraplegia alone is often used for the latter condition. A *diplegia* is a paralysis in which upper and lower limbs are affected on both sides of the body, usually attended with spasm of all the extremities, although the term is also employed for bilateral facial paralysis. Though commonly congenital, diplegia may also be acquired.

Impairment of voluntary muscular power, as thus tested, must be the result of structural change in the motor area of the cortex, in the great motor tract of the brain or cord, or impairment in the integrity of the efferent nerves, or it may be more rarely in the muscle itself, "myopathic palsy"; or the power of the will may be abrogated. In diseases of the peripheral nerves, when the paralysis is called peripheral, it is limited to the region of distribu-

Fig. 84.—Illustrating Crossed Paralysis—(after Hirt).

O. Medulla oblongata. *pyx.* Decussation of anterior pyramids. E. Nerve-fiber going to extremities. F. Nerve-fiber to face.

tion of the affected nerves, whether one or many. It may be said in general that hemiplegia is the usual form of cerebral paralysis, while paraplegia is the expression of spinal paralysis. Monoplegias are usually either due to lesions of the cortex, or are peripheral palsies; cortical monoplegia, however, is rare.

In all hemiplegias caused by lesions above the pons the palsy, including that of the face and extremities, is on the side opposite the lesion, but in most lesions in the middle or lower part of the pons there is *crossed paralysis*—that is, there is paralysis of the extremities on one side, and of the face on the other side, provided the central fibers of the extremities and the facial nerve are involved in the lesion. The reason of this is that the central fibers of the facial nerve cross much higher than do the fibers to the extremities, and in such a lesion the intra-medullary portion of the facial nerve, and not the central fibers connecting its nucleus with the brain cortex, are injured. The result is a paralysis of the face on the same side as the lesion and of the extremities on the other. This would be the case with a lesion at *b*, Figure

84. If, on the other hand, the lesion is higher up, above the decussation of both the facial and pyramidal tracts, as at *a*, the paralysis is on the side opposite the lesion in both face and extremities. Other nerves may substitute the facial in this crossed paralysis as the oculomotorius (third nerve) or hypoglossal (twelfth nerve) or abducens (sixth nerve). In rarer instances it is possible that a lesion at the very decussation of the pyramids, by cutting the motor fibers of one extremity before they cross, and those of another after crossing, may produce the very rare event of paralysis of an arm on one side and of a leg on the other. That this is theoretically possible may be seen from Fig. 85, in which the black lines represent fibers to the upper extremities and red lines fibers to the lower, and the red circle the seat of a small hemorrhage.

(2) Having determined this question of muscular strength, and the corollaries which grow out of it, we have next to ascertain to what extent the power of *co-ordination* is influenced. Every muscular act requires the duly proportioned co-operation of a number of muscles; and as the complexity of the act increases, the number of muscles required to co-operate also increases. Such co-operation is termed *co-ordination*, and its absence is recognized in the staggering gait of the drunkard, and the condition is known as *ataxia*. There are certain parts of the nervous system which

Fig. 85.—Illustrating the possibility of paralysis of arm on one side and of leg on the other.

preside over co-ordination—such as the cerebellum, and the posterior columns, and probably the direct cerebellar tract, of the spinal cord. Disease of any of these may, therefore, produce ataxia. The ataxia or tabetic gait is described under *tabes dorsalis*, p. 926.

A corollary, growing out of the investigation of the co-ordinating power, is the study of *station*, or the steadiness with which one stands with the eyes closed or open, and it is measured by sway of the head and body, laterally and anteroposteriorly. In health a lateral sway of the head exists to the extent of half an inch (1.25 cm.), and an anteroposterior sway of an inch (2.5 cm.). A sway much beyond these limits is abnormal.

(3) After ascertaining the condition of voluntary motion, co-ordination, and station, we must inquire into the question of possible *motor irritation* or *excessive muscular action* or *spasm*. Spasm may be continuous,—*i. e.* lasting for minutes, hours, or days,—when it is known as *tonic* or *tetanic*; it may be intermittent or *clonic*; or it may be an admixture of both, when it is termed *tonic-clonic*. Tonic spasm is well illustrated by *trismus* or lock-jaw, while tetanic contraction of the muscles of the back produces *opisthotonos*, in which the vertebral column is arched and the body rests upon the back of the head and upon the heels. Tonic spasms are often attended with pain, probably due to pressure on intramuscular nerves,

when they are called "cramps." Spasm occurs also in involuntary non-striated muscular tissue. The presence of spasm implies irritation of motor centers, motor tract, or motor nerves, but motor irritation may also be excited secondarily by some reflex route, the result being a reflex spasm.

Spasm and paralysis are often associated. Thus, a limb may be paralyzed in a state of contraction, exhibiting a peculiar rigidity, and to such a condition the name *spastic paralysis* is applied. This condition may also exist as a state of persistent contraction of the antagonists of the paralyzed muscles, constituting the so-called *contractures*. Paralysis in which there is no such resistance to passive motion are known as *flaccid paralysis*.

Through the combination of tonic and clonic spasm result different varieties of morbid involuntary movements more or less complex. Some of these are the following:

1. *The Epileptiform Convulsion*.—This consists in a succession of clonic and tonic-clonic spasms extending over the whole or a part of the body, throwing the part involved into violent motion. The masseter and the temporal muscles share in the contraction, whence the tongue is often bitten. The convulsion of epilepsy is the type of this form, but the convulsions of uremia, or hysteria, and of organic disease of the brain may be epileptoid.

2. *Rhythmical Contractions*.—These occur in single groups of muscles, and are sometimes seen in apoplexy and cerebral sclerosis. They may usher in the epileptiform convulsion, or the convulsion may terminate by a gradual substitution of the rhythmical contractions for the more violent spasms.

3. *Tremors or Trembling Motions*.—These are limited movements—*i. e.*, movements of short excursion which rapidly succeed each other. "Shaking" is a more pronounced degree of tremor. Tremor is characteristic of paralysis agitans and of some other nervous affections. It occurs in old persons as senile tremor, and in abusers of alcohol and tobacco. When it occurs or increases during voluntary motion, it is known as *intention tremor*, and is characteristic of multiple sclerosis. The immediate anatomical changes on which tremors depend are not known.

4. *Single Contractions*.—These are either sudden twitchings or slow contractions of muscles, seen especially in diseases of the nerves,—as, for example, in old facial palsy. They may be single or multiple and persistent. They may be the result of direct motor irritation or reflex in origin.

5. *Fibrillary Contractions*.—These are contractions of separate small bundles of muscular fibrillæ, comparable to the "quivering" of raw flesh. They are independent of voluntary or passive motion. They may be pronounced and wave-like over the muscular substance. They are seen especially when the motor nerve cells are degenerating, as in progressive spinal muscular atrophy or bulbar paralysis. The "quivering" of the eyelid and of the orbicularis muscle below the eye, the so-called "jumper," often an annoying symptom, is an instance of this condition.

6. *Choreic Movements*.—These are inco-ordinated movements, usually separated by short intervals of time, often first seen in the face, later in one limb or over the whole body. They may be very complex and general. They are characteristic of chorea, but also accompany other nervous affections, such as posthemiplegic chorea. Under the term posthemiplegic chorea, however, a variety of movements are included.

7. *Athetosis*.—This is a peculiar slow, involuntary rhythmical move-

ment, usually of the fingers and hands, but also of the head and trunk, or of the toes. The fingers make slow movements of the nature of extension and flexion, spreading and approximating each other in a striking way. They are a symptom of certain central nervous diseases, especially of the cerebral palsies of children.

8. *Constant or Co-ordinate Spasms*.—These consist in irresistible complicated movements, like moving forward or moving in a circle or rotating on the axis of the body; also complicated forms of spasm resembling jumping, laughing, screaming, all involuntary and forced. The first group of these is especially seen in disease of the cerebellum and cerebellar peduncles, the latter in severe forms of hysteria.

9. *Nystagmus* is a clonic rhythmical oscillatory and involuntary movement of the eyeball, usually horizontal, sometimes rotatory, more rarely vertical, the result of spasm of muscles supplied by the third nerve, especially the internal rectus and *levator palpebræ*. It is noticed in congenital and acquired affections of the brain, including Friedreich's ataxia and insular sclerosis; also in albinism and in *miners* who work in dimly lighted mines, using the pick while reclining and directing the eyes laterally.

10. *Cataleptic Rigidity*.—In this there is also a tonic contraction of muscles whereby a limb remains for a considerable time in any position in which it may be passively placed, the will being abrogated. If the position of the limb be changed, it remains again in this situation, and from a resemblance to the behavior of wax under like circumstances it has received the name of "waxy flexibility." It is characteristic of certain forms of hysteria, and may be produced at times in hypnotism. In hysteria it is commonly associated with anesthesia and loss of consciousness. It is also associated with psychoses, especially grave forms of melancholia known as *melancholia attonita* and with *katatonia*.

11. *Associated Movements*.—These are unintentional and uncontrollable movements which take place in muscles coincident with other motions actually intended—as, for instance, a motion in the arm when the patient wills to move only the leg.

(4) *Bladder control* and *rectum control* are next to be looked into. Full control over the acts of these organs implies, first, an integrity of the sacral portion of the cord, in which reside the reflex centers regulating these acts; second, the integrity of volition, which, to a certain extent, fortifies such regulation; and thirdly, integrity of the afferent and efferent nerve fibers constituting the reflex arcs. Through the operation of the reflex center, bladder and rectum both empty themselves when a certain degree of distention is attained. Through the operation of the will such evacuation is put off to a convenient time. Through an undue irritability of the reflex center such evacuation is imperative, and does not bide the will, or it may take place while the will is in abeyance, as in sleep. Thus may be explained some of the cases of incontinence of urine in children. Again, if will-power is lost from disease of the cerebral cortex, evacuations of the bowels and bladder take place involuntarily so long as the sacral cord is intact, but not in a normal manner.

On the other hand, if the integrity of the sacral cord is lost, there will be no response to the sensory impressions conveyed from a full bladder or rectum, because the reflex arc is interrupted, and the organ remains unemptied; whence torpor or complete paralysis of the bowels and bladder are common symptoms of spinal disease; and while the repletion of the

latter may finally overcome the resistance of its sphincter and lead to dribbling, the rectum may go on filling up until it is emptied by the finger or the handle of a spoon. A lesion situated higher in the central nervous system than the sacral portion of the cord may also cause similar disturbance of defecation and urination, probably because of a spastic condition of the sphincters, so that the latter do not relax until the bladder or rectum becomes distended, and finally they lose all function.

Again, if it should happen that the sphincter center is destroyed while the detrusor center is intact, there would be dribbling of urine from the outset, but this is not likely to occur.

(5) The state of the *reflexes*, as they are called, is next ascertained. As here used, the term "reflex" is applied to a muscular contraction stimu-

Fig. 86.—Diagram Showing Probable Plan of the Center for Micturition—(Gowers).

MT. Motor tract. ST. Sensory tract in the spinal cord. MS. Center, and *ms* motor nerve for sphincter. MD. Center, and *md* motor nerve for detrusor. *s* Afferent nerve from mucous membrane to S, sensory portion of center. B. Bladder. At *r* the position during rest is indicated, the sphincter center in action, the detrusor center not acting. At *a* the condition during action is indicated, the sphincter center inhibited, the detrusor center acting.

lated by a sensory impression, the simplest illustration of which is the retraction of the leg of the sleeper when the sole of the foot is tickled. For diagnostic purposes the reflexes are divided into the "cutaneous reflexes" and the "tendon reflexes."

The *cutaneous* or superficial reflexes are muscular contractions which take place in different parts of the body in response to irritation of sensory nerves of the skin, as by tapping the skin lightly or drawing the finger or a pointed instrument lightly over it. The sudden application of heat or cold or the prick of a pin or pinching are modes of excitation. The contractions are generally confined to the neighborhood of the locality irritated. The skin reflexes are much more easily excited in children than in adults, and in the lower extremities rather than in the upper; also with varying facility in different persons. They receive various names, according to the situations where they are readily excited. Thus we have the "plantar reflex," where contraction is excited by tickling the sole of the feet, resulting in a movement of the toes or foot, or even in a drawing up of

the leg; the "cremaster reflex," contraction of the cremaster muscle and consequent drawing up of the scrotum on stroking or scratching the inside of the thigh. The retraction may take place on the one side of the scrotum only or on both. Then there is the "abdominal reflex," or a contraction of the abdominal muscles when the skin of the abdomen is stroked or scratched. A subdivision of the latter is the "epigastric reflex," produced by an irritation on the side of the thorax in the fourth, fifth, and sixth interspaces. The result is a dimpling of the epigastrium on the side stimulated. Cutaneous reflexes may be brought out in other portions of the body, as in the gluteal region by irritating the skin of the buttock. A contraction of the muscles about the scapula, the "scapular reflex," is produced by an irritation between the scapulæ. To test for the cutaneous reflexes is more important in the lower extremity than in the upper.

The *tendon* reflexes, or deep reflexes, are so called because they are generally elicited by striking upon tendons, while the corresponding muscles are placed slightly on the stretch, care being taken, however, to avoid all active tension in the muscle by the person examined. The blow is made either with the edge of the hand or with a hammer adapted to the purpose, commonly made of rubber. A sharp, sudden contraction of the muscle usually takes place. A similar, though less decided, contraction may be elicited by the mechanical irritation of parts analogous to tendons, as periosteum and fasciæ, and by striking the muscle itself. When the reflexes are in excess, sudden tension alone will excite them.

The most commonly tried of the tendon reflexes is the *knee-jerk*, or *patellar tendon reflex*, produced by striking the tendon of the quadriceps femoris between its insertion and the patella, while the leg is crossed upon its neighbor. The weight of the pendent leg gives a sufficient degree of tenseness. When the knee-jerk is normal, there is a decided rise of the foot with each blow of the hand hammer. This motion may become abnormally increased or diminished. A more limited movement may also be produced by striking the patella itself or the quadriceps tendon above the patella, and, when the reflex is exaggerated, by a very light tap in these situations or even on the tibia. When thus exaggerated, the reflex may also be brought out in bed, as follows: the quadriceps tendon being put on the stretch by pressing the patella downward in the direction of the leg with the finger, the patella is percussed in the same direction. With each stroke there is a contraction, and the finger and patella are drawn upward. A "clonus," or repeated contraction, may even be produced thus.

Similar is the *ankle reflex*, produced by tapping the *tendo Achillis* when the calf muscles are placed slightly on the stretch by a slight dorsal flexion of the foot. In health the ankle reflex is not always producible, but in disease in connection with this contraction is shown the most remarkable of the exaggerated reflexes, the "ankle clonus" or "foot clonus." It consists in contractions rapidly repeated so long as the tension of the calf muscle is kept up by pressing the foot toward dorsal flexion. From six to nine such contractions may occur in a second, and sometimes the whole leg is thrown into vigorous contractions. One of the best ways to obtain the *tendo Achillis* jerk is to have the patient kneel on a chair with the feet projecting over the edge of the chair; the muscles are thus relaxed, and a tap over the *tendo Achillis* produces a movement of the foot.

The Babinski reflex or phenomenon is the extension or turning upward of the toes, and especially of the great toe, obtained by stroking

the sole of the foot. In the normal individual, stroking the sole, if it produces any response, causes plantar flexion or turning downward of the toes, especially of the four outer toes. The reflex usually indicates a lesion or compression of the motor tracts in the cord and brain, and probably also of the motor centers in the brain. The response is usually best brought out by stroking the inner surface of the sole from the heel toward the toe, although in marked cases it may be elicited by applying the stimulus to the sole in various positions and directions. In infancy some observations have shown that the toes tend to turn upward normally when the sole is stimulated.

The reflex is obtainable in about 70 per cent. of cases of hemiplegia and diplegia, and in about the same proportion of diseases involving the motor tract in the spinal cord. It is found only exceptionally in cases of another class, viz., meningitis, hydrocephalus, poisoning, as for example alcohol or uremia.

Reflexes are also elicited in the upper extremities, but they are much less striking, and often cannot be shown in health. The most important of these are the *arm-jerks*, produced by striking the biceps tendon at the elbow-joint in front, or by striking the triceps tendon above the olecranon. So-called *periosteal reflexes*—reflexes excited by striking the periosteum—may in exaggerated states be produced in the supinator longus and biceps of the upper extremity by striking the lower end of the radius and ulna; also in the adductors of the thigh by striking the internal condyle of the femur.

A wrist clonus, resembling the ankle clonus of the lower limbs, may sometimes be obtained when the tendon reflexes of the upper limbs are much exaggerated. It is produced by pushing the hand of the patient forcibly backward and holding it dorsally flexed; involuntary antero-posterior movements of the hand may then occur. The *jaw-jerk* is produced by tapping on the front of the jaw, while the closing muscles of the jaw—viz., the pterygoids, masseters, and temporals—are placed on the stretch by partially opening the mouth.

The *ophthalmic* (supraorbital) reflex is a pure sensori-motor reflex, elicited by mechanical irritation (tapping lightly with the percussion hammer), or by the application of heat, cold, or pain-stimuli over the distribution of the ophthalmic nerve, especially in the distribution of the supraorbital branch on the forehead. It is manifested by a fibrillary contraction of the individual fibers in the inferior half of the orbicularis palpebrarum. The sensory impulse travels through the supraorbital nerve (purely sensory) to the pons and thence through the facial fibers (purely motor) to the orbicularis palpebrarum.

The value of the reflex depends upon the loss of the contractions from a lesion cutting the arc either in the ophthalmic branch of the trifacial, in the nucleus of the trifacial or facial in the pons, or in the fibers of the facial going to the orbicularis palpebrarum. It is therefore of value in localizing lesions of the pons in which it may be lost, and differentiating a facial paralysis due to a lesion of the nucleus or its peripheral fibers, where it is likewise lost, from a supranuclear or cortical lesion in which case the reflex is present and increased. It has the same significance as the reflex closure of the eyelids from irritation of the conjunctiva, as this also is a reflex in the distribution of the facial and trigeminal nerves.

Physiology of Tendon Reflexes.—The tendon reflexes were first studied by Erb and Westphal, and later by Tschirjew, Gowers, Jèndrássik, Weir

Mitchell, Lombard, and others. Erb explained the phenomena as purely reflex in their character, requiring the offices of a centripetal and a centrifugal nerve, an intermediate center, and an excitant. Westphal, on the other hand, regarded them as simple muscular contractions, stimulated as are the bared, quivering muscles of the recently killed animal, the tendon being simply the intermediary substance through which the irritation is conveyed. It was early objected to the purely reflex nature of these phenomena that a shorter time is usually required to produce them than to produce an ordinary reflex action, being but from 1-40 to 1-30 of a second, as compared with 1-15 of a second. But the strongest objection is found in the results of the experiment of Tschirjew, who cut all the nerves to the patellar tendon and found that the reflex still remained excitable.

Nevertheless, the tendon reflexes are arrested by any lesion which arrests reflex action. Hence reflex action must somewhere come into play. Accordingly, Gowers suggests that "the irritability is developed by the passive tension. If the muscle is relaxed, the fibers may contract, if they are struck directly, as do the fibers of a separated frog's muscle, but no contraction ensues on striking the tendon. Hence we must assume that the tension excites, by a reflex influence, a state of irritability to local mechanical stimulation, such as a tap on the muscle, its tendon, or even the vibration from a tap on adjacent parts. But only that form of mechanical stimulation is effective which suddenly increases the previous tension. It is only because the tap on the tendon does this so readily that the tendon is the means by which the contractions are most easily produced, and through which they have been chiefly studied and prematurely named. If the tension put on a muscle is gentle and gradual, it may only develop the irritability, and an additional local stimulation is necessary to produce a visible contraction. If, however, the tension is sudden and forcible, it not only develops the irritability, but produces visible contraction in the muscle thus rendered irritable, as in setting up foot-clonus." Hence, too, according to Gowers, the term "tendon reflex" is altogether too inaccurate, and he suggests the word *myotatic*, from *μυών*, muscle, and *τατινός*, extended, because tension is necessary for the production of the contractions. Weir Mitchell describes it well in these words: "A muscle moves when struck because of its innate capacity to twitch when irritated, but it does not move when excited by a blow on its tendon unless it has, besides its own excitability, a constant influx of tone-waves from spinal centers."*

Hence in a complete examination the "muscle jerk," or idiomuscular contraction, also known as mechanical muscular irritability, should be tested as well. It is done by a sharp, sudden tap on the muscle with the hammer. The response is of two kinds, first as a sudden contraction, and second as a hump-like rise which subsides slowly. The pectoral muscles are favorite sites for eliciting the pure muscle reflexes. It is, of course, impossible to deny that there is nerve as well as muscle irritation in such a blow.

Both the tendon jerk and muscle jerk are capable of re-enforcement by coincident muscular exertion, as in lifting weights or clinching fists, originally discovered by Jendrassik † in 1883 in the case of the tendon jerk. Mitchell and Lewis ‡ also discovered in the course of their study of ataxic cases that the pure *muscle* jerk or hump could be produced after the tendon

* Mitchell and Lewis, "Tendon and Muscle Jerk," "Trans. Assoc. of Amer. Physicians," vol. i. p. 13, 1886.

‡ *Loc. cit.*

reflex could no longer be elicited, and that both could be produced by the re-enforcement referred to after they had disappeared to ordinary conditions.

Significance of Abnormal Reflexes.—What are the conclusions to be drawn from modifications in the reflexes? In the first place, it is to be remembered that they vary somewhat within the limits of health. Especially is this true of the cutaneous reflexes, which are also less easily elicited than those of the tendons. In general terms, *diminution or absence of a reflex normally present in health* implies either, first, a breach of integrity somewhere in the reflex arc as formed by the centripetal nerve, the motor nerve cells in the spinal cord situated in the anterior cornua of the gray matter, and the motor nerve; or, second, an increase in the reflex cerebral inhibitory influence. The latter would be irritative. Thus, it is well known that disease of one cerebral hemisphere may lessen or abolish the superficial reflexes on the opposite or paralyzed side of the body soon after the onset of a hemiplegia. Breach of integrity may lie in the spinal cord or in the centrifugal or the centripetal nerve; more commonly, of course, in the former. If it is in the centripetal nerve, it may be accompanied by impaired sensation; if in the centrifugal, there will be defective motion. Disease of the centrifugal nerve and of the motor center in the cord may also cause degeneration and wasting of muscle with loss of its irritability.

Increase of the reflexes, on the other hand, implies increased irritability of the motor areas of the cord—when the reflexes are spinal (anterior cornua and possibly of the pyramidal fibers) or a withdrawal of cerebral inhibition, as in certain cases of destructive brain disease or disease of the cord high up. In the case of a cortical lesion the increase in the reflexes is greater on the side opposite that of the brain lesion, but the reflexes on the same side as the lesion may also be somewhat increased. In certain diseases of the cord there is a *delay* in the manifestation of the *cutaneous reflexes* after the irritation has been applied to the skin, an interval of from ten to fifteen seconds being often recorded before the response ensues. *Increase of cutaneous reflexes* is manifested by an unusual readiness of response in the normal areas, or an extension of these areas beyond their normal boundaries.

In general it may be said that absence of the tendon reflexes is especially characteristic of poliomyelitis and tabes dorsalis, and of all peripheral paralyses and neuritis; also of advanced diabetes mellitus. Abnormal increase is present in spastic spinal paralysis and in cerebral paralyses, being due in the latter instance to withdrawal of the normal inhibitory influences.

Appended is a table showing the conditions under which the tendon reflexes as represented by the knee-jerk are increased or diminished:

TENDON REFLEXES.	
INCREASED.	DECREASED.
Spastic spinal paralysis.	Poliomyelitis, acute and chronic.
Amyotrophic lateral sclerosis.	Tabes dorsalis.
Cerebral paralysis in which the inhibitory center is impaired.	Progressive spinal muscular atrophy.
Lesions of the cord above the reflex arcs.	Muscular dystrophy.
Disseminated cerebrospinal sclerosis.	Peripheral paralysis.
Irritability of cord, as in maniacal hysteria.	Neuritis.
Strychnin poisoning.	Degenerated muscle.
Cerebral palsies of children.	Exhausted spinal centers.
	Poisoning from drugs (?)
	Advanced diabetes mellitus.

INCREASED OR DIMINISHED.

Paretic dementia: Diminished as a tabetic symptom; increased in beginning spastic paralysis of the leg.
Cerebellar tumor, not infrequently diminished.

Segments of the Cord Presiding over Certain Reflexes.—Further accuracy in the application of a knowledge of the reflexes and of their modifications is secured by a knowledge of the exact portion of the gray matter presiding over the most important of them. Premising that some of these centers are of considerable extent vertically, the following from Gowers may be regarded as approximate for each of the reflexes named:

Superficial Reflexes.—Plantar, opposite second sacral nerve; gluteal, fourth lumbar; cremaster, second lumbar; abdominal, sixth to seventh dorsal; epigastric, sixth dorsal; scapular, fifth cervical to first dorsal.

Tendon or Deep Reflexes—Calf muscles (foot clonus), fifth lumbar and

Fig. 87.—Motor Points on Face and Neck—(after Erb and de Watteville.)

first sacral; knee-jerk, third and fourth lumbar; flexor digitorum and tripeps, seventh cervical; biceps and supinator longus, sixth cervical.

(6) *Paradoxical contraction* is a symptom allied to the reflexes for which no satisfactory explanation has been afforded. It was first studied by Westphal, and is only occasionally observed. In the *tibialis anticus* muscle it is induced by forcibly flexing the foot on the leg. As a result, the foot remains thus flexed for a considerable time, after which it slowly relaxes. In one case the flexion continued for twenty-seven minutes. On repeating the flexion, the phenomenon recurs, but the response gradually diminishes in intensity. Contractions induced by faradism may similarly persist. It has been noticed in both spinal and cerebral disease, including the early stage of tabes dorsalis, multiple sclerosis, and paralysis agitans. More rarely it may be induced in the flexors of the leg and forearms.

(7) *Electrical excitation of motion* is an important means of investigation in nervous diseases. In health nerves and muscles are excitable by electricity, and in diseased conditions these reactions are liable to change. Motion may be excited by electrical stimulus applied to the muscle through its nerve or directly to the muscle itself. The latter is called direct, the

Fig. 88.—Motor Points on Upper Limb, Flexor Surface—(after Erb and de Watteville).

former indirect. This is equally true of the constant or galvanic current, and of faradism or the induced current.* Hence every complete investigation should include the use of both currents.

* Under all ordinary circumstances electrical contraction produced in muscles is indirect—that is, through the nerve filaments distributed to the muscle. That the two are, however, distinct may be shown through the influence of curare, which destroys nerve irritability, but allows that of muscle protoplasm to remain.

In order to test the electrical condition of muscles and nerves, one electrode, the indifferent pole, may be held in the hand of the patient or placed over the sternum or at the back of the neck, while the other or *testing* pole is applied to the nerve or muscle, selected in accordance with the well-known nerve points of Erb in Ziemssen's plates; or the indifferent pole may be placed on the nerve point of a given muscle or set of muscles, and the

Fig. 89.—Motor Points on Upper Limb, Extensor Surface—(after Erb and de Watteville.)

testing pole applied to the belly of the same muscle. The testing electrode should be small enough to permit the isolation of a single nerve or muscle.

With the faradic or galvanic battery contractions may generally be produced in health with great facility, either directly or indirectly, although stronger currents are required for direct stimulation. Contractions take place with the galvanic battery only at the making and breaking of the current by the "commutator" or "reverser." A definite law of response exists with galvanism. Thus, beginning with very weak currents, it is observed that contraction first takes place at the moment of that closure which makes

the testing pole the kathode or negative pole—kathodal closure (KaCl). As the strength of the current is increased the kathodal closure contractions become stronger, and anodal closure (AnCl) contractions make their appearance. With still stronger currents the anodal opening (AnO) contraction occurs, and, last of all, when the kathodal closure contractions become tetanic (Te), slight kathodal opening (KaO) contractions appear. *These facts are equally true of normal muscle and nerve, and may be formulated.* Representing slight contraction by a small "c," decided contraction by a large "C," and the absence of contraction by a minus sign (—):

With weak currents, KaClc, AnCl—, AnO—, KaO—; with stronger currents, KaClC, AnClc, AnO—, KaO—; with still stronger currents, Ka-

Fig. 90.—Motor Points on Thigh, Anterior Surface—(after Erb and de Watteville)

ClC, AnClC, AnOc, KaO—; with strongest currents, KaClTe, AnClC, AnOc, KaOc.

In *pathological states* two sets of deviations from the normal reaction to electrical stimulus are observed—viz., *quantitative* and *qualitative*.

In the *quantitative* deviations there is simply an increase or a diminution of the normal irritability of both nerve and muscle to either faradism or galvanism. These differences are, of course, most easily measured when the alteration exists only on one side of the body, which may then be compared with the other. When both sides are affected, estimates can be made only by comparison with a healthy body or by the galvanometer. For this purpose superficial nerves, such as the frontal, ulnar, and peroneal, are usually selected. *Instances:* Increased quantitative changes are found in tetanus and in the early stage of certain peripheral palsies, while diminished electrical

excitability is found when the lower motor segments (motor spinal cells, motor nerves, including the muscles) are involved—as, for example, in progressive spinal muscular atrophy, bulbar paralysis, and muscular dystrophy.

More important from a diagnostic point of view, at least, are the so-called *qualitative* deviations from the normal law of contraction known as the *reaction of degeneration*. These are produced by the *galvanic* current only, and may, in general terms, be regarded as a reversal of the usual order of response to interruption of currents and in the substitution of a slow and vermicular contraction for the usual sudden and jerking contraction. The entire group of events is best illustrated by describing the electrical phenomena which present themselves in an ordinary case of peripheral paralysis. In two or three days to a week after its appearance there begins a gradually diminishing response in the *nerve* to both faradic and galvanic currents. This goes on for one or two weeks, at the end of which time it disappears to both currents, even the strongest. The nerve is now dead. During this same time the *muscle* is also losing its responsiveness to the faradic current, but not to the galvanic. There may be also at first a slight diminution to the galvanic current, lasting, say, one week, and constituting the “first degree” or “first stage” of degeneration. But during the second week this is substituted by an increased excitability, so that there is now marked response to weak currents—increased quantitative deviation. But there is also *qualitative* change. The anodic closure contractions become now as strong as or stronger than the cathodic closure contractions. Nay, more: the cathodal opening contractions, which in health were exceedingly weak and could be brought about only by the strongest currents, are now often stronger than the cathodal closure. This state of affairs for *muscle* may be represented thus:

First stage of reaction of degeneration—one week :	{ Diminished quantitative response to galvanism. { No qualitative deviation.
Second stage of reaction of degeneration—four to eight weeks :	

The phenomena of qualitative change are purely muscular, and it should be mentioned that they are not always typically present. Even more constant and equally distinctive and more reliable as a sign of reaction of degeneration is the second qualitative change in the muscular contractions excited by galvanism in this stage. Instead of being quick or sudden, they become *slow, prolonged, and vermicular*.

The second stage lasts from four to eight weeks, increasing during the third and fourth. In cases of recovery the abnormal muscle irritability to galvanism often persists after return of voluntary power, but it diminishes as the faradic irritability returns. In severe cases, when recovery does not take place and the nerve is not restored to its natural state, *all nerve* irritability and *faradic muscular* irritability remaining permanently absent, the *increased galvanic muscular* irritability may continue for months, but ultimately also decreases, disappearing finally with the muscular substance.

Certain exceptions to these laws must be mentioned. Thus, when the nerve lesion is slight, the fall in *quantitative nerve* irritability is sometimes preceded by a corresponding rise, or the rise may persist throughout, and

such rise may be considered as evidence of a slight lesion. Further, the change is not always the same to faradism and galvanism, and is often brought out much better by the slow interruptions in the faradic battery than by the rapid interruptions in the same or by the galvanic current. Gowers noticed in one instance moderate but prolonged diminution of faradic irritability when no change could be found with galvanism, and Bernhardt has noticed lessened irritability to faradism with distinct increase to galvanism in an ulnar nerve the seat of traumatic paralysis. Again, *faradic* irritability may not diminish to the same degree in the muscle as in the nerve in mild

Fig. 91.—Motor Points on Lower Limb, Posterior Surface—(after Erb and de Watteville).

cases, and conduction of voluntary impulses from the brain may be possible when there is no response to electrical currents, and there may be response to electrical currents when there is no conduction of voluntary impulses from the brain. In still milder peripheral paralyses there is no reaction of degeneration at all, whence a favorable prognosis may always be made. It is to be especially observed in recovery from nerve lesions that *voluntary* motion often returns decidedly earlier than the electrical excitability of peripheral nerves.

What do reactions of degeneration teach us? Simply that the disease

is seated in the anterior cornua of the gray matter of the cord, or in the peripheral nerves. They teach us nothing as to the nature of the lesion. Upon the integrity of the cells in the anterior cornua and their "trophic influence" depends the nutrition of the nerve and the muscle over which the cells preside. Hence with disease of the cornua result degeneration of the nerve and wasting of the muscle. The muscular fasciculi become reduced in size and ultimately totally disappear. This is associated with a certain amount of interstitial overgrowth. In the transition referred to, certain fasciculi assume the yellow, glassy appearance known as waxy degeneration. The *sensibility* of the muscle, if the sensory nerve is intact, becomes increased, and there may be pain, partly due to compression of the nerves by morbid contraction, and partly to a morbid sensitiveness of the nerve-endings and to

Fig. 92.—Motor Points on Leg, External Surface—(after Erb and de Watteville).

the interstitial inflammation. The recovery of the nerve is followed not only by gradual restoration of its power over the muscle, but also by restoration of the nutrition and redevelopment of the muscle. For this, however, much time is required, and it often remains permanently smaller than normal. The atrophy of muscle can be prevented to some extent by massage.

Lesions of motor nerves, whether inflammatory or traumatic, are followed by similar results—degenerative atrophy of nerve and muscle because of interference with the conduction of the atrophic influence. Occasionally in cerebral palsies and in spinal paralyses in which the lesion is above these ganglion cells there is some wasting, but no reaction of degeneration is developed, because the nutrition is maintained by the intact cell body of the lower neuron.

From the foregoing the diagnostic and prognostic value of the reaction of degeneration is at once apparent. The seat of the lesion, whatever its nature, is easily determined, in so far as it is within the cerebral or peripheral motor segments, but we may not be able to say whether the nerve-cells or their peripheral processes (the peripheral nerves) are diseased. We are also informed that recovery, though not impossible, must be delayed in proportion to the degree of degenerative reaction, because of the extensive repair necessitated in muscle and nerve. Much experience with the use of electricity should, however, be had before the physician permits himself to draw conclusions.

II. SENSORY PHENOMENA.—Under this head naturally fall first the *subjective sensations* of the patient. They include, strictly speaking, only the various modifications of sensibility appreciable to him alone and independent of external impression,—pre-eminently, *pain*. They also include those peculiar modifications due to internal irritation as contrasted with external impression, and known as *paresthesias*—viz., numbness, tingling, prickling, formication, or a feeling as of ants crawling over the skin; also a sensation like that of the contact of wool or fur,—a furry feeling,—vertigo, tinnitus aurium, or ringing in the ears, and a sense of unpleasant odors or tastes.

After these come modifications of the different varieties of cutaneous sensibility as excited by external impressions—*objective sensations*. They are of the nature of increase or decrease, the former being known as *hyperesthesias* and the latter as *anesthesias*, the latter being further characterized as partial or complete. To the latter the term paralysis of sensation, partial or complete, is also applied.

1. *Tactile sensibility*, the sense of touch or pure contact, is usually first investigated. The simplest method is by the touch of a finger or other blunt object of about the same temperature as the body, for both heat and cold must be eliminated in this test. The patient should be directed to close his eyes or avert his head. More refined measures are the application of rough, smooth, or coarsely uneven surfaces. More delicate still is the esthesiometer, essentially a pair of compasses with blunt and sharp points and graduated quadrant attached, by which the distance between the two points is accurately measured. By this instrument, in connection with a normal standard of relative sensibility worked out by E. H. Weber, the degree of impairment in delicacy of touch may be measured. Closer approximation may be recognized if the two points of the compasses are put down one after the other and varying the test by touching the same place twice or a different place each time. Weber's table is as follows:

Minimum distance at which the two points of a pair of compasses in contact with the skin may be recognized as two points:

Cheek, 11 to 15 millimeters.	Backs of the hands, 31 millimeters.
Tip of the nose, 6 millimeters.	Backs of the fingers, 11 to 16 millimeters.
Forehead, 22 millimeters.	Tips of the fingers, 2 or 3 millimeters.
Tip of the tongue, 1.2 millimeter.	Back, 55 to 77 millimeters.
Back of tongue and on the lips, 4 or 5 millimeters.	Chest, 45 millimeters.
Neck, 34 millimeters.	Thigh, 77 millimeters.
Upper arm, 77 millimeters.	Leg, 40 millimeters.
Forearm, 40 millimeters.	Instep, 40 millimeters.

These figures can, however, only be used within limits, as they are by no means constant for different individuals, or, indeed, for the same indi-

vidual at different times. Marked deviations from them may, however, be accepted as indicating derangements of tactile sense.

2. *The sense of pain* is of equal importance to that of pure touch, because these two not infrequently fail to diminish or increase *pari passu* in morbid states. Parts insensible to touch may respond decidedly to painful impressions. Pain is most easily investigated by pricking with a pin or pinching a fold of skin, by painful electrical currents or painfully hot metals. The special term *analgesia* is applied to loss of sense of pain while the tactile sense is preserved. Analgesia exists in peripheral and central nervous disease and may be observed especially in syringomyelia.

Tenderness or pain on pressure in the course of nerves should be studied in connection with the sense of pain. It is found in nerves which are the seat of inflammation, especially in sciatic neuritis and multiple neuritis.

3. *The sense of temperature* may be roughly tested by ascertaining the power of the patient to discriminate between the warm breath close to the skin and the cooler current produced by blowing from a distance. More precisely, the sense of temperature is studied by testing the ability to recognize differences in the temperature of flat-bottomed test-tubes filled with water of different temperatures and brought into contact with the skin. The therm-esthesiometer has been devised by Eulenburg for the same purpose, but the student is referred to works on nervous diseases for its description.

In health differences of 1-2° to 1° F. (0.27° to 0.55° C.) may be recognized on the fingers and face at temperatures from 80° to 100° F. (26° to 37° C.), while on the back differences to be recognized must amount to 2° F. (1° C.).

In disease we sometimes notice complete loss of sense of temperature, while the skin appreciates other forms of irritation, and, again, this state of affairs is precisely reversed; or the temperature and pain sense may be lost or impaired, while tactile sense is preserved, as in syringomyelia. This is known as dissociation of sensation. It occurs most commonly in syringomyelia, but has been seen in other diseases. Strümpell has called attention to a peculiar reversal of the sense of temperature, as the result of which cold objects appear warm. This has been noticed in various diseases.

4. *Sense of Locality*.—By this sense we know, without looking, what part of the body is being touched. While cutaneous sensibility may remain intact, the sense of locality may be seriously deranged. Thus, a patient may think he is being touched on the leg when the contact is with the foot.

5. *Delayed conduction of sensory impressions* represents a form of modified sensibility of which after-sensations are a further subdivision. In delayed conduction an irritation, more particularly a painful one, like the prick of a pin, is noticed by a patient after an appreciable interval, whereas in health the recognition is instantaneous so far as the unaided perception is able to judge. Touch and pain may even be thus separated, the immediate contact of the pin being promptly recognized, while the sense of pain presents itself a few seconds later. It is likely, also, that the sense of touch may be delayed.

6. An *after-sensation* is a prolonged sense of pain which succeeds a momentary impression. Such is the prolonged burning on the sole of the foot which sometimes succeeds the prick of a pin, or which may occur once or oftener after a short interval, as if additional pricks had been made. Occasionally an isolated prick of a pin is not perceived, and repeated pricks are

necessary, the whole producing a painful sensation; this is known as summation of sensation.

These abnormal sensations occur particularly in diseases of the spinal cord or of the nerves, and especially in *tabes dorsalis*.

7. *The muscular sense*, it were better named the sense of position, is that sense by which we become aware of the position of any of our limbs without the aid of vision, as well as of any degree of motion by them. It is probable, however, that the sensibility of the articular surfaces, ligaments, tendons, and skin aids the sensibility of the muscles in furnishing this information, and it is better to call this sense the *sense of position* when we speak of it in reference to the position of the limbs, or *deep sensation*. This power is diminished in nervous diseases, and may be tested by having the patient first touch a certain object with his eyes open and asking him to repeat the act with the eyes closed; or by moving the fingers or toes of a patient and requesting him to give their positions when his eyes are closed and voluntary movements of the parts are restrained.

The "muscular sense" is not only thus estimated, but the strength required to lift a leg or an arm, more plainly evident when one is tired, is also measured through it. It is the muscular sense which causes the parietic to say that his leg feels heavy. By the muscular sense, too, or by the "sense of power," we estimate the amount of strength demanded by any muscular contraction, and thus measure the difference in weight of objects, eliminating, however, the sense of pressure, which may be done by suspending the object in a towel.

In *tabes dorsalis*, as well as in paralysis of cerebral origin and in cortical lesions, the muscular sense may be defective; also in hysterical affections. It is also found defective in diseases of the peripheral nerves and in diseases of the lemniscus, or of the internal capsule, or of the nerve fibers passing to the cortex around the fissure of Rolando.

It is disputed whether the muscular sense has a center separate from that of motion in the cortex or from the pain or tactile or temperature senses, but a recent observation by Allen Starr* would go to show that it has a separate center two inches behind the fissure of Rolando and about an inch and a half to the left of the median line. It seems probable that the posterior columns of the spinal cord and the parietal lobes are especially concerned with the muscular sense.

The muscular sense is estimated by the amount required to be added to an existing weight on the skin before the addition is appreciated. Thus it has been ascertained that in health an addition of 1-20 or 1-30 to an existing weight can be appreciated. Thus, if a weight of ninety-five gm. be placed on the skin, an addition of a single gram will not be recognized, but nearly five gm. must be added before the increase is appreciated, while if considerably more than this is necessary, it means that the sense of pressure is less delicate. Sufficiently accurate measures are coins of different weights. Temperature must be eliminated by placing non-conducting substances between the weight and the skin, while the part to be tested must also be supported.

It is not unusual to find, in paralysis of the muscular sense, failure to recognize a doubling and even tripling of weights. It is more especially in *tabes dorsalis* that such paralyzes are found while the tactile sense proper is

* "Psychological Review," January, 1895.

intact, a light touch of the skin being felt, while a considerable pressure is not appreciated.

Stereognosis—the faculty of recognizing the nature and uses of objects by contact in handling them. *Astereognosis*, or, as some prefer to call it, *stereoagnosis*, is the inability to so recognize objects.

The ability to recognize objects by handling them depends upon the integrity of the afferent nerves, the cortical sensory area, and the cortical perceptive area. Disease of either of these will make it impossible for the patient to recognize objects by handling them.*

8. *Anesthesia* is said to be peripheral, spinal, or cerebral, in accordance with the seat of the broken conduction between the terminal apparatus and the cerebral cortex. *Peripheral* anesthesia occurs after chilling of the skin through the action of ether, from cocain, aconite, veratrum, as well as corrosive agents like acids, alkalis, and carbolic acid. Spasm of the small vessels, forming the so-called spastic anemias, is also attended by anesthesia. The anesthetics of washerwomen, who have their hands in water all day long, may belong to this class. Lesions of nerve trunks by pressure, inflammation, and degeneration may cause anesthesia. The *paresthesias* referred to—numbness, formication, and tingling—are among the effects of such lesions. Spinal anesthetics are found, especially in connection with disease of the posterior roots, posterior columns, and posterior cornua of the cord. Such a disease is *tabes dorsalis* especially. Anesthesia is found, however, also in myelitis, acute and chronic, and when there is pressure on the cord from hemorrhage into the spinal canal or pressure by diseased or broken vertebrae or from tumors. Such anesthesia is usually bilateral and is known as *para-anesthesia*. *Cerebral* anesthesia occurs as the result of hemorrhages, softening, or tumors, which impinge on the posterior limb of the internal capsule, through which the sensory fibers, probably after interruption in the thalamus, pass upward to the cerebral cortex. If the cerebral anesthesia affects half of the body, it is known as *hemianesthesia*, and the half of the body affected is opposite the hemisphere of the brain in which the lesion lies, since the sensory fibers also decussate in their course from the periphery, and most of them throughout the cord very soon after their entrance into the posterior roots.

The hysterical anesthetics, and anesthetics due to the action of narcotics and anesthetics, are regarded as cerebral in their origin. Those succeeding such acute infectious diseases as typhoid fever have been ascribed to both peripheral and spinal origin. The hysterical hemianesthesia is much commoner than the organic cerebral hemianesthesia.

III. SENSORY MOTOR PHENOMENA.—These words explain themselves, but in addition to the general application they include such special conditions as *akinesia algera* in which all sorts of muscular action are attended with pain in the active muscles—even the act of speaking is attended with pain. It is a symptom of several neuroses, among which hysteria and neurasthenia are conspicuous. *Atremia*, which resembles akinesia, differs from it in the absence of tenderness of the muscles affected.

IV. VASOMOTOR AND TROPHIC PHENOMENA.—We pass next to the study of *vasomotor* and *trophic alterations*. Two sets of vasomotor nerves

* See Burr, "American Journal of the Medical Sciences," March, 1901.

have been demonstrated by physiologists,—the vasoconstrictors and vasodilators—the former contracting the arteries when stimulated and permitting their dilatation when paralyzed. The vasodilators are influenced in an opposite manner by the same agencies, but their number, so far as proved, is not great, as they include up to the present time only fibers in the chorda tympani, *nervi erigentes*, and sciatic nerve. Blushing may be the result of stimulation of vasodilators. Moreover, pathology has as yet failed to separate lesions of the two sets of nerves and their consequences, and the latter are generally looked upon as results of *paralysis* or of *irritation* of vasoconstrictors. Instances of the former are redness, a feeling of warmth, and sometimes an actual elevation of temperature, sweating, all in circumscribed areas or half the body. They may persist or intermit. Instances of vasomotor irritation are pallor, coldness, accompanied by stiffness, formication, and even pain. These are the phenomena of vasomotor spasm. A more or less permanent condition of the hands sometimes results, characterized by a blueness or mottled appearance accompanied by a lowered temperature further augmented by external cold. Still higher degrees are said to have produced circumscribed gangrene (Raynaud's disease).

Symptoms of vasomotor paralysis occur in connection with cerebral and spinal lesions and with injuries of the sympathetic system and nerve trunks which include vasomotor fibers. The essential causes of vasomotor spasm are less easy to locate. It is found associated with prolonged convulsive seizures, and in angina pectoris at the beginning of the attack, as if caused by irritation of the sympathetic ganglia in the heart.

That *trophic* or nutritive phenomena are closely allied to vasomotor phenomena is commonly admitted. That they are under the control of the same nerves is doubtful, although the proof of the existence of separate trophic nerves is still wanting. Vesicular eruptions in the area of distribution of nerves, such as herpes zoster, certain atrophic skin diseases, pigmentations and depigmentations, such as morphea, Addison's disease and vitiligo, scleroderma, and the glassy skin which succeeds certain injuries to nerve trunks are illustrations of trophic influences. Similar are the changes in the skin, hair, and nails, as the result of which the first becomes dry, the second is lost or becomes rapidly gray, and the last grow brittle, thicken, or drop off. The latter events are the result of spinal and even cerebral lesions. The circumscribed edema known as acute angioneurotic edema and the more permanent condition of myxedema are also probably trophic. So, also, are the atrophies which result from disease of the cells of the anterior horns of the gray matter of the cord, or from injuries to nerves by which they are essentially cut off from the trophic cells; also unilateral facial atrophy, including even atrophy of bone, and the still more remarkable spinal *arthropathies* of Charcot, as the result of which the joints enlarge or become the seat of effusions.

Finally, there is the acute bed-sore or eschar, so well described by Charcot,* beginning in an erythematous patch on which bullæ and blebs are rapidly developed, quickly succeeded by gangrene. While pressure or irritation may be necessary to the production of these sores as exciting causes, they are more easily invited in spinal paralyses than in non-paralytic conditions. Such results follow cerebral lesions and lesions in the medulla oblongata, spinal cord, and sympathetic nerve.

It is well known that the vasomotor nerves surrounding the various

* "Lectures on Diseases of the Nervous System," Philadelphia, 1879.

blood-vessels are derived from the sympathetic trunks, which, in turn, receive their vasomotor filaments from the roots of the spinal nerves.

V. MENTAL PHENOMENA.—Under this head come the phenomena of consciousness or unconsciousness, coma, the state of the will, the various perversions of mental process, including delirium, hallucinations, delusions, illusions, and insane acts. *Hallucinations* are states of the mind in which the subject conceives that he perceives external objects which do not exist. The victim of delirium tremens who conceives that he is pursued by monsters of various sorts is the subject of hallucinations. Hallucinations may exist through any of the special senses. A *delusion* is a false idea unassociated with sensory conceptions. The deluded person imagines that he is the happy possessor of millions when he is actually a pauper, or complains of poverty although affluent. An *illusion* is based upon an actual perception, but an erroneous impression arises therefrom. In a hallucination no object is actually seen; there is no sensory impression. The idea of relief obtained on looking at a picture in the stereoscope is an illusion; and Gowers adds that if used in connection with morbid mental states, the term illusion should be confined to false ideas and images the erroneousness of which the patient recognizes.

Delirium is the more or less acute manifestation of one or all these perversions of mental process, associated with muttering or active speech suggested by them or with action growing out of them. Thus constituted, delirium may be the result of toxic states or acute disease other than of the brain.

The same perversions of mental process continued and unaccompanied by fever constitute *insanity*, which is probably always associated with structural change in the brain or its membranes, although such may not always be demonstrable. Other symptoms are added, however, in *insanity*, such as extreme depression of spirits, while hallucination, delusion, and illusion may be present in various degrees. Special insane acts should be specified and modifications of normal sleep noticed.

VI. ALTERATIONS IN VISION AND HEARING.—In addition to the ordinary defects of vision, the *response of the pupil to light* should be noticed; also its *accommodating power*. The former is absent in three-fourths of all cases of locomotor ataxia, while the latter remains. The pupil thus failing to respond to light, but retaining its accommodation to change of distance, is known as the Argyll Robertson pupil. Each eye should be tested separately, the other being covered. Finally, the eye-ground should be examined in every exhaustive study of a nervous case.

Modifications in *hearing* are of the nature of increased and diminished intensity, and there is that very common symptom known as *tinnitus aurium*, or ringing in the ears, already alluded to as a good instance of a subjective symptom. Hyperacusis occurs in association with augmented acuteness of the other senses in acute affections of the brain or when there is hyperemia of the brain from any cause. It is also often complained of in hysteria. Deafness, on the other hand, is more frequently the consequence of diseases of the ear itself. Ringing in the ears occurs in many conditions, known and unknown. While some more than usual impression on the nerve is a condition of tinnitus, it by no means follows that the cause resides in the nervous system. In addition to the numerous forms of irritation due to ear disease,

the blood in an adjacent vessel may be thrown into vibration and produce an audible murmur. On the other hand, tinnitus is sometimes due to intracranial irritation either of the nerve or of the auditory centers.

VII. ALTERATIONS IN BREATHING AND PULSE.—*Alterations of breathing* are very common in nervous diseases. Respiration may be rapid or slow, and labored and sighing, or irregular, but especially peculiar is the *Cheyne-Stokes breathing*, in which, succeeding a long pause, so long sometimes that it seems as though the patient would never breathe again, follows gentle and shallow respiration, which gradually grows deeper and more frequent until an acme of dyspnea breathing is reached, when it again gradually diminishes in depth and frequency until the pause again occurs. It is an arrhythmical breathing of a periodic type. During the pause the pupil often contracts and the heart's action becomes less frequent. Cheyne-Stokes breathing may occur in tubercular meningitis, cerebral hemorrhage, embolism, thrombosis, and aneurysms of the basilar artery; also in uremia, heart disease, and more rarely in other conditions, including the infectious fevers, in which the respiratory center is influenced. The period of arrest varies from five to forty seconds, and the duration of each cycle may be from fifteen to seventy-five seconds, and may vary.

A modification of Cheyne-Stokes breathing is a form in which there are periods of deep and energetic breathing which begin suddenly, and in which the respirations gradually become shallower until they cease, and after a pause energetically recommence.

Cheyne-Stokes breathing was ascribed by Walsh and later by Traube and Rosenbach to lessened excitability of the respiratory center in the medulla oblongata. Filehne suggested that the rhythmogenic purpose of the *respiratory* center is modified by a periodical vasomotor spasm caused by stimulation of the *vasomotor* center by the asphyxiated blood. The arterial spasm in the medulla oblongata thus caused prolongs the stimulation of the respiratory center as well as that of the vasomotor center by hindering the access of oxygenated blood. The respiratory center being less excitable, the respiratory movements, therefore, continue energetic—run riot as it were—after the blood has become oxygenated. The gradual onset of the breathing may be due to the fact that the reactive vasomotor dilatation exceeds the normal, and thus the quantity of blood reaching the respiratory center lessens the stimulating influence of its quality; but these are merely theories.

The *pulse* is influenced chiefly by diseases of the cranial contents, especially of the medulla oblongata, the cerebrum, and the meninges. It is at times very slow, as in meningitis and apoplexy, or when there is intracranial pressure from any cause or when there is pneumogastric irritation. It may be accelerated when there is inflammatory pyrexia or irritation of the cardiac center. Again, it may be irregular, acting through the nervous system, of which opium poisoning is among the familiar causes; uremia is another cause, rarely also is influenza.

Changes in the order of investigation proposed in this section will, of course, be demanded by circumstances, while at times certain steps may be omitted altogether.

AFFECTIONS OF THE PERIPHERAL NERVES.

NEURITIS.

Definition.—Neuritis, or inflammation of a nerve, may be confined to a single trunk, whence it is called *localized*; or it may involve a large number of nerves, when it is known as *multiple* neuritis or *polyneuritis*. In *perineuritis* the connective tissue surrounding a nerve is the seat of the inflammation; in *interstitial* neuritis the tissue between the bundles of nerve-fibers is involved, and in *parenchymatous* or *degenerative* neuritis the substance of the nerve-fibers themselves is affected.

LOCALIZED NEURITIS.

Etiology.—Exposure to cold is the most frequent cause of neuritis, and the nerve most frequently thus affected is the facial. Trauma is another cause, including compression, contusions, or cuts, as with glass, or stretching and laceration such as occur when there are dislocation, fracture, and other violent injuries. Neuritis may also occur as the result of extension of inflammation from contiguous parts, as from caries in a bone through which the nerve passes, adjacent joint inflammation, pleurisy, and meningitis. Finally, neuritis may be caused by toxins and morbid states of the blood, such as produce the infectious and constitutional diseases, as diphtheria, syphilis, and gout. The mineral poisons, especially lead and arsenic, are frequent causes. Alcohol is also a cause of this kind of neuritis, although it more frequently produces multiple neuritis.

Morbid Anatomy.—An inflamed nerve is reddish, from hyperemia of the *vasa nervorum*, though the stage of demonstrable hyperemia may have passed away when the nerve comes under observation. In *perineuritis* and *interstitial neuritis* the primary change is in the connective tissue—in the former, an infiltration of the nerve sheath with leukocytes, and in the latter, of the interstitial tissue with the same cells. There may even be minute extravasations of blood. These changes are more apt to occur in places along the course of the nerve where it is exposed to special irritation, as in passing through foramina or over bone. The lymphoid cells gradually become fusiform cells, resulting in the formation of true connective tissue. The pressure of this new tissue gradually destroys the nerve itself, the medullary sheath being gradually broken up into drops, which subsequently disappear, while the nuclei of the sheath of Schwann increase; finally, the axis-cylinder also becomes granular and disappears—all this in varying degrees. The nerve-fiber may be substituted by a fiber of connective tissue, in which there may be a deposit of fat, a condition seen in the lipomatous neuritis of Leyden.

In *parenchymatous neuritis* the primary change is in the nerve-fiber itself. Here the medullary sheath and the axis-cylinder are the first involved, the former breaking up into drops, as described, and the latter into granules, both ultimately disappearing, while the interstitial connective tissue remains comparatively unchanged; but the nuclei of the sheath of Schwann proliferate and become a part of the interstitial connective tissue. The muscles connected with the inflamed nerve also atrophy,—in the case of the motor

nerves, at least,—being practically cut off from their center of nutrition. The change in the nerve is essentially the Wallerian change noticed in the nerve-fiber of a cut nerve. In some instances the changes noticed in the sheath of Schwann extend over into the interstitial tissue of the muscle.

Symptoms.—There is not much constitutional disturbance in localized neuritis, though the thermometer may show some rise of temperature. *Pain*, especially pain on motion, and tenderness, are the salient symptoms. The pain may be confined to the seat of the inflammation or may involve the distribution of the nerve, or the whole limb may be involved. It varies in degree and also in character, being sometimes burning and at other times aching, boring, or shooting. It is apt to be worse at night, and when in situations involving pressure on the nerve itself. The nerve may be swollen appreciably, and rarely the skin over it is reddened.

The pain in the trunk of an inflamed nerve is probably due to pressure on the *nervi nervorum*. Weir Mitchell has especially called attention to this. An interesting fact is that the nerves composed almost purely of motor fibers are less tender than sensory nerves. This would imply that fewer sensory nerves are distributed to the motor nerve trunks than to sensory nerves. Mitchell also describes elevation of surface temperature and trophic disturbances, such as sweating, herpes, and effusion into neighboring joints. Other motor disturbances, including twitchings and contractions, are noticed. Trophic derangements, including muscle wasting, associated with peculiar “glossy skin” or slight edema, may be present. Vesicles, bullæ, and herpetic eruptions may occur. The nails become brittle, rough, and marked with transverse ridges. The bones in the fingers may even become atrophied. There may be thickening of the skin and a condition resembling ichthyosis may be present. Ultimately the hyperesthesia and paresthesia may become anesthesia, though usually limited to small areas.

The electrical condition of the nerves and muscles must be studied. It may be normal in slight cases. In more severe cases there may be the reaction of degeneration, with the slow, lazy contraction of the muscles, and the reversed reaction to opening and closing currents, described on page 856.

The course of the disease is variously prolonged. Many acute cases terminate favorably in a few weeks. More cases become chronic, extending over months and even years, after which they may gradually subside.

A rare variety is “ascending neuritis,” in which the inflammation extends from smaller to larger branches, until finally most of the nerves of a limb may be involved, or possibly even the spinal cord, producing myelitis, with or without spinal meningitis. Paralysis may result from such a condition. This is possibly the rare form of paralysis that succeeds visceral disease, as that of the bladder. Even the corresponding nerves of the other side may be involved. It is the opinion of some of the best neuropathologists that this ascending neuritis occurs only from a suppurating wound. The theory of an ascending neuritis is not universally accepted.

ADDITIONAL SYMPTOMS DUE TO NERVES INVOLVED.—In inflammation of the *facial* nerve there is complete paralysis of all the muscles supplied by the nerve. In inflammation of the *median* nerve there is disturbance on the palmar surface of the thumb, forefinger, and middle finger on its radial side, and there is often intense pain in these same situations. In inflammation of the *ulnar nerve*, there are pain and loss of sensation in the outer half of the third finger and in the fourth finger, with wasting of the flexor carpi radialis,

the intrinsic muscles of the little finger, the interossei, lumbricales, and the adductor of the thumb. Here, in case of long standing, we have the "claw hand," the result of overextension of the first phalanges and flexion of the last two.

In inflammation of the *musculospiral* there are great pain and tenderness of the upper arm and forearm, the region of the brachial anticus and triceps extensor, the extensors of the wrist and fingers, the two supinators—the back of the hand, thumb, and index finger. In extreme degrees we have the characteristic wrist drop and inability to extend the first phalanges of the fingers and thumb, with partial anesthesia of the base of the thumb and forefinger.

The *circumflex nerve* supplies the deltoid and teres minor. There may be pain or impaired sensation in the muscles and the skin over them, to which may succeed loss of power and atrophy of the deltoid and the arm cannot be raised.

In inflammation of the *brachial plexus*, which is prone to occur in gouty subjects over fifty years old, there may be a combination of the symptoms belonging to the last-named four nerves. A subvariety of brachial neuritis is *radicular* neuritis, in which the pain suggests the involvement of the roots of the nerves.

Diagnosis.—The disease is chiefly to be differentiated from *neuralgia*. This depends upon pain and tenderness in the course of the nerve and upon the limitation of the symptoms to its distribution. Neuralgia is more intermittent, and is relieved rather than aggravated by pressure. The presence of the paresthesia points to neuritis and the diagnosis is confirmed if there is ultimately lessened sensibility. In neuralgia, nerve and muscle reactions remain normal. It is possible, however, that neuralgia may result in neuritis. The distal pain of *central spinal disease* must be separated. In brachial neuritis the pain may radiate to the left side, suggesting *angina pectoris*, and there may even be a tendency to cardiac distress, but there is no tenderness in the course of the nerve in angina.

Prognosis.—The prognosis varies greatly, being favorable in mild and in most traumatic cases. Those consequent upon local suppuration are the gravest. In ordinary cases from cold or contusion recovery ensues sooner or later, although some last a long time and recurrences are not unusual, especially in neuropathic dispositions, in which, too, recovery is slower.

Treatment.—Here, as elsewhere, if a cause is discoverable, it should be removed. Exposure to cold and dampness should be avoided, pressure by cicatricial tissue or dislocated bones should be relieved, and constitutional states favoring neuritis, such as gout and syphilis, should be corrected.

Of curative measures, rest is the most important. When a limb can be splinted, this should be done, pressure by muscular contraction being thus prevented. Cold may be a useful application, as by an ice-bag. In other instances heat, now dry and again moist, subserves a useful purpose. A blister or blisters may be applied over the tender nerve. Especially convenient is the Paquelin cautery, which should be used earlier than it commonly is; its application takes but a second, and may be rendered painless by previously applying, for a few minutes, a mixture of ice and salt to the spot to be burned, although this has been largely superseded of late by the more convenient ethyl chlorid. Morphine is sometimes indispensable, and the hypodermic method of application is best—1-6 to 1-4 grain (0.011 to 0.0165 gm.) for an adult. But the morphine habit is easily acquired, and the patient

should not be allowed to use the syringe himself. Cocain may be similarly used—1-10 to 1-3 grain (0.0066 to 0.022 gm.)—and Gowers recommends it highly, more particularly for its power in arresting local transmission of the impulses that cause pain. Eucain is even better. Here, too, the injection should be made at the seat of the pain by the physician or a trusted attendant. Gowers, whose large experience always bespeaks respect, considers mercury also a most efficient agent, in the shape of a blue pill, one grain (0.066 gm.) once or twice a day, associated, if necessary, with morphin, the constipating effect of which it counteracts. Salicylate of sodium is undoubtedly sometimes useful, as is also more rarely iodid of potassium. Strychnin is also of service.

In the chronic form also Paquelin's cautery should be repeatedly used, or if not at hand, blistering may be substituted. Electricity here comes into play, and galvanism is the form to be used, the positive electrode being placed over the nerve or seat of pain, and the negative indifferently placed. A weak current should be used, but its strength may be increased if such current be inefficient. The application should continue for about ten minutes. The wasted muscles usually recover as the inflammation subsides, but massage and galvanic electricity help them. Faradism is less favorably regarded, especially in the active stage.

Special Variety of Localized Neuritis—Sciatica.

Definition.—This term is applied to all painful affections in the distribution of the sciatic nerve, some of which may be neuralgic, but the vast majority are inflammatory and perineuritic, as it is the sheath of the nerve that is usually involved.

Etiology.—Sciatica is far more common in men than in women, in the ratio of about four to one. Brachial neuritis affects both sexes about equally. It is also a disease of adults, being unknown in children and very rare in the second decade. It is most frequent between forty and fifty, next between fifty and sixty, and next between thirty and forty.

Gout and rheumatism are favoring causes, especially fibrous rheumatism. Very rarely syphilis may be a predisposing cause. Exposure to cold is the most frequent exciting cause, especially after severe muscular exertion, while standing in water, sitting or lying on the cold ground, and the like are frequent causes. Exposure to drafts, though less frequently so than in neuritis of the upper extremity, is still a cause. A sciatica may also arise by extension from a rheumatic focus, especially that form of lumbago involving the fibrous attachments of muscles at the back of the sacrum, whence the inflammation extends to the sheath of the sciatic nerve. Pressure by mechanical agents and possibly muscular contraction may be a cause; also pressure by tumors and other new formations within the pelvis. Even fecal accumulations may cause it by pressure. In bilateral sciatica the possibility of intrapelvic tumor should be carefully considered. In addition to the intrapelvic causes referred to, secondary sciaticas may be caused by bone disease and other foci of suppuration external to the pelvis.

Morbid Anatomy.—The morbid changes are those already described under neuritis.

Symptoms.—The leading symptom, is, of course, *pain in the course of the nerve*. Felt first in the back of the thigh, it also travels above the hip-joint, into the sciatic notch, behind the knee, below the head of the fibula,

behind the *internal* malleolus, and on the dorsum of the foot. It may be more diffuse, but the course of the main trunk of the nerve is often indicated by it, and the points previously named, especially the back of the middle of the thigh and the sciatic notch, will often be pointed out by the patient as seats of special tenderness. It usually begins gradually, but it may start suddenly, especially in cases of rheumatic origin. Motion, particularly in walking, and positions in which the nerve is put in a state of tension or is compressed, aggravate it. A valuable sign of sciatica is pain produced by passive flexion of the thigh upon the pelvis with the knee extended (Lasègues sign); by this means the sciatic nerve is stretched, and pain is readily produced if the nerve is inflamed. The characteristics of the pain are those already described under neuritis. The other more unusual symptoms of neuritis may also be present, as herpes, edema, and wasting, but the reaction of degeneration is almost never present. The loss of the *tendo Achillis* jerk is an important sign.

Diagnosis.—This is not difficult, although a careful study should be made of each case with a view to determining its primary or secondary origin. *Pelvic tumors*, especially in women, and *rectal accumulations* should be sought for. *Lumbago*, *hip disease*, and *sacro-iliac diseases* are all to be recalled, but in none of these is there pain on pressure in the course of the nerve. In the last only is there sometimes pain in the posterior part of the thigh. Pain felt only in the outer side of the thigh is not sciatica. The rare cases of *sciatic neuralgia* are not characterized by tenderness. They occur in persons subject to neuralgia, and the pain is not influenced by position and motion. It is purely spontaneous. *Disease of the vertebræ*, of the *cauda equina*, and even of the *spinal cord* may produce sciatic pain; but here, again, there is no tenderness in the course of the nerve, the pain is peripheral and is more apt to be bilateral. Inflammation of the roots of the sciatic nerve, however, may extend downward. Bilateral pain is indicative of disease of the nerve-roots, although bilateral sciatica does occasionally occur. The shooting pains of *tabes dorsalis* are like those of sciatica, but the other symptoms of the former disease are present.

Prognosis.—Cases of sciatica, however obstinate, usually sooner or later get well, although they may persist for months. A case came under my observation which lasted seven years.

Treatment.—Every case of sciatica should be at once ordered to rest, and the more complete the rest, the sooner the recovery. Splinting of the limb as recommended by Weir Mitchell, is necessary in some cases, and would probably hasten cure if used earlier, but it is so inconvenient that the temptation to temporize is very strong. Rest being secured, I am confident that recoveries would be prompter if Paquelin's cautery were oftener used at the onset. Counterirritation by blisters, mustard, and iodine is relatively inefficient. Treatment by cold along the course of the nerve certainly relieves the pain for a time, but in my experience the relief thus obtained is not permanent.

First, attention should be paid to the local causes, if these are discoverable, and to constitutional causes as well. If of rheumatic or gouty origin, the salicylates will be found useful; in other cases they are useless. Here, as in neuritis from other causes, Gowfers commends the pill of blue mass, one grain (0.06 gm.) twice daily, when there is active inflammation.

For the relief of mild degrees of pain phenacetin and antifebrin, and especially a combination of phenacetin and caffeine citrate, say ten grains

(0.66 gm.) of the former and three grains (0.2 gm.) of the latter every two hours are often efficient. For severe degrees morphin is necessary, and is best given hypodermically in doses of from 1-8 to 1-4 grain (0.008 to 0.0165 gm.). The danger of establishing the morphin habit must always be kept in mind, and cocain should be tried first as a deep-seated injection in doses of from 1-8 to 1-4 grain (0.008 to 0.0165 gm.). Acupuncture over the course of the nerve is of service for the same purpose—relief of pain rather than cure. Anodyne liniments may be used, and although not curative, do give some comfort and meet the wishes of the patient that something should be done. Recently the internal administration of ichthyol in small doses has been highly recommended by Crocq. Ichthyol locally is sometimes serviceable.

In chronic cases change of scene is often of advantage, and if associated with thermal bath treatment may accomplish a cure in otherwise obstinate cases. The mud-bath is a measure of treatment applied in Europe with some success. In the chronic stage electricity also meets the demands of patients and friends and may do some good. The galvanic current should be employed. Massage is less efficient than in muscular rheumatism, though it should be tried. Nerve-stretching may be resorted to. I have had it done in cases with uncertain result.

MULTIPLE NEURITIS.

SYNONYMS.—*Polyn neuritis; Peripheral Neuritis.*

Definition.—An inflammatory condition involving many peripheral nerves, either simultaneously or in rapid succession.

Historical.—Multiple neuritis is a disease of modern recognition. The symptoms peculiar to the condition were described first, probably, by James Jackson, Sr., of Boston, Mass., as early as 1822. In 1854 Robert Bentley Todd, of London, wrote of lead palsy: "The nervous system is thus first affected at its periphery, in the nerves, and, the poisoning influence continuing, the contamination gradually advances toward the center." Duchenne described the symptoms fully in 1858. Samuel Wilks described alcoholic paraplegia, but the existence of multiple neuritis as an actual disease was first demonstrated by Dumenil, at Rouen, in 1864, and the literature was further contributed to by Joffroy in 1879, Leyden in 1880, Grainger Stewart in 1881, Buzzard in 1886, James Ross, Henry Hun, and Charles K. Mills in 1892. W. R. Gowers' article in the second edition of "Diseases of the Nervous System," 1891, is a very complete one.

Etiology.—The causes of multiple neuritis are numerous, and by no means easy of classification. They include:

1. The commonly acknowledged poisons introduced from without: (*a*) Organic, including alcohol, by far the most frequent cause, ergot, morphin, ether, carbon monoxid, carbon bisulphid, benzine and its products, and anilin; (*b*) inorganic, including lead, arsenic, phosphorus, and mercury.

2. Endogenous toxins generated in the organism by chemical changes. Such is the cause of the neuritis of diabetes mellitus, whether oxybutyric acid, diacetic acid, or acetone, all of which are found in the blood in that disease.

3. Toxins inherent to the infectious diseases, whether an organism or its product. Instances of the former are malarial neuritis, leprous neuritis, beri-beri or so-called endemic neuritis, also, probably, the neuritis of acute infectious jaundice (Weil's disease). In these instances the cause is an organism. Of the latter, diphtheritic neuritis, septicemic neuritis, the

neuritis of smallpox, typhoid fever, tuberculosis, and possibly syphilis are instances. The cause is here a toxin generated by an organism.

4. Intrinsic states of the blood of undetermined nature, with which cold may or may not co-operate as an exciting cause—viz., rheumatism, gout; also the puerperal state, and chorea. Advanced microbic doctrines would place rheumatic neuritis in 3, while a greater conservatism might place septicemic neuritis in 4. Malnutrition such as characterizes cachectic and senile states, cancer, tuberculosis, and wasting diseases generally are also causes. It is not impossible that cold alone may, by its operation, generate a poison capable of producing a polyneuritis, but more probably it acts by lowering the vitality of the nerves and rendering them liable to attacks from other agents.

Age and Sex.—Multiple neuritis is a disease of adults. Aside from rare cases of diphtheritic neuritis, the most common form met in children is a complication of acute poliomyelitis. Gowers says "it may, perhaps, now and then be met with apart from the spinal malady as an infantile variety of multiple adventitious neuritis irregular in distribution." It is not improbable that in some of the cases of poliomyelitis the changes in the nerves are secondary to alterations of the nerve cells in the anterior horns of the spinal cord.

The remaining chief forms occur usually between the ages of twenty and fifty, the alcoholic between thirty and forty or later, and senile neuritis at a still later age. The alcoholic form is more frequent than all others put together, and of this form 70 per cent. occur among women. This preponderance of the disease in women has been especially noticed in England, where alcoholism among females is more common than in this country. More than one cause may co-operate, when one may be the predisposing and the other the exciting. Cold probably most frequently plays the latter rôle, but there may be others, such as depressing emotions, anemia, and the like.

Morbid Anatomy.—The special characteristic of multiple neuritis is that it is *parenchymatous*, as contrasted with interstitial and perineural—that is, the changes begin in the nerve-fibers themselves, as described on page 867, rather than in the connective tissue between and around them. Yet this is not invariable. Indeed, it is improbable that either form of neuritis exists without the other for any length of time. It is further characteristic of multiple neuritis that the involvement is symmetrical—that is, the corresponding nerves on the opposite side of the body are affected. The more this is the case, the more likely is it that the change is parenchymatous. The changes are also more marked in the peripheral distribution of the nerve than in the trunk of nerves. Macroscopic changes are very rarely appreciable. In acute changes the nerve may be swollen, reddened, hemorrhagic, or in old cases hardened from overgrowth of connective tissue.

Symptoms.—The symptoms vary greatly in different varieties of neuritis, but there are some more or less common to all varieties, particularly illustrated by the alcoholic and rheumatic. These common symptoms will be considered first, and afterward some special features of varieties due to specific causes, particularly the metallic poisons, the acute infectious diseases, and the poison of beri-beri.

The symptoms are easily divided into three classes: *Motor* weakness, *sensory* derangement, and *inco-ordination*. The first is the result of the involvement of motor nerves, and manifests itself usually first in the extensors of the wrist and fingers, flexors of the ankle, and extensors of the toes. The

sensory disturbances are tingling, numbness, and pain, while the inco-ordination resembles that of the mildest degree of tabes. According as one or the other of these sets of symptoms predominates we have a motor form, a sensory form, and an ataxic form.

The onset may be rapid or slow. In the rheumatic form, or that due to cold, it is usually sudden, with chill and fever and a temperature of 103° or 104° F. (39.5° to 40° C.), headache, and backache. The slow onset is characteristic of alcoholic neuritis, though it may be precipitated by some exciting cause, as cold, exposure, fatigue, or some toxic state. It is rarely febrile. In the initial stage *sensory symptoms* are numbness and tingling of the fingers and toes, palms of the hands and soles of the feet, and other parts of the lower arms and legs; then hyperesthesia, tenderness, and pain, more marked in the legs, including cramps in the calves. These may in mild degree precede the onset as premonitory symptoms for weeks and for months, especially in the alcoholic form.

The *motor symptoms*, seldom absent, soon follow the sensory phenomena previously mentioned. They include palsy or inco-ordination or both in upper and lower limbs, but with this characteristic—that the involvement of the limbs is symmetrical and the distal extremities, as the feet and hands are affected, the former more frequently. Motor symptoms may exist in the feet and sensory symptoms in the hands, the latter commonly preceding.

The muscles commonly involved are those supplied by the peroneal nerve in the lower, and by the posterior interosseous branch of the musculospiral in the upper extremity. With weakness in the legs comes *loss of knee-jerk* and *ankle-jerk*, quite constant, but not invariable, depending, of course, on the involvement of the nerves forming these reflex arcs. The muscles above the knee are less frequently affected, and still less frequently those which move the hip-joint.

The paralysis of the muscles innervated by the peroneal nerve gives rise to a peculiar and distinctive walk known as the *steppage* gait, and occasionally it is unilateral, when only one peroneal nerve is affected. It is the gait of polyneuritis in which the foot drops, and in order to raise it from the ground and thereby to “shorten” the limb, the thigh is drawn up unnecessarily high and the knee is flexed excessively so that the gait resembles that of the “high-stepping” horse. The extremity of the foot strikes the ground first, followed by the heel, so that there is often a recognized interval of time between the two events. Closing of the eyes does not affect this gait.

As contrasted with the *diminished tendon reflexes*, the reflex action from the skin may be increased, especially when there is hyperesthesia, even when there is considerable motor paralysis, the movement being caused by the muscles which escape involvement. In severe cases, on the other hand, when there is much loss of sensation and motion, the skin reflex is absent; exceptionally, it may be absent when sensation is perfect. Myotatic irritability is almost always lost, although some rare cases are reported in which it was said to be present.

Very characteristic is the *tenderness of the muscles* themselves, developed as they become weaker, and elicited by grasping them, the slightest pressure often causing the patient to cry out with pain. This is regarded as evidence that all the nerves of the muscles are involved, the sensory as well as the motor. The nerve-trunks are also tender, although this tenderness is less marked than in simple neuritis, because the contrast with the hyperesthesia of the surrounding skin is less conspicuous.

In the arms it is the extensors of the wrist and fingers which are first affected, and these symmetrically, illustrated by one of the best recognized toxic forms of neuritis, lead palsy. In the latter there is paralysis of the extensors, though the extensor of the metacarpal bone of the thumb and the supinator longus usually escape, although in some cases of lead palsy these muscles are affected. After the extensors, the flexors of the wrists and fingers are involved, then the interosseous muscles, and, finally, the thenar and hypothenar muscles are attacked, always to a less degree than the extensors. The muscles above the elbow suffer less.

Occasionally the fibers of the *pneumogastric* are involved, causing frequent pulse-rate and paralysis of the vocal cords, cardiac failure, and death. Still more rarely the diaphragm and muscles of the thorax and abdomen are involved. The facial and motor oculi nerves are possible seats. Neuritis confined to the cranial nerves has been described. The sphincters are also rarely affected.

The muscles exhibit the *reaction of degeneration*, faradic irritability being lost, while galvanic irritability is increased, but not always altered in quality. In the nerves, irritability to both currents diminishes and ultimately disappears, although in the very first stage there may be increased galvanic irritability, as described under the reaction of degeneration. In severe cases total loss of excitability may occur at once because of a corresponding destruction of muscular substance, instead of being preceded by an intermediate state of increased excitability.

Wasting of the muscles is sooner or later inevitable, unless the disease is of short duration, although it may be obscured by a temporary edema or a condition of fatty infiltration, in which the fat accumulates between the wasting fasciculi, keeping up for a time the bulk of the muscle. The less affected muscles are apt to undergo shortening and contracture because of maintaining so long a fixed position, either from being given over to gravitation or as a result of an effort to relieve pain. This alteration occurs most frequently in the lower extremity, contributing to intensify the "foot-drop" at the ankle, and more rarely to produce flexure at the knee-joint and to a less degree even at the hip, both of the latter being the result of posture. The foot-drop may possibly be increased by the pressure of the bedclothes upon the foot.

The sensory and motor phenomena are commonly associated *pari passu*, the latter extending from the hands and feet up the outside of the arm and leg. Very rarely either set of symptoms may occur alone.

Tremor is a marked symptom in some alcoholic cases and may precede loss of power.

Ataxic phenomena are usually associated with the sensory and motor symptoms. They are manifested by difficulty in balancing while standing, or by inability to execute finer movements with the fingers. Indeed these may be the first symptoms, and may lead when studied to the knowledge of some defect in extending the wrist and fingers, or in raising the toes, or foot, from the ground while walking. The ataxia is more marked in the lower extremities, and is believed to depend chiefly upon the afferent nerve involvement, since these are supposed to have most to do with co-ordination. Involvement of the motor nerves may possibly also cause ataxia. Because of the associated absence of the knee-jerk, the term peripheral pseudotabes has been applied to the ataxic stage. The neuritis may in some cases not progress beyond this stage. The symptoms may closely resemble those of tabes, but

the phenomena always fall short of those of true tabes. It may be said, too, of the ataxic form that the sensory disturbances are sometimes less severe than in other typical cases. Absence of the Argyll Robertson pupil and of vesical disturbance, rapid development of the disease, a history of the case suggesting a cause for neuritis, and, finally, recovery, are diagnostic points in favor of the ataxic form of neuritis.

Trophic changes may occur in prolonged cases, including mainly glossy skin, arthritic adhesions, and thickening; also vasomotor derangement, shown by edema, especially about the ankles and the dorsum of the foot; also pallor of the fingers, and changes in the nails and hair.

Mental symptoms are found more particularly in connection with the alcoholic form of neuritis. Besides irritability and general ill temper, more active symptoms are at times present. A childish jocularity in women, hysteria, and skillful duplicity in obtaining alcohol are characteristic. The phenomena may be those of delirium tremens or simple hallucination with extravagant ideas. Especially peculiar is the condition described by Wilks, in which there is a loss of appreciation of time and place, the patient describing with minute detail impossible journeys recently taken and persons whom he imagines he has seen. Convulsions and optic neuritis are rarely present; if present, they are probably due to meningeal inflammation. A simple mild delirium may occur in toxemic cases from the action of the poisons on the brain-cells. Mental symptoms are not usually present in multiple neuritis from other causes.

The number and variety of the symptoms vary greatly in different forms, being most widespread in those cases due to alcoholism, to cold, or to combined causes, and limited in the cases due to metallic poisons, as lead. The more acute the case, the more widespread are the symptoms.

Complications.—These are the other diseases to which alcoholics are subject—cirrhotic and fatty livers, gastric catarrh, and diseased kidneys and their consequences. The chief one in the toxic form is gout the result of mineral poisons, almost exclusively of lead. Pulmonary tuberculosis is common, and pneumonia, invading especially the middle portion of the lung, and sometimes bilateral, is a frequent cause of death.

Diagnosis.—The diagnosis of alcoholic cases is usually easy from the history, although sometimes skillful deception, especially in women, deprives the physician of this assistance. The distinctive features of the disease are the symmetrical localization of the sensory and motor symptoms, first and mainly in the extremities, and the tenderness of the skin, nerve trunks and muscles. There are, however, great variations in different cases, even in those dependent on the same cause, some being very acute and general and even rapidly fatal, others slow and limited to groups of muscles; some mainly motor, others sensory and ataxic (pseudotabes).

The possible sources of confusion are *rheumatism*, acute and chronic; *neuralgia*, *tabes dorsalis*, *poliomyelitis*, acute and subacute; *pachymeningitis*, damaging the nerve-roots, *acute ascending paralysis*, and *hysterical palsy*.

In *rheumatism* the tingling characteristic of neuritis is not present, and although the tenderness of a nerve passing in the neighborhood of a joint, especially apt to be aggravated in motion, may be mistaken for joint pain, careful examination will elicit its true nature. Neuritis differs from *neuralgia* in the bilateral symmetry of the pain, and in the persistence of tenderness and hyperesthesia as contrasted with the spontaneous pain of neuralgia.

The ataxic form of the disease, especially the form called neurotabes

(peripheral pseudotabes), sometimes resembles *tabes dorsalis* very closely. In neurotabes the lesion consists only in the nerve degeneration, while the spinal cord is free, its claim to the title being the fact that the loss of motor power may be slight in neurotabes, as in most cases of true tabes. The diagnosis from tabes may generally be easily made. The association of absolute paralysis or distinct weakness of extensors with inco-ordination would indicate neuritis. The "lightning pains" of tabes are seldom found in neuritis, nor are waist constriction nor pupillary symptoms, while the muscular tenderness is not found in tabes. Rapid onset of the disease and ultimate recovery occur in pseudotabes. The extreme hyperesthesia, so distinctive a symptom of neuritis, is less valuable in diagnosis, because it is often absent in the ataxic form. Girdle pains, paralysis of the sphincters of bladder and rectum, all point to cord involvement, even in alcoholic cases.

Poliomyelitis—inflammation, acute or subacute, of the gray matter of the cord—resembles the rheumatic and toxemic forms of neuritis, which have, like it, a febrile onset, *initial* rheumatic pains, and muscular wasting with the reaction of degeneration. But, again, we contrast the symmetrical distribution of the palsy of neuritis and its limitation to nerve distribution with the random distribution of poliomyelitis. Pain on pressure and subjective sensory disturbances are not prominent in poliomyelitis.

In *pachymeningitis* which involves the nerve-roots, producing paralysis, wasting, and anesthesia, the legs do not suffer early in the disease, as a rule; and while the upper parts of the arms and trunk may be anesthetic, there is no tenderness of the nerve trunks, unless these are also inflamed.

Acute ascending paralysis (Landry's) resembles the most rapid form of multiple neuritis in some of its symptoms, but the paralysis usually ascends the trunk from the legs to the arms, and does not begin in the hands and feet at the same time, nor does it affect the trunk last, as in neuritis. There is, moreover, no anesthesia in typical ascending paralysis. There are, however, transitional cases between multiple neuritis and Landry's paralysis, and the term Landy's paralysis is somewhat in disfavor.

Some assistance in diagnosis may be had from the etiological standpoint; the history of metallic poisoning, of alcoholic excesses, or of exposure to infectious diseases, or the presence of diabetes being suggestive.

Prognosis.—A very large number of cases of multiple neuritis get well, though slowly, especially if the cause be discovered and removed. Especially is this true of the alcoholic cases, although improvement does not always begin immediately on withdrawing the cause—indeed, the disease may even progress for a time, and improvement may not be observed for several months. Hence the prognosis should be guarded. The acute and widespread cases are the most dangerous to life, and in such the prognosis should always be guarded. The involvement of the muscles of respiration, including the diaphragm, is most to be feared. Pain in the trunk muscles is a grave symptom if the motor power of the limbs has diminished much. Paralysis of the diaphragm may be insidious and unnoticed until that of the intercostals is added, when there may be accumulation of mucus, bronchitis, and death by suffocation. Involvement of the cardiac nerves is also serious, and is manifested by frequency of pulse. Superadded involvement of the spinal cord increases the danger. At best, months are required for recovery, and even years may be necessary. Involvement of the spinal cord precludes total recovery. The return of faradic irritability in nerve and muscle is favorable. To sum up with Gowers: "The prognosis is better in the sensory

than in the motor form, better when the arm escapes than when all the limbs are involved, better in cases of chronic than acute onset, and better if a case of apparently acute onset is really such than if it succeeds slight symptoms of longer duration."

Treatment.—The removal of the cause, if possible, is a primary step in treatment. Along with this, rest is most important, and the rest should be complete—in bed, and this should be enforced in the earlier stages; later the pain and loss of motor power make rest obligatory. Care should be taken to avoid any pressure of the bed-clothes upon the feet, which might aid in the contracture of the muscles in the position of foot-drop. There should be no compromise with alcohol, although in some cases of great debility, when the cardiac action is feeble, gradual withdrawal may be justifiable. The patient should, on the other hand, be fed on the most nutritious food. Local anodyne applications may be resorted to to relieve the pain, and may be varied according to effect. Dry heat, moist heat, applications of lead-water and laudanum, and ointments of aconite and veratrum are some of those which may be employed. Wrapping in cotton or wool is sometimes beneficial. Warm baths are soothing; sometimes very hot ones give relief.

Postures assumed because of the relief they give to pain should not be too long permitted lest deformity result by contraction and adhesion, difficult or impossible to overcome. Dropping of the feet should be prevented by splints or by support with sand-bags. The same is true of flexion at the knee and hip.

As to drugs, they are of little use; the salicylates, phenacetin, antifebrin, and antipyrin may be useful in mild cases, and should be tried in doses of from five to fifteen grains (0.3 to 1 gm.). They are more particularly useful in cases due to cold. Extreme pain may demand the cautious use of morphin hypodermically in doses of from 1-6 to 1-3 grain (0.011 to 0.022 gm.) combined with 1-150 grain (0.00044 gm.) of atropin, which modifies and improves the action of morphin most happily. For the mental symptoms the hydrobromate of hyoscin in doses of from 1-200 to 1-100 grain (0.00033 to 0.00066 gm.) hypodermically, or hyoscin in doses of from 1-400 to 1-150 grain (0.00016 to 0.00044 gm.) may be tried. Mercurials, so highly approved by Gowers in simple neuritis, are useless here. The iodids are sometimes beneficial in chronic cases and in cases due to lead absorption.

Roborant medicines, such as iron and cod-liver oil, are indicated to build up the patient, who is generally broken down. Electricity and massage are very useful after convalescence has set in.

ENDEMIC NEURITIS.

Definition.—This term is applied to certain forms of multiple neuritis, supposed to be due to vegetable organisms, limited, or endemic to certain localities. Three separate varieties have been recognized, but others probably exist. The three referred to are malarial neuritis, beri-beri, and leprous neuritis.

I. **MALARIAL NEURITIS.**—This corresponds in its clinical features to the simpler forms of multiple neuritis, and requires no detailed description. Its malarial nature is based on its prevalence in malarial districts and its curability by quinin. While it is believed to be caused by the plasmodium of

malaria, I am not aware that this organism has as yet been discovered in the blood of patients suffering from it; the plasmodium, however, has been found in the central nervous system of persons who have manifested various symptoms of nervous disease.

2. BERI-BERI, THE KAKKÉ OF JAPAN.—Beri-beri is a disease prevalent in Japan, the Eastern Archipelago, India, New Zealand, Ceylon, the South Pacific Islands, and the coast of Brazil. It is especially prevalent in the Dutch East Indies among soldiers and in prisons, and has been thoroughly investigated under the Netherlands Government. In this country, J. J. Putman has described a similar disorder among New England fishermen who frequent the Grand Banks of Newfoundland, and Bondurant has observed it among sailors in the Gulf ports of Alabama. It is also not uncommon among Norwegian sailors. Seguin, of New York, has described cases originating in the West Indies and coming to this country.

Etiology.—Sheube and Baelz first determined its true nature, but our knowledge has been greatly increased of late by the studies of Pekelharing and Winkler.* It is believed to be due to a special organism, of which rods and cocci have been described, and of which cultures have been made. These, when inoculated, produced peripheral neuritis of the same distribution as beri-beri. Repeated inoculations having, however, been required to produce the disease, it has been reasonably concluded that repeated exposures are necessary before infection results. It is transmissible from individual to individual. The disease is also acquired by residence in certain houses, and patients recover after removal to a district which is free, relapsing on returning. It has been thought that a nitrogenous and especially an exclusive fish diet predisposes to the disease, and, again, a rice diet. Roll † has shown that in all probability the disease is transmitted through drinking-water, since he traced two epidemics on board ship to this cause. In both cases the sailors were free so long as they had a supply of European water; but in one instance, after laying in fresh water at Batavia, and again in Mauritius, where the disease prevailed endemically, it appeared among the crew at the end of five weeks.

Symptoms.—There are several types of cases. Among the earliest symptoms is a *change in the electrical excitability of the peroneal nerves and the flexors of the ankles*, consisting in a slight degree of reaction of degeneration, quantitative and often qualitative, this even before there are any subjective symptoms. Sometimes, indeed, the disease goes no further. Generally, however, the subjective symptoms begin as a *sense of heaviness of the legs, a tendency to tire easily, perverted sensation, diminished tactile sense in the lower part of the legs, and irritability of the heart*. In an acute pernicious form the nervous phenomena are less marked. There are *fever, anemia, and general anasarca*. The edema is quite constant, beginning in the legs. The *urine* is scanty, but not otherwise altered, and contains no albumin. A critical increase in the quantity of urine indicates an improvement. In the second group the neuritic symptoms are more marked, there being *numbness, anesthesia, loss of tendon reflexes, muscular atrophy, and anasarca*. In the third group, the *atrophy and paralysis* are most conspicuous, and the clinical picture is that of a rapidly progressing multiple neuritis with sensory and motor symptoms. The mortality varies from 3 to 60 and even to

* Pekelharing and Winkler, "Centralblatt f. Nervenkrankheiten," 1899, and "Deutsche med. Wochenschr.," 1888 No. 30.

† "Norsk Magazin for Lægevidenskaben," November, 1895, and May, 1896.

70 per cent. The *diaphragm* and *larynx* may become paralyzed, and the cardiac branches of the vagus involved, producing cardiac failure and death.

Treatment.—The treatment calls for the removal of the cause by disinfection or removal of the patient from the infected house or district and by the withdrawal of suspected food or drinking-water.

The symptoms are treated as in other forms of neuritis. In consequence of the tendency to cardiac weakness heart tonics may be needed, such as digitalis, strychnin, strophanthus, and caffeine.

3. **LEPROUS NEURITIS.**—Similar to beri-beri is leprous neuritis, already considered as to its etiology, symptomatology, and treatment. (See Infectious Diseases.) It differs from beri-beri in being transmitted from parent to offspring and in its extreme slowness of development after exposure, as much as ten years intervening. It differs also from beri-beri in that the neuritis is not an essential part of the disease. The neuritis is a symptom of the so-called "anesthetic leprosy." Leprous neuritis differs, further, from the usual forms of multiple neuritis in not being perfectly symmetrical and in being a perineuritis and an interstitial neuritis instead of parenchymatous. The bacillus is also found in the tissue, by its presence causing the inflammation, while in beri-beri the virus circulates in the blood. Hence the irregular distribution of the neuritis in the leprous form, resembling in this respect the more isolated neuritis of syphilis.

Symptoms.—The special symptoms are muscular wasting and anesthesia, more marked toward the extremities of the limbs, but not confined to them, being found elsewhere, as in the face, involving the fifth and seventh pairs of nerves. Sometimes tenderness and pain are present; the latter is, however, not severe. There may be tingling, also anesthesia, and diminished electrical excitability, with reaction of degeneration. The irregular areas of anesthesia are generally associated with irregular patches of pigmentation and pallor.

The **diagnosis**, **prognosis**, and **treatment** are the same as those of leprosy.

NEURALGIA.

Definition.—Strictly speaking, the term neuralgia should be restricted to such varieties of nerve pain as are unattended with structural changes in the nerve. Formerly, many cases now regarded as cases of neuritis were called neuralgias, and it is probable that, as our knowledge grows, other so-called neuralgias will be eliminated. Finally, the border-line existing between neuralgia and neuritis cannot be drawn sharply, but as far as possible, the term neuralgia should be restricted to nerve pain without organic change.

Etiology.—Neuralgia is a disease of adults. It rarely occurs before puberty, and is relatively rare in old age. It is more common in women than in men, although not so very rare in old men. Heredity is responsible for a tendency to neuralgia. It is frequent in so-called neurotic families. According to Anstie, fully one-fourth of all cases are the result of heredity. Neuralgia is prone to occur in the so-called "nervous" person—*i. e.*, one who is excitable, anxious, and worrisome in disposition. In this category, too, come the hysterical neuralgias. The debilitated, anemic, and poorly fed are liable to it. So are they who are overworked and worried.

The most frequent *exciting* cause is cold. Malaria is one of the most

common causes, producing, especially, hemicrania, while the malarial cachexia also predisposes to neuralgia. The pain of carious teeth is not regarded as neuralgic, but when such pain causes irritation of the peripheral branches of the fifth nerve, a neuralgia may be produced in the distal distribution.

Symptoms.—*Pain* is, of course, the leading symptom. “Spontaneous pain,” by which is meant pain independent of neuritis or irritation of the nerve, and the modifications to which it is subject in severity and distribution, constitute, in fact, the disease. This pain is irregularly paroxysmal, shooting, darting, or burning in character, not usually increased by motion, and if not relieved by pressure, may be by gentle friction. The more the pain is increased by motion and the more there is pain over the nerve-trunks on pressure, the more is it a neuritis and the less a neuralgia. Yet we cannot literally adhere to this, as evidenced by the “tender points” of Valleix, which will be further referred to under the different varieties of neuralgia. Multiple dartings and shootings, separated by seconds or minutes of freedom from pain, are characteristic.

The absence of primary tenderness is also characteristic; but after the pain has continued for some time there often succeed tenderness of the skin and even a redness and swelling, the absence of any unnatural degree of which at the beginning is considered distinctive. These phenomena, including edematous swellings, are regarded as vasomotor in origin. Other vasomotor symptoms are hyperidrosis, increased secretion of saliva and tears, and elevation of temperature. Trophic effects are seen in shedding of the hair and its rapid blanching, and other symptoms to be referred to. Muscular twitchings are also not uncommon at the seat of the pain, and sometimes even muscular spasm.

The duration of an attack of neuralgia varies from an hour or even less to many hours. Sooner or later, if not relieved, it subsides spontaneously, though with a greater tendency to recur than when relieved by treatment.

VARIETIES DEPENDING UPON NERVES INVOLVED.

Neuralgias are variously named in accordance with the nerves affected, whence we have the following varieties:

1. *Trifacial Neuralgia* (*Neuralgia of the Fifth Pair; Tic douloureux; Prosopalgia*).—This form involves one or more of the branches of the fifth pair, rarely all. It is more common than all other varieties of neuralgia combined. Here, doubtless, we have sometimes to do with a neuritis not always easily separable. One or more numerous tender points are usually demonstrable, of which those at the supra-orbital and infra-orbital foramen are the most conspicuous.

Of the branches of the fifth, the *ophthalmic*, or the first division, is that most frequently affected, giving rise to the well-known supra-orbital neuralgia. The pain radiates from the “tender point” at the supra-orbital notch over the anterior half of the head sometimes to the eye itself, the eyelid, and half of the nose. There may be injection of the eye and suffusion. There is sometimes pain in the occipital protuberance and cervical spines. This supra-orbital form must most frequently be distinguished from catarrh of the frontal sinuses, but the latter is more likely to be symmetrical, and while the pain is severe, it is duller, less shooting, and is accompanied by

coryza; it terminates suddenly with a free discharge of purulent matter, sometimes offensive.

When the distribution of the *infra-orbital*, or second branch is involved, the pain occupies the area between the orbit and the mouth, over the cheek to the ala of the nose. The "tender points" are at the emergence of the nerve below the orbit, at the side of the nose, over the most prominent part of the malar bone, and along the gingival line in the upper jaw, rarely in the upper lip.

When there is involvement of the third, or *inferior maxillary*, division, less common as an isolated form,—except as to its inferior dental branch,—there is a much more extensive area of pain, including the parietal eminence, the temple, the ear, the lower jaw, and the tongue. The "tender point" is in front of the ear where the auriculotemporal crosses the zygomatic arch, where there is often burning pain. The movements of mastication and speaking may be painful, and there may be salivation. A herpetic eruption about the eyes or lips is occasionally present and is then distinctive. Atrophy and induration of the skin have been included in the symptoms, but these are ascribable only to a neuritis.

There is a pure *ocular neuralgia* involving the eyeball only. It may or may not be due to errors of refraction. Of these, hypermetropia, or farsightedness, is the most common cause. Either one or both eyes may be affected. It may be accompanied by dimness of vision.

A form of trigeminal neuralgia, called by Trousseau "epileptiform," consists in sudden, severe, and frequent attacks of pain, lasting from a few seconds to a few minutes, many times repeated during the day.

2. *Cervico-occipital Neuralgia*.—This affects the area of the neck supplied by the posterior branches of the first four cervical nerves, and the posterior part of the head supplied by the great occipital branch of the posterior division of the second cervical nerve, at the exit of which there is a tender point about half way between the mastoid process and the first cervical vertebra. Two other tender points are just above the parietal eminence, and between the sternomastoid and trapezius muscles. The pain may extend over the greater part of the neck and head, as far forward as the parietal eminence and the ear.

Exposure to cold or a draft of air is the most common cause of this form. Nephritis has been believed to be a cause.

3. *Cervico-brachial and Brachial Neuralgia*.—This involves the area supplied by the four lower cervical and the first thoracic nerves, the area of sensory distribution of the brachial plexus.

The tender points are the axillary, the circumflex at the posterior part of the deltoid, the superior ulnar behind the elbow, and the inferior ulnar in front of the wrist. This form is often confounded with neuritis due to rheumatic affections of the joints or injury.

4. *Neuralgia of the Phrenic Nerve*.—This is rare, the pain in its area during pleurisy and pericarditis being rather a neuritis. The pain is at the lower part of the thorax, at the attachment of the diaphragm. Breathing is shallow, because pain is caused by the breathing movements. Coughing and even deglutition cause pain.

5. *Trunk Neuralgia*.—This naturally divides itself into two subvarieties: dorso-intercostal and lumbo-abdominal.

(a) *Dorso-intercostal neuralgia* covers the area supplied by the intercostal nerves from the third to the ninth, and is characterized by pain along

the intercostal spaces or in parts of them. It is sometimes bilateral. There is usually a constant dull pain with or without acute stabbing exacerbations, or the latter may be excited by deep breathing or motion. There may be special tenderness at the points of emergence of the three branches of the intercostal nerve—viz., near the vertebræ, anteriorly near the median line, and midway between these two points in the midaxillary line.

The term *pleurodynia* has been used with a good deal of vagueness. Strictly speaking, it should be limited, as it is by Gowers, to neuralgia of the pleural nerves. Consistently with this it should not be applied to pain localized in the course or point of exit of an intercostal nerve. It is very acute in character and excited by expansion of the thorax rather than by lateral movements of the trunk. The pain of herpes zoster is not a neuralgia, but a neuritis.

Another variety in this locality is the inframammary neuralgia of anemic women.

(b) *Lumbo-abdominal neuralgia* involves the posterior branches of the lumbar nerves, especially the ilioscrotal branch. The area of the pain is the region of the iliac crest, along the inguinal canal and the spermatic cord in the scrotum, or round ligament in the labium majus. The pain is often bilateral, sometimes resembling the constricting girdle pains of spinal cord disease, from which it differs, however, by its changing place. It is especially frequent in connection with diseases of the pelvic organs, particularly in women. The testes and penis are the seat of neuralgic pains.

6. *Neuralgia of the spinal column* is the more modern term for the "spinal tenderness" of the older authors. It is common in feeble and hysterical women, and a sequel of the modern railway accident under the name of "spinal congestion." The pain in most cases is felt along a considerable vertical extent of the spine, but is more intense in certain spots. The thoracic region is the most common seat, next the lower cervical, and least frequently the lumbar region.

7. *Sacral neuralgia and coccygodynia* are defined by their names. These affections reside in the nerves between the bone and the skin, and are often exceedingly difficult to cure. The pain really may be due to organic lesions in the part.

8. *Neuralgia of the feet* includes painful heel, plantar neuralgia, and erythromelalgia. In the latter, first described by Weir Mitchell, vascular changes, including either acute hyperemia or cyanosis,—probably of vasomotor origin,—are associated with severe pain in the heel or sole of the foot. It is probably a neuritis in some cases.

9. *Visceral neuralgia* means neuralgia affecting the gastro-intestinal tract, the kidneys, ovaries, and other pelvic organs. Idiopathic nephralgia, or neuralgia of the kidney, I regard as a rare event. It and testicular neuralgia are more frequently secondary to inflammation of adjacent urinary passages, but idiopathic testicular neuralgia is less rare than nephralgia.

Neuralgias are further classified according to character and cause. Thus, in addition to the epileptiform variety alluded to, there are reflex or symptomatic neuralgias, traumatic neuralgias, herpetic neuralgias accompanying herpes, hysterical, rheumatic, gouty, diabetic, anemic, malarial, syphilitic, and degenerative neuralgias. Many of these terms are loosely applied. The term rheumatic neuralgia is often erroneously applied to muscular rheumatism. It should not be used.

Very interesting and important is the subject of *reflex neuralgias* and

referred pains which have been especially studied by the late Dr. Anstie in England and Charles L. Dana in this country. Reflex neuralgias are due to disease in organs distant from the actual seat of the neuralgia. The fifth nerve is a favorite seat of such neuralgias. Thus, an irritation of the distribution of one branch of this nerve by a carious tooth may excite a neuralgia in another distribution of the same nerve. Illustrations of referred pain are the "pain in the back" or spinal pain in ulcer of the stomach, the left scapular pain in diseases of the liver, the sacral pain in uterine disease, and the testicular pain in renal colic.

Diagnosis.—Neuralgia is chiefly to be distinguished from *neuritis* and the effects of *pressure on nerves*; and also *rheumatism*. From *neuritis* it is separated by its unilateral distribution as contrasted with the more frequent symmetrical distribution of *neuritis*, although *neuritis* is not infrequently unilateral; also by its numerous remissions and intermissions, and the shifting of the pain from one spot to another. The fixed neuralgias are more difficult of separation from *neuritis*, especially mild cases. The severe forms of *neuritis* are soon recognized by the anesthesia which succeeds upon the hyperesthesia in the case of sensory nerves, and muscular wasting with changes in the electrical irritability in mixed nerves. In the case of *compression of nerves* the pain is continuous, while the symptoms and consequences of *neuritis* will, sooner or later, show themselves. Nevertheless, doubt and error must not infrequently occur.

Muscular rheumatism differs in its localization in muscles or groups of muscles such as the lumbar or shoulder muscles, its continuousness and pain increased by motion.

Prognosis.—The prognosis in neuralgia is usually ultimately favorable, although some forms and cases are very stubborn. Especially true is this of neuralgia of the fifth pair. The more frequent the recurrence and the wider the distribution, the more difficult is the cure. On the other hand, the severity of the pain is not, in my experience, a measure of obstinacy to cure, some of the severest cases being easiest relieved. Hereditary cases are the most obstinate. The same is true of cases occurring in the decline of life. Epileptiform neuralgia is said to be incurable.

Treatment.—The treatment of neuralgia is divided into that of the *condition predisposing* to it and of the *paroxysm*. The anemias,—especially chlorosis,—malaria, and other predisposing causes should be corrected by quinin, iron, and arsenic. Good nourishing food is important. Change of scene and residence is often necessary. Reflex causes should be carefully sought for and removed. Until these predisposing causes are removed, the treatment of the paroxysm affords but temporary relief.

For the paroxysm quinin is by far the most efficient remedy, and will cure many cases. Two or three grains (0.12 to 0.194 gm.) should be given hourly until the paroxysm is relieved or decided cinchonism is produced. The salicylate of cinchonidia is a valuable preparation. Some cases are relieved by phenacetin or antifebrin (acetanilid) in from ten to fifteen-grain (0.66 to 1 gm.) doses. A combination of phenacetin and caffeine, three grains (0.33 gm.) of the former and one (0.11 gm.) of the latter each, in hourly doses, is often efficient. Some cases can only be relieved by sulphate of morphin. The hypodermic injection is the promptest and surest remedy, in doses of from 1-8 to 1-4 grain (0.008 to 0.016 gm.), but morphin is a drug to be avoided in neuralgia, if possible, as the danger of acquiring the morphin habit is extremely great. The patient should never be allowed to use

the hypodermic syringe himself. The use of anodynes is sometimes more than palliative, the repeated removal of the pain tending to prevent its recurrence. The combination of atropin with morphin undoubtedly modifies the unpleasant effect of the latter drug and increases its efficiency.

Belladonna, and its active principle, atropin, are remedies which have long enjoyed reputation in the treatment of neuralgia, when uncombined with other drugs, but in my hands they have been feeble remedies. The doses recommended are from 1-6 to 1-2 grain (0.011 to 0.03 gm.) of the extract and from 1-120 to 1-60 grain (0.0005 to 0.0011 gm.) of atropin. Aconite and gelsemium have also some reputation, especially in neuralgia of the fifth nerve. Gelsemium may be given in doses of fifteen minims (0.92 c. c.) of the tincture, frequently repeated. Gelsemia may be given hypodermically in doses of from 1-60 to 1-30 grain (0.0011 to 0.0022 gm.), and aconitin in doses of from 1-250 to 1-100 grain (0.00027 to 0.00066 gm.), but the latter is a remedy so dangerous that I rarely employ it. Cannabis indica is also sometimes useful in doses of 1-4 grain (0.016 gm.) three times a day, but the drug varies so much in strength that it cannot be relied upon.

Local applications are sometimes very useful. Pressure relieves many mild cases, especially when associated with gentle friction. Local anesthetics, such as menthol, the ointments of veratria and aconitia, are similarly useful; so is the tincture of aconite painted over the involved area. The local use of opiates, at least without first removing the epidermis, and of atropin (5 per cent. strength), is, however, commended. The extract of belladonna, diluted with glycerin so as to admit its being smeared on, is sometimes useful. Frequent renewals of all these local applications should be made in the course of the day. Counterirritation by blisters or sinapisms, by chloroform either pure or variously diluted, and by camphor may be used. The last two may be applied on lint and covered with oiled silk. Both will blister if left on too long.

Cocain might be reasonably expected to be useful, but to act through the skin the ointments and solutions containing it should be strong—from 10 to 15 per cent. For mucous surfaces this strength should be used with caution. A cocain habit is as easily established as morphinism, and is about as unpleasant in its results. The hypodermic injection of cocain is much more efficient. The usual dose is 1-4 grain (0.016 gm.), but smaller doses may be commenced with. The Paquelin cautery is often a prompt and efficient agent.

Acupuncture and *aquapuncture* are employed, the latter consisting of injecting water under the skin. For their local effect, also, *chloroform*, *carbolic acid*, and *osmic acid* have been injected *hypodermically*. From fifteen to twenty minims (0.92 c. c. to 1.23 c. c.) of the first may be used, from five to ten minims (0.31 c. c. to 0.62 c. c.) of the second, and one or two drops of a 1 per cent solution of osmic acid in water and glycerin. Chloroform should be cautiously used in this manner, as it may occasion ugly sloughing. It is more especially in sciatica that these measures have been employed. *Local* applications of *heat* and *cold* have been found useful—cold by freezing or by the ether spray; heat by the hot-water bag, or in the case of a supra-orbital neuralgia, by the nasal douche. Heat is usually more efficient than cold; indeed, the latter sometimes aggraves neuralgia.

Electricity is of uncertain value in neuralgia, but is sometimes very useful. The constant current is the form most frequently used, but faradism may also be employed. It is used in two ways: a strong current is applied at

once with a view to removing the neuralgia promptly (this is scarcely to be recommended); in the second method a sedative effect is sought by a weak current, preferably of galvanism, just sufficient to produce a tingling or burning sensation. Experience goes to show that the direction of the current may be ignored, but it is commonly recommended to apply the positive pole to the painful part, the sponge being well wet with warm water, and if faradism is used, it should be with rapid interruptions.

The *surgical treatment* of neuralgia has been followed by brilliant results, and has met signal failures. The most common procedure is division of a nerve, or, better, the exsection of a portion of the nerve. It has been most frequently done in the case of the fifth nerve, and is almost always followed by temporary relief, but, sooner or later, an operation on the Gasserian ganglion usually becomes necessary. Operation is to be recommended in intractable cases, and should be done at a point as near the origin of the nerve as possible, as second operations are not infrequently necessary on account of the recurrence of the pain.

Nerve stretching is also performed with a measure of relief less thorough than exsection, but in view of the fact that its disadvantages are less lasting, it is the better operation to do first in the case of certain nerves. It is important to remember that relief does not always immediately follow the operation. The sciatic is the nerve most frequently stretched, but the intercostals and branches of the fifth, including the lingual, have been similarly treated with satisfactory results. The removal of the Gasserian ganglion affords relief in tic douloureux, but is a serious operation.

TUMORS OF NERVES.

Definitions and Morbid Anatomy.—Strictly speaking, the term *neuroma* should be restricted to tumors composed purely of nervous tissue, which are to be distinguished from *fibrous tumors* or *fibromata*, often seated on nerves and known as *false neuromata*. Some, however, dispute the existence of true neuromata, and they are certainly very uncommon. Another form of false neuroma is a variety of the small, subcutaneous, painful tumor—*tubercula dolorosa*—occurring in nerves of the skin in the neighborhood of the joints on the face, and on the breast. Myxomata, sarcomata, and even carcinomata are found in connection with nerves. The latter are commonly the result of extension by contiguity, infiltrating the connective tissue between the fibers. The nervous tissue represented in the true neuroma is usually fibrous, but very rarely ganglionic nerve-cells are found, and in such event the tumor may be regarded either as dislocated nerve tissue or as a glioma the cells of which closely resemble true nerve-cells. The nervous tissue may be of the medullated or non-medullated variety—*i. e.*, myelinic or non-myelinic. Connective tissue varying in quantity is associated with both, producing various degrees of hardness, which is most striking in the multiple fibroneuroma.

An interesting variety is the *plexiform neuroma*, nodular and tortuous in appearance to the naked eye, the internal structure of which is composed also of interlacing nodular and tortuous nervous cords made up of connective tissue and nerve-fibers. It is most frequently found in connection with the fifth pair of nerves in the orbit, on the upper eyelid, or on the

temporal bone, but is seen also in connection with any of the spinal and even sympathetic nerves. It grows slowly, and probably begins in fetal life.

True neuromata are usually small, but may be three or four inches (7.5 to 10 cm.) in diameter and even larger. They are usually found seated in nerve-trunks, or at their ends, are often multiple, and their number is sometimes large.

Etiology.—Nerve tumors which are not congenital may be traumatic. More than one member of a family has been found affected. Their growth seems stimulated by perversion in the healing process, since they are found on the ends of nerves in cicatrices after amputation.

Symptoms.—Neuromata may be totally without symptoms. At other times they are very painful, the *pain* being aggravated by pressure. There may be *numbness* and *formication* and even *loss of sensation* on the one hand, *muscular twitching and paralysis* on the other, the latter especially when the tumor is in the course of the nerve.

Neuromata of the cauda equina may cause paraplegia. Reflex spasm in adjacent or distant muscles, and even epileptiform convulsions, are occasionally present. A neuroma may give rise to visible swelling, or it may be beneath the surface out of sight and touch.

Diagnosis.—Except in the case of plexiform neuroma, which has a characteristic form described, the exact diagnosis of the variety of nerve tumor can for the most part be made only by microscopic examination after removal, since all the symptoms occasioned by true neuroma may be caused by pressure on nerves by any form of morbid growth. Multiple neuromata are usually false neuromata.

Prognosis.—Nerve tumors rarely cause death, though they sometimes undergo malignant change, and in this way cause a fatal termination. The extreme pain which is so characteristic may in time exhaust a patient, but the course of the disease is always prolonged.

Treatment.—Excision is the proper treatment for neuromata and all other forms of tumors connected with nerves, if they can be reached, and if the symptoms demand active treatment. Often such treatment is not demanded. If syphilitic origin be suspected, syphilitic treatment should be adopted. In operations involving section of a nerve trunk the possibility of loss of function is to be remembered.

Local anodyne applications may be used to palliate in mild cases, but they are useless in severe ones. Cocain in doses of from 1-6 to 1-2 grain (0.011 to 0.033 gm.) may be injected hypodermically, but morphin should not be used, as the conditions are especially favorable to the production of morphinism.

AFFECTIONS OF THE SPINAL CORD.

Anatomical.—The spinal cord, covered by its membranes, the dura and pia arachnoid, hangs loosely in the spinal canal from the atlas to the second lumbar vertebra. It is, therefore, much shorter than the spinal canal itself. The remainder of the canal is occupied by the cauda equina. Each pair of spinal nerve-roots arises above the foramen of exit, and descends to the latter within the canal. The part of the cord whence each pair arises is known as the *segment of that particular pair of nerves*. The following from Deaver's "Surgical Anatomy" locates with sufficient accuracy the origin of these nerves: "The eight cervical nerves arise above the sixth cervical spine, the upper six thoracic nerves between the sixth cervical and fourth thoracic spines, the lower six thoracic nerves between the fourth and eleventh thoracic spines, the five lumbar nerves between the eleventh and twelfth thoracic spines, and the five sacral nerves between the last thoracic and first lumbar spines." See Fig. 93.

In transverse section the cord is easily seen by the naked eye to be made up of central gray matter and external white substance. The former is composed largely of cells, the latter of fibers. The gray matter, roughly comparable to two crescents placed back to back, reaches the surface only by its posterior horns at the two points, whence enter the posterior roots of the spinal nerves. The broad, blunt anterior cornua do not reach the surface, but the white fibers of the anterior roots are seen perforating the white matter to enter the gray. The cord is separated into halves by the anterior median fissure, and by the posterior median septum, which is not a fissure.

At the bottom of the anterior median fissure is the transverse commissure of white matter, in front of the central spinal canal. A short distance to the outside of the posterior median septum is another less distinct septum, the *posterior intermediate septum*, which bounds the *posterior median column* or column of Goll, which does not extend as a distinct column below the cervical and thoracic portions of the cord. Outside of this, bounded by the posterior horn, is the *posterior external column*, or column of Burdach, limited in like manner to the cervical and thoracic parts of the cord. The *antero-lateral column* is divided artificially by a line coinciding with the outermost of the anterior nerve roots, and thus is made an anterior and lateral column, which, with the *posterior column*, makes three columns for each half cord. The white matter is composed of the usual medullated nerve-fibers unprovided with neurilemma and of neuroglia supporting the nerve fibers. The further divisions of the cord in transverse section are clearly indicated in Fig. 95, representing a transverse section of the cord in the cervical region, with description.

Of these parts, the anterior (or direct) pyramidal tract, the lateral (or crossed) pyramidal tract (adjacent to the posterior cornua), and anterior cornua may be characterized, generally speaking, as motor, while the posterior columns, the *direct cerebellar tract*, the antero-lateral ascending tract of Gowers, part of the antero-lateral ground bundles, and the *posterior cornua*, may be described as sensory.

The white matter gradually diminishes as the cord is descended. The gray matter also varies in extent and shape at different levels, which will be appreciated by the examination of Fig. 94, which explains itself. It should

Fig. 93.—Diagram from an Original Investigation by W. R. Gowers, Showing Relation of Vertebral Spines to their Bodies and to the Nerve-roots. Only in the lumbar region are the ends of the vertebral spines opposite the middle of their bodies. They correspond to the lower edge of their bodies in the cervical and at the last two dorsal; and to the upper part of the body below them in the rest of the dorsal region. (See also text.)

Fig. 94.—Diagram Showing Relative Size and Shape of the Cord and Gray matter at Different Levels—(after Gowers).

be added that certain tracts recently described, and at present chiefly of interest to the anatomist, are not included in this diagram. Mention should be made of *Clarke's column*, a group of nerve-cells in the inner part of the neck of the posterior horn, from the upper dorsal to the second lumbar, also known as the lateral fascicular column. Above this, in the upper dorsal and lower cervical regions, a group of cells projects outward from the gray matter into the lateral column, called by Lockhart Clarke the *intermediolateral process*, but well named also the lateral horn. The *lateral or crossed pyramidal tracts*, representing about three-fourths of the motor fibers, passing down from the cortex decussate at the lower part of the anterior pyramids, and pass over into the lateral columns. The remaining fibers, which do not decussate, pass down the same side of the cord in the inner part of the antero-lateral column, constituting the *anterior or direct pyramidal tract*, also known as Türck's column. At every level of the spinal cord axis-

cylinders leave the crossed pyramidal tract to enter the anterior horns and end about the cell bodies of the lower motor neurons. This tract extends down to the end of the cord, but becomes smaller and smaller. The fibers of the direct anterior or pyramidal tract possibly cross at different levels in the anterior white commissure, to end about the nerve-cells in the anterior horn on the opposite side of the cord. If primarily small, this tract may not extend beyond the middle of the cervical enlargement. If originally large, it may be traced as far as the lumbar enlargement, or even into the sacral part of the cord. Throughout the greater part of the cervical and dorsal regions the lateral pyramidal tract is separated from the surface by a narrow layer of fibers, the *direct cerebellar tract*, which in the upper cervical region lies further forward, so that the pyramidal tract comes up to the surface close to the posterior horn.

The axis-cylinder processes forming the *anterior roots* of the spinal nerves start from the nerve-cells in the segments where these roots arise, and pass out as a part of the anterior roots to be distributed to the muscles they supply.

The relation of the axis-cylinders of the *posterior roots* after they enter the cord is not, however, so simple. It has already been said (p. 841) that

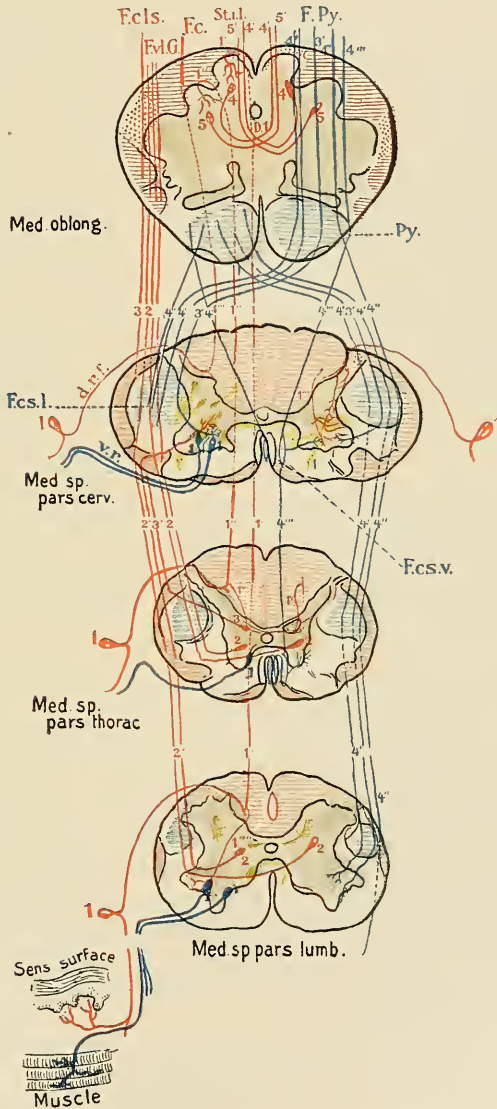

Fig. 96.—Sensory and Motor Paths in the Spinal Cord—(after Barker).

the single process which leaves the cell in the ganglion on the posterior roots of the spinal nerves divides in a T-shaped manner, one limb traversing the spinal nerve to the periphery of the body, the other passing toward the spinal cord as an axis-cylinder. After entering the cord each axis-cylinder process

again divides into an ascending and a descending limb, which run in the posterior columns. The descending branch runs a short distance and ends in the gray matter of the same side of the cord. The ascending branch may end in the gray matter soon after entering it or may run upward in the posterior columns to the medulla oblongata, ending probably in the nuclei situated in the posterior columns of the medulla oblongata (nucleus gracilis and nucleus cuneatus), remaining up to this point on the same side of the middle line. From the nuclei of the posterior columns of the medulla oblongata the axis-cylinder processes, after crossing, run toward the brain, form the fillet, into which possibly enter also the ascending fibers of the lateral column containing the crossed fibers of the upper sensory neurons. The exact termination of sensory processes in the cerebral hemispheres is not known. The position of the tract in the crus is posterior. The lower sensory neurons also have endings in the cells or about the cells in Clarke's column, from which cells the axis-cylinders run in the direct cerebellar tract of the same side; also about cells the axis-cylinder processes of which run but a short distance in the cord to end in the gray matter on a different level. Thus the possible paths of sensory conduction, probably many, are not definitely determined, whence disturbances of sensation do not give us so much help in topical diagnosis as those of motion. It may, however, be said in summary that cutaneous sensory impulses in man are conducted toward the brain chiefly on the opposite side of the cord. The crossing of sensory impulses takes place partly in the central gray matter soon after the path enters the cord, and partly after the fibers leave the higher nuclei in the posterior columns of the medulla oblongata. The muscular sense "or sense of position" is probably conducted on the same side of the cord in the posterior columns, to cross in the medulla oblongata, and we have some evidence that the tactile fibers ascend in the posterior columns. Thermal and pain impulses probably cross to the antero-lateral columns of the other side very soon after entering the cord.

Spinal Cord Localization.—It has already been said that the areas of distribution of spinal nerves, sensory and motor, are not sharply defined for each nerve as it emanates from the spinal cord, and that the regions thus supplied overlap. At the same time physiologists and clinicians have been able to map out with approximate accuracy the motor and sensory areas corresponding to the distribution of each pair of nerves emanating from different segments of the cord. Among those who have especially devoted themselves to this subject are M. Allen Starr, Charles K. Mills, and Charles L. Dana in America, and William Thorburn and Henry Head in England.

The results of various observers differ in detail, but agree in essentials. The appended table is that originally devised by Starr, further modified by C. L. Dana and C. K. Mills.

It must not be forgotten that these areas of distribution correspond to a nerve *constituted as it is when it emanates from a corresponding segment of the cord*, and not to a nerve as it is constituted immediately before it begins to spread.

LOCALIZATION OF THE FUNCTIONS OF THE SEGMENTS OF THE SPINAL CORD.

SEGMENT.	MUSCLES.	REFLEX AND CENTERS.	SENSATION.
I C.	Rectus lateralis. Rectus capitis. Anticus and posticus. Sterno-hyoid. Sterno-thyroid.		
II and III C.	Sterno-mastoid. Trapezius. Scaleni and neck. Omo-hyoid. Diaphragm.	<i>Hypochondrium</i> (?). Sudden inspiration produced by sudden pressure beneath the lower border of ribs.	Back of head to vertex and neck. (Occipitalis major, occipitalis minor, auricularis magnus, superficialis colli, and supraclavicular.)
IV C.	Diaphragm. Deltoid. Biceps. Coraco-brachialis. Supinator longus. Rhomboid. Supra- and infra-spinatus.	<i>Pupillary</i> (4th cervical to 2d dorsal). Dilatation of the pupil produced by irritation of neck.	Neck. Shoulder, anterior surface. Outer arm. (Supraclavicular, circumflex, external musculo-cutaneous, cutaneous.)
V C.	Deltoid. Biceps. Coraco-brachialis. Brachialis anticus. Supinator longus. Supinator brevis. Deep muscles of shoulder-blade. Rhomboid. Teres minor. Pectoralis (clavicular part) Serratus magnus.	<i>Scapular</i> (5th cervical to 1st dorsal). Irritation of skin over the scapular produces contraction of scapular muscles. <i>Supinator longus</i> . Tapping the tendon of the supinator longus produces flexion of forearm.	Back of shoulder and arm. Outer side of arm and forearm to the wrist. (Supraclavicular, circumflex, external cutaneous, internal cutaneous, posterior spinal branches.)
VI C.	Deltoid. Biceps. Brachialis anticus. Subscapular. Pectoralis (clavicular part). Serratus magnus. Triceps. Pronators. Rhomboid. Latissimus dorsi.	<i>Triceps</i> (5th to 6th cervical). Tapping elbow tendon produces extension of forearm. <i>Posterior wrist</i> (6th to 8th cervical). Tapping tendons causes extension of hand.	Outer side and front of forearm. Back of hand, radial distribution. (Chiefly external cutaneous, internal cutaneous, radial.)
VII C.	Triceps (long head). Extensors of wrist and fingers. Pronators of wrist. Flexors of wrist. Subscapular. Pectoralis (costal part). Serratus magnus. Latissimus dorsi. Teres major.	<i>Anterior wrist</i> (7th to 8th cervical). Tapping anterior tendons causes flexion of wrist. <i>Palmar</i> (7th cervical to 1st dorsal). Stroking palm causes closure of fingers.	Radial distribution in the hand. Median distribution in the palm, thumb, index, and one-half middle finger. (External cutaneous, internal cutaneous, radial, median, posterior, spinal branches.)
VIII C.	Triceps (long head). Flexors of wrist and fingers. Intrinsic hand muscles.	Ulnar area of hand, back, and palm, inner border of forearm. (Internal cutaneous, ulnar.)
I D.	Extensors of thumb. Intrinsic hand muscles. Thenar and hypothenar muscles.	Chiefly inner side of forearm and arm to near the axilla. (Chiefly internal cutaneous and nerve of Wrisberg or lesser internal cutaneous.)
II D.	Inner side of arm near and in axilla. (Intercostohumeral.)
II to XII D.	Muscles of back and abdomen. Erectores spinæ.	<i>Epigastric</i> (4th to 7th dorsal). Tickling mammary region causes retraction of the epigastrium. <i>Abdominal</i> (7th to 11th dorsal). Stroking side of abdomen causes retraction of belly. Vasomotor centers. Second dorsal to 2d lumbar.	Skin of chest and abdomen, in bands running around and downward, corresponding to spinal nerves. Upper gluteal region. (Intercostals and dorsal posterior nerves.)

LOCALIZATION OF THE FUNCTIONS OF THE SEGMENTS OF THE SPINAL CORD—(Continued).

SEGMENT.	MUSCLES.	REFLEX AND CENTERS.	SENSATION.
I L.	None.	<i>Cremasteric</i> (1st to 3d lumbar). Stroking inner thigh causes retraction of scrotum.	Skin over groin and front of scrotum. (Ilio-hypogastric, ilio-inguinal.)
II L.	Vastus internus.	<i>Patellar</i> . Striking patellar tendon causes extension of leg.	Outer side and upper front of thigh. Lumbar region. (Genito-crural, external cutaneous.)
III L.	Sartorius; adductors of thigh. Flexors of thigh.	Front and outer side of thigh. Inner side of leg and foot.
IV L.	Extensors of knee. Abductors of thigh.	<i>Gluteal</i> (4th to 5th lumbar). Stroking buttock causes dimpling in fold of buttock.	Inner side of thigh, leg, and foot. (Internal cutaneous, long saphenous, obturator.)
V L.	Outward rotators. Flexors of knee. Flexors of ankle. Peronei. Extensors of toes.	<i>Achilles tendon</i> . Over-extension causes rapid flexion of ankle, called ankle clonus.	Back of thigh and outer side of leg and ankle; sole; dorsum of foot. (External popliteal, external saphenous, musculo-cutaneous, plantar.)
I and II S.	Calf muscles. Glutei. Peronei. Extensors of ankle. Small muscles of foot.	<i>Plantar</i> (5th lumbar to 2d sacral). Tickling sole of foot causes flexion of toes and retraction of leg.	Back of buttock and thigh, side of leg and ankle; sole; dorsum of foot.
III to V S.	Perineal. Muscles of bladder, rectum, and external genitals.	Genital center. Vesical centre. Anal centre.	Circum-anal region, anus, rectum, penis, urethra, vagina, perineum. (Small sciatic, pudic, inferior hemorrhoidal, inferior pudendal.)

The preceding table includes only the distribution of spinal nerves.

The following table includes the distribution of nerves starting from the nuclei in the pons and medulla oblongata, so far as these are concerned with motion:

<i>Nuclei.</i>	<i>Muscles.</i>
III Cranial.	{ Sphincter iris. Ciliary muscles. Levator palpebræ superioris. Rectus internus in convergence. Superior rectus. Inferior rectus.
IV "	{ Obliquus inferioris. Obliquus superioris. (Upper facial group.)
VI "	{ Rectus externus. Rectus internus of opposite side in lateral movements.
V "	{ Associated movement of levator palpebræ. Muscles of the lower jaw.
VII "	{ Facial muscles.
XII "	{ Lower facial group. Muscles of tongue.
IX "	{ Muscles of pharynx.
X "	{ Muscles of esophagus.
XI "	{ Muscles of larynx.

The study of the sensory areas is facilitated by the use of diagrams in which the areas are mapped out and indicated by color or a shading which will permit one to separate them easily one from another, like those annexed, in which, too, the areas corresponding to each spinal segment are indicated by suitable lettering.

Interpreting by the data contained in tables and diagrams such motor

or sensory derangements as may be present, one may deduce with more or less accuracy the seat of the lesions in the cord producing them. It has been mentioned that motor localization, being more definite, its arrangement permits more exact inference than sensory derangements.

The union of both adds further facility. Results vary also according as a lesion involves only one half or a complete section of the cord. Recalling the distribution of the two tracts, as given on page 890, it is evident that an injury involving the *entire transverse section* of the cord must produce, *first*, motor paralysis in all parts supplied with

Fig. 97.—Diagram of Lesion Showing Brown-Séquard's Paralysis—(after Starr).

L. Lesion in left half of cord cuts off motor impulses to left leg, sensory impulses from right leg, and sensory impulses from eleventh dorsal nerve.

Fig. 98.—Schema Showing Chief Symptoms in Left Unilateral Lesion of the Dorsal Cord—(after Erb).

Oblique shading at *a* signifies motor and vasomotor paralysis; vertical shading cutaneous anesthesia at *b* and *d*; dots on a cutaneous hyperæsthesia. *b*. Small anesthetic zone. *c*. Small hyperæsthetic zone.

nerves emanating from segments below it. In less complete lesions correspondingly limited degree and extent of motor paralysis succeed. Such paralysis may extend to the bladder and rectum. After complete or nearly complete section, the muscles are usually flaccid and the deep reflexes absent. There is no rapidly developing atrophy, and the muscles respond normally to electricity. No satisfactory explanation has as yet been offered of the abolition of the deep reflexes in complete or nearly complete transverse lesion of the cord; even above the level of the reflex arcs, although neuritis is supposed by some to be the cause of this

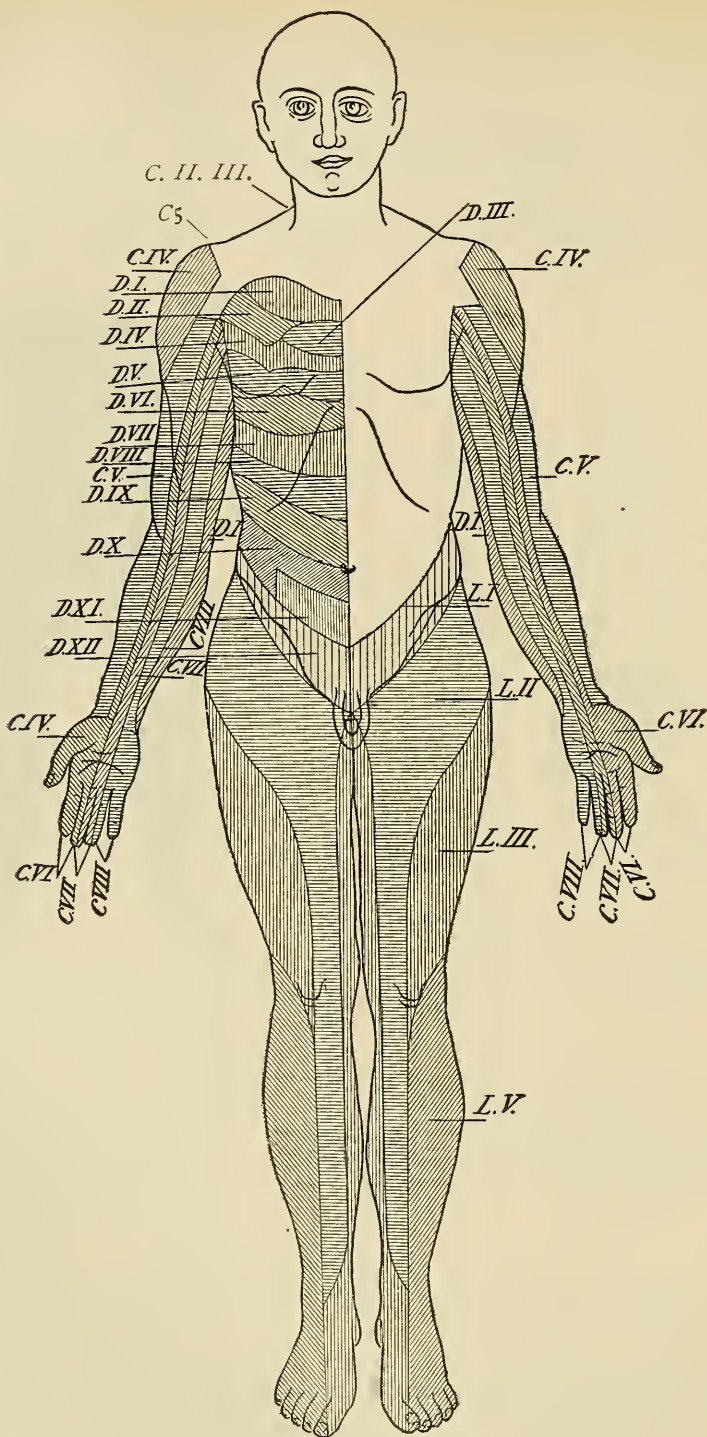

Fig. 99.—Diagram of Skin Areas Corresponding to Different Spinal Segments—(chiefly after Starr. Trunk areas from Head).
Roman numerals refer to nerves.

loss of the deep reflexes, it is probably not the cause in all cases. *Second*, there is impaired sensibility in the parts supplied by sensory nerves associated with corresponding segments below the lesion. Anesthesia does not, however, reach quite to the level of the lesion, because of the overlapping of sensory areas by nerves which enter the cord above the section. Thus, if the lesion be in the segment of the sixth thoracic, the anesthesia may extend only as high as the area supplied by the seventh. Moreover, above the anesthetic area there is also at times an area of increased sensibility,—the effect of the section possibly being to increase the sensitiveness of the cord above it by increasing its vascularity,—due to section of vasomotor nerves by the lesion. By means of these facts we may be enabled to ascertain the level of the disease. Muscular sense or sense of position is lost. Reflex excitability, at first slightly impaired, may subsequently be increased when the lesion is not complete and is above the reflex arcs, but may remain impaired in complete transverse lesions of the cord or in those portions of the body whose reflex arcs are situated in the damaged region of the cord.

The phenomena are modified if the lesion be a *hemi*-lesion of the cord. In such an event there is, *first*, motor paralysis in the portion of the body on the same side supplied by nerves whose cells of origin are below the lesion (Fig. 106 *a*), varying, however, with the seat of the lesion. If the lesion is in the cervical part of the cord, the motor paralysis is of the arm and leg on the same side, while if in the lumbar part of the cord there is loss of motion in the leg only of the same side. On the other hand, there is loss of sensation in the arm and leg of the opposite side. The anesthesia may be to pain and to thermic sense only, the tactile sense being unimpaired. Such anesthesia exists on the *opposite* side, because of the fact, already mentioned, that one of the many routes of sensory impressions crosses the cord soon after it enters it from the periphery. More than this: the sensibility on the same side, below the segment of the lesion, so far from being diminished as to touch, pain, and temperature, may even be slightly increased, possibly owing to the vasomotor paralysis caused by the lesion, in consequence of which, too, there may be a slight rise of temperature on the same side. Slight pricks may be painful, and the soles of the feet may be unusually sensitive. In the area corresponding exactly to the segment involved on the same side there is anesthesia, while just above it on the same side, again, there is a small zone of hyperesthesia. The anesthesia is due to the fact that the sensory nerves coming from the same side are cut just as they enter the cord. It begins somewhat lower down than the exact seat of the lesion, because of the overlapping of the upper sensory area. The hyperesthesia in the lower portions of the body on the side of the lesion has been said to be inexplicable, but may it not depend on hyperemia due to section of vasoconstrictor nerves? It may be for this reason also that the temperature is higher on the side of the lesion—from 1° to 2° F. (0.5° to 1° C.). The upper hyperesthetic zone above the anesthetic area on the side of the lesion may be explained as the result of irritation of sensory nerve fibers entering just above the lesion. The muscular sense or sense of position on the same side is impaired, a condition ascribed by Brown-Séquard to the fact that the fibers of this sense run on the same side uncrossed, and probably in the posterior columns, until the medulla oblongata is reached. Reflex excitability, at first diminished on the side of lesion, is subsequently increased and there is often a good ankle clonus, explainable by the interruption of the inhibiting influence from above.

The phenomena detailed in the foregoing paragraph are those of the so-called *Brown-Séguard's paralysis*, due to unilateral lesion of the spinal cord, caused by knife-cuts, stabs, by pressure from tumors or inflammatory products.

On the opposite side muscular power is intact, sensibility is impaired, and the derangement may include the senses of pain, touch, and temperature, or any one or two, touch sometimes escaping; there is no elevation of temperature, the muscular sense is intact, and reflex action is normal.

All these results, as described, may be produced by the experiments on the spinal cord originally suggested by Brown-Séguard, which included also section along the median line of the spinal cord, which impaired sensation on both sides, leaving motion intact. So far as completed, minute anatomical studies furnish results quite consistent with the derangements of motion produced by diseased states, and, to a less extent, also with the morbid phenomena of sensation as illustrated by disease. Thus, anatomy, experiment and pathology contribute to the same conclusion. It should be mentioned, however, that the explanation of the Brown-Séguard type of paralysis here given has not been fully accepted.

More circumscribed lesions produce more limited results. Thus, a local lesion may produce paralysis in only a few groups of muscles. Destructive lesion of the anterior cornua produces lower segment paralysis in the parts innervated by nerves arising in the injured cornua, with secondary degeneration and muscular atrophy, the reaction of degeneration, diminished reflexes, and diminished muscular tension; while irritative lesions in the central motor tract cause spastic conditions, including exaggerated tendon reflexes, all of which have been described. More commonly such symptoms are the result of diminished inhibition of the brain.

It is also a matter of importance to know whether a lesion lies in a nerve or in the cord itself. Frequently this is at once apparent. At other times it is more difficult to settle. It has already been said that hemiplegias are almost invariably cerebral in their origin, while paraplegias are usually of nerve origin or spinal. It is chiefly with localized palsies that difficulties in diagnosis arise. Etiology aids us somewhat. Thus, localized palsies succeeding localized exposure to cold are apt to be peripheral. Some assistance is rendered if there be an associated anesthesia. Thus, if a part be anesthetic and palsied as to motion, and if the same nerve supplies sensory and motor fibers to the muscles, the lesion is in that nerve. If, on the other hand, the muscles are supplied by several nerves from a given segment of the cord, and the anesthesia corresponds to the area of distribution of nerves from the same segment of the cord, the lesion is probably in the cord or in the nerves at their origin from it.

Affections of the Membranes of the Cord.

As in the case of the brain, the dura mater and pia arachnoid may be separate seats of disease, chiefly inflammatory, not quite so well understood nor quite so definitely separated in their clinical features. As in the case of the brain, too, we call inflammation of the dura mater pachymeningitis; of the pia mater, leptomeningitis.

SPINAL PACHYMENINGITIS.

The dura mater is separated by loose connective tissue from the bony canal which surrounds it, and an inflammation may invade this outer or the inner layer, affording a *pachymeningitis externa* or *interna*, though it is not easy to separate these two conditions symptomatically or even anatomically as the external form is apt to extend to the inner layer and even the pia mater.

EXTERNAL PACHYMENINGITIS.—This is usually secondary to disease of the vertebræ or similar morbid processes or to trauma or aneurysmal erosion. While an acute condition may thus supervene, it is much more commonly chronic.

Etiology and Morbid Anatomy.—Perhaps its most frequent cause is tuberculosis of the spine, with its pathological cheesy product and its traumatic result—the spinal curvature known as Pott's disease. It may be confined to a limited area, corresponding to the primary seat of the disease, or it may extend over a large area of the meninges, corresponding to six or eight vertebræ. As already mentioned, such inflammations spread to the inner layer and pia.

Symptoms.—These are those of the vertebral lesion, together with those of the internal form detailed below.

INTERNAL PACHYMENINGITIS.—This occurs in two forms, first as an inflammation of the internal layer of the dura, usually confined, primarily, at least, to the cervical part of the cord. It was first fully described by Charcot in 1871, and later by his pupil Joffroy, under the name of "*pachymeningitis cervicalis hypertrophica*"; second, as a *pachymeningitis interna hæmorrhagica*, in every way anatomically identical with the same disease to be described in connection with the dura of the brain.

Etiology and Morbid Anatomy.—Cervical hypertrophic pachymeningitis, ascribed to exposure to cold, to the abuse of alcohol, and to syphilis, is a chronic process, consisting in an accumulation on the inner surface of the dura of concentric layers of a firm, fibrinous growth, covering either a small extent or a considerable portion of the cervical enlargement, and sometimes causing adhesion of the dura to the pia.

Symptoms.—To the subjective symptoms of the inflammation itself are naturally added compression symptoms, which, in fact, overshadow the former. The former include *pain*, not merely at the seat of inflammation in the back, but also in the area of distribution of the spinal nerves, the roots of which are involved in the process.

The compression of the cord and of the nerve roots which are involved produces symptoms divisible into three stages:

1. *The Painful Stage.*—In this there is pain in the region supplied by the nerves whose roots are thus compressed,—viz., that of the arms, cervical region, and occiput,—pain at times of great severity. In addition are observed paresthesia, numbness, and tingling, rarely herpes.

2. *The Stage of Paralysis.*—After two or three months the second period, or stage of paralysis, sets in—an atrophic paralysis, in which there is weakness of the arms, resulting from pressure on the anterior nerve-roots. The wasting affects certain muscular groups, as the flexors of the hands, supplied by the ulnar and median nerves, while the distribution of the posterior interosseous to the antagonistic extensors remains free. The result is the very striking claw-hand, or *main en griffe*. In extreme cases the

atrophy of the arms and shoulders becomes very great. There may be anesthesia of the skin at this stage.

3. *The Stage of Spastic Paralysis in the Lower Extremities.*—If the compression of the cord continues, we reach the third stage of the disease. The motor fibers to the lower extremities which pass through the cervical cord become involved, and the result is a spastic paralysis of the lower extremities—a paresis with *increased reflexes*, and without wasting of the muscles, because the trophic centers for the muscles of the lower extremities in the anterior cornua of the lumbar cord remain intact. In cases of long duration, however, the compression of the cervical cord may lead to anesthesia of the lower extremities, paralysis of the bladder, and bed-sores.

The symptoms of internal *hemorrhagic* pachymeningitis are not essentially different from those detailed, but are commonly superadded to those of hematoma of the dura mater of the brain, with which it is usually concurrent. It has generally been observed in the same class of persons, general paralytics and drunkards. It may occur at any part of the cord, or it may be limited to the cervical region, producing corresponding symptoms, but it is rarely recognized before death and is an extremely rare finding.

Diagnosis.—The superaddition to the symptoms of spinal caries of those detailed as characteristic of spinal pressure determines at once the condition. The forms arising in other ways are to be distinguished from *amyotrophic lateral sclerosis*, *syringomyelia*, and *tumors*. From the first it can be differentiated by the presence of the characteristic severe pain in the neck and arms, and by the absence of bulbar symptoms; from syringomyelia, by the absence of the sensory changes peculiar to that disease; but from tumors in the same locality it is often distinguished with difficulty because the pressure symptoms in both are the same.

Prognosis.—Cases are described in which decided improvement has taken place, if not recovery.

Treatment.—The usual methods of treating spinal caries by extension or operation constitute the treatment of the external forms thus arising. The symptoms are to be relieved by appropriate measures. Baths, iodid of potassium, counterirritation, and electricity have been recommended.

The first three are reasonable; the last is of doubtful value. Iodid of potassium is indicated in cases of syphilitic origin. Joffroy recommends the application of the hot iron to the neck. Paquelin's cautery would answer the purpose as well.

SPINAL LEPTOMENINGITIS.

ACUTE SPINAL LEPTOMENINGITIS.

Etiology.—As a disease separate and distinct from epidemic cerebrospinal meningitis, described under infectious diseases, acute leptomeningitis may occur:

1. As the result of tuberculosis, its most common cause. When thus occurring, it is as a tuberculous infection separate and independent of the tuberculous extension in Pott's disease.
2. From localization of the poison of the infectious diseases, as syphilis and typhoid fever.
3. As the result of extension by contiguity.
4. Possibly as the result of exposure to cold.

Morbid Anatomy.—The pathological changes are similar to those of epidemic cerebrospinal meningitis. Injection, accumulation of fluid in the pia-arachnoid space, either a serofibrinous or a purulent exudate, round-cell infiltration, and, finally, thickening of the membrane, all are more or less in evidence. As determined by the position of the body, the fluid exudate tends to gravitate downward or toward the posterior aspect. Not infrequently the morbid process more or less extensively invades the cord, especially at its peripheral portions, producing a meningomyelitis.

Symptoms.—The symptoms are those of the disease with which the meningitis is associated, in addition to fever and such other symptoms as are the result of vascular derangement and mechanical interference. These have already been detailed under cerebrospinal meningitis, including *pain in the back* of varying severity, *stiffness, sensitiveness of the spine*, symptoms of *irritation of nerve trunks*, and *disturbances of sensation*. The reflexes may be increased. Kernig's sign of "flexion contraction" at the knee-joint, described in connection with cerebrospinal fever (p. 171), should be looked for.

Paralytic symptoms are a late and also a rare development. At such time the reflexes are sometimes diminished or abolished on account of the destructive involvement of nerve-roots or of the spinal cord. The urinary and bowel functions are sometimes deranged.

Diagnosis.—The diagnosis of simple acute meningitis in association with the infectious diseases should not be too hastily made, because of its simulation by these diseases. Such simulation is, however, less common with spinal meningitis than with cerebral. Here, as in cerebral meningitis, the etiological factor may help us out; while, on the other hand, given the disease, the special variety present cannot always be told. The tuberculous form is most easily recognized, because of possible pre-existing symptoms of the disease. Stiffness and pain in the back are not so distinctive as hyperesthesia and pain in distant parts supplied by nerves from the seat of special spinal involvement. Again, cases of spinal meningitis have been found on the autopsy table in which no symptoms were recognized during life.

Prognosis.—This is generally unfavorable in all forms. Except in the cerebrospinal form recovery rarely occurs, though it is more likely to occur when the disease is secondary to the infectious diseases.

Treatment.—This is mainly symptomatic, and the details are, those given under the head of cerebrospinal meningitis.

CHRONIC SPINAL LEPTOMENINGITIS.

Etiology.—So rare is primary chronic meningitis that its existence as a separate disease may be doubted. It may, however, remain as a remnant of an acute inflammation, especially of epidemic meningitis. The possibility of its occurrence secondary to chronic disease of the cord, such as *tabes dorsalis*, is admitted, but it then almost never gives rise to symptoms. It is regarded as a possible consequence of syphilis and alcoholism.

Morbid Anatomy.—The distinctive morbid change would be a thickening and opacity of the membrane, and adhesions between the dura and arachnoid, localized or general. Certain white cartilaginous plates sometimes found on the posterior surface of the spinal arachnoid are not to be regarded as inflammatory.

Symptoms.—The symptoms would be those described in connection

with the acute form, milder in degree and less definite. In fact, the diagnosis is rarely made. A long-continued, otherwise inexplicable stiffness in the trunk and extremities would justify suspicion.

Treatment.—This is symptomatic. Counterirritation would naturally be indicated if the diagnosis is made; Paquelin's cautery is the best instrument for the purpose.

HEMORRHAGE INTO THE SPINAL MEMBRANES.

SYNONYMS.—*Hematorrhachis; Meningeal Apoplexy.*

Hemorrhage may take place between the dura mater and its bony collar, *extrameningeal*, or within the dura mater, *intrameningeal*. A third variety of spinal hemorrhage, *medullary*, into the substance of the cord, is described elsewhere, p. 909.

Etiology.—Extrameningeal hemorrhage is usually the result of trauma, such as concussion or fracture of the spinal column, puncture, or gunshot wound. The blood comes from the rich plexus of veins that surrounds the dura. A considerable amount of blood may be thus effused without compressing the cord, because of the free communication of the subdural space in the brain and cord. An aneurysm may burst into the spinal canal with fatal consequences.

Intrameningeal hemorrhage is rare, and is naturally more limited, as are the sources of the hemorrhage. Punctiform hemorrhages, such as occur in cerebrospinal meningitis, are possibly of little significance. Intrameningeal hemorrhages occur sometimes in connection with the infectious diseases, and William Osler observed two such cases in malignant smallpox, while they have been found after death from convulsive diseases, such as epilepsy, tetanus, and strychnin poisoning. So, also, in ventricular apoplexy the same observer has found blood in transit down from the fourth ventricle into the meninges. Aneurysm of the basilar or vertebral arteries is, however, the most frequent cause of this form of hemorrhage.

Symptoms.—The symptoms in both varieties are those of pressure on the cord, and may be slight and scarcely recognizable, or decided, with resulting paralysis and pain on the one hand, or anesthesia on the other. The symptoms are as sudden as is usually the event which causes them. Sometimes, however, the extravasation is slower and the symptoms are correspondingly gradual in their appearance. The absence of all cerebral symptoms from a complex including the above points to spinal rather than cerebral hemorrhage.

The extent of the paralysis and the other nervous symptoms depend on the seat of the hemorrhage. If in the lumbar region, the legs are alone involved, the lower deep reflexes may be absent, and the functions of bladder and rectum are impaired. If in the thoracic, there may be complete paraplegia, while the reflexes are retained, and there may be girdle pains. Herpes may be present. If in the cervical region, arms and legs may be paralyzed, and there may be pain or anesthesia in the upper extremities and neck. Embarrassed breathing, stiffness of the muscles of the neck, and even pupillary symptoms may be added when the hemorrhage is thus situated.

Diagnosis.—The diagnosis is based on the absence of brain symptoms in connection with the suddenness of the symptoms due to the disease and the history of possible cause.

Prognosis.—In certain cases in which the hemorrhage is small, contraction and absorption of the clot may take place, and the symptoms may pass away. In others the hemorrhage is fulminating and death follows early from involvement of the medulla oblongata in the pressure. In intermediate states there is corresponding improvement.

Treatment.—Conditions favoring the arrest of hemorrhage and the absorption of blood should be secured. Absolute rest is most important. If symptoms remain permanent, without aggravation, iodid of potassium may be used to promote absorption, and the usual measures intended to restore muscular and nervous power, such as massage, baths, and electricity, should be employed.

AFFECTIONS OF THE SUBSTANCE OF THE CORD.

GENERAL CONSIDERATIONS.

Two separate sets of pathological changes invade the substance of the spinal cord. In one they are confined with marked constancy to certain *definite areas* which have precise functions, residing in "systems of fibers," so that the clinical phenomena of the disease are exactly defined. These affections are called *system* or *systemic* diseases. They include such as tabes dorsalis, an affection of the posterior columns; amyotrophic lateral sclerosis, a disease of the lateral columns and anterior horns. Why certain definite areas of the cord are specially involved, and why this peculiar selective systemic implication, we do not know any more than we know why certain poisons, such as curare, strychnin, and lead, select certain tissues for their operation.

In the second group there is no such limitation of area invaded, but the cord in its entire transverse section is involved in one large focus, or several combined foci separated by areas of sound tissue are invaded. In this group are included acute and chronic diffuse inflammations, the hemorrhages and traumatic lesions, multiple sclerosis, etc. These are the *non-systemic diseases*. Since, in the diffuse affections, all the parts involved in the systemic lesions are also affected, the symptoms of the latter are found associated with those growing out of the diffuse lesion. The diagnosis arrived at by a study of these symptoms is still, however, mainly a "topical" one, for it is an important fact growing out of the functions of the cord that all diseases involving certain areas produce the same symptoms, whence we infer the *seat* of the lesion rather than its nature or exact cause. This may, however, be determined with a varying degree of certainty from other symptoms. A further peculiarity of all disease of the substance of the cord is that its symptoms are commonly *bilateral*. This depends upon two causes: first, the fact that the two halves of the cord are in such close proximity that almost any cause of a violent kind, such as hemorrhage, affecting one half, must also extend its influence to the other; and, second, the causes of system diseases commonly select corresponding parts in two halves of the cord for their operation. Again, symptoms vary according as the lesion affects the conducting path to and from the brain, or portion of the peripheral system of fibers within or without the spinal cord. The symptoms are accordingly known as "central," and as "root" symptoms.

SECONDARY SYSTEMIC DEGENERATIONS OF THE SPINAL CORD.

Very important in connection with nervous diseases is the subject of *secondary degenerations*. These succeed cerebral lesions and lesions in the spinal cord itself. They depend upon the fact, several times referred to,

Fig. 101.—Secondary Descending Degeneration of the Pyramidal Tracts in a Primary Lesion of the Left Half of the Cerebrum—(after Erb).

The lateral pyramidal tract of *right* half is degenerated down to the lowest part of the lumbar region. 1-8. The anterior pyramidal tract at left half is degenerated to beginning of lumbar enlargement.

that a trophic influence is exerted by ganglion cells upon the fibers originating from them, so that the latter degenerate when the conduction of the trophic influence is interrupted or when the trophic ganglion cells are destroyed.

For motor fibers such ganglion cells exist in two situations—in the motor areas of the cortex cerebri and in the anterior cornua of the spinal cord. The former exert on the motor fibers arising from them a trophic influence which extends down the cord as far as the latter. For sensory fibers in the cord the trophic influence resides in cells, probably on the posterior spinal root ganglia, and also ganglion cells in the posterior gray matter. The fibers of the lateral cerebellar column in the periphery of the cord arise in the cells of the column of Clarke, or posterior vesicular column—the group of cells in the inner part of the neck of the posterior horn.

Secondary Degeneration in the Spinal Cord after Cerebral Lesions.—If there be disease in the motor area of the cortex or in any part of the motor tract in the brain,—that is, in the motor fibers of the corona radiata, the internal capsule, the crus, or the pons,—interrupting conduction, a secondary degeneration of the motor fibers takes place below in the related pyramidal tracts, anterior on the same side of the cord, lateral on the opposite side, as far as the anterior cornua of the gray matter. In many cases there is slight degeneration in the lateral tract on the same side as far as the lumbar region, showing that some fibers of each anterior pyramid find their way to the lateral tract on the same side. The relative proportion of the crossed lateral fibers and the anterior fibers that remain uncrossed varies within limits. In cases in which no anterior pyramidal tracts exist—that is, where all the fibers pass over to the lateral column of the opposite side—there is no descending degeneration of the anterior column. Fig. 101, after Erb, shows secondary descending degeneration of the pyramidal tracts succeeding a primary lesion of the left half of the cerebrum. Fig. 102, after Edinger, shows graphically the descending degeneration in the pyramidal tracts due to a lesion in the left internal capsule. Fig. 103 shows secondary ascending and descending degeneration of the cord as occurring after transverse section of the cord in the upper dorsal region.

Secondary Degeneration of the Spinal Cord after Transverse Lesion of the Cord Itself.—If a lesion be seated in any part of the cord affecting more or less its transverse section, the interruption of conduction in these fibres is also followed by secondary degeneration, which may be traced in two directions upward and downward, ascending and descending. Such lesions may be transverse myelitis, compression of the spinal cord, and tumors—any lesion, in fact, involving the whole of the cord.

The descending degeneration of the pyramidal tract is like the descending degeneration after cerebral lesions, except that after spinal lesions the degeneration of the pyramidal tract is usually more extensive; as the transverse disease affects the pyramidal tract on the two sides, the secondary descending degeneration will affect both lateral pyramidal tracts below the seat of lesion. The ascending secondary degeneration developing upward from the seat of lesion affects the columns of Goll—*i. e.*, the posterior median columns—and the columns of Burdach,—*i. e.*, the posterior lateral columns and the lateral cerebellar tracts on the periphery of the lateral columns, because the conduction in those parts which receive their trophic influence from the more peripheral ganglionic cells is interrupted. The ganglionic cells which act trophically on the fibers of Goll are probably in the ganglia on the posterior roots. The lateral cerebellar tracts share in the ascending degeneration, because they are cut off from the cells of the column of Clarke, and when this occurs or these cells are destroyed, such degeneration may be traced upward into the restiform bodies.

Clinical Effect of the Secondary Degenerations.—This is disputed, Charcot and some of the French clinicians ascribing to them the contractures and increase of the tendon reflexes in the paralyzed limbs of hemiplegia, while Strümpell and others think they have no clinical import. It is more probable that the symptoms are caused by an interruption of the nerve-fibers and that the sclerotic tissue in the degenerated tracts produces no clinical signs of disease.

Secondary Degeneration in the Spinal Cord after Injuries of the Cauda Equina.—After fractures, caries, or other injuries to the lower lumbar vertebræ or sacrum producing injury to the cauda equina, or as the result

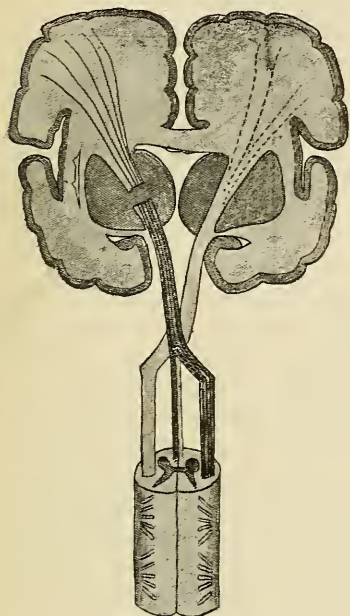

Fig. 102.—Diagram of Descending Degeneration of the Pyramidal Tracts Due to a Lesion in the left Internal Capsule—(after Edinger).

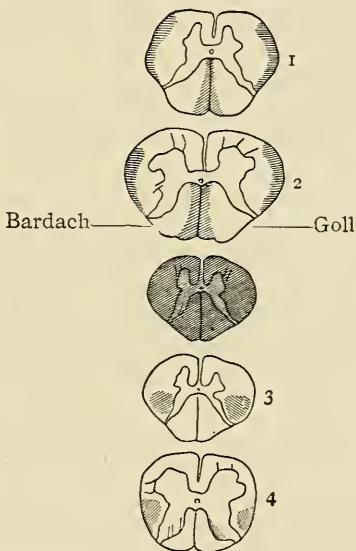

Fig. 103.—Secondary Ascending and Descending Degeneration in a Transverse Section of the Upper Dorsal Region—(after Strümpell).

The columns of Goll and the direct cerebellar tracts are degenerated upward, shown in 1 and 2, the anterior and lateral pyramidal tracts downward, as in 3 and 4.

of new growths in this region, a secondary ascending degeneration takes place in the cord after the rupture of continuity has existed for some time. This is due to involvement of the posterior nerve-roots; whence the degeneration is confined to the posterior columns of the spinal cord, and in its distribution it resembles closely the state of the cord in *tubes dorsalis*. In the lumbar cord all of the posterior column is degenerated except a small median zone and the most anterior portion. The ascending degeneration grows smaller as we ascend, and finally is confined in the cervical cord to the regions of the columns of Goll, which include, in part at least, the prolongation of the fibers from the root zones of the lumbar and sacral cord.

Acute Affections of the Spinal Cord.

DISTURBANCES OF THE CIRCULATION OF THE SPINAL CORD.

CONGESTION.—From the standpoint either of clinical observation or postmortem examination but little is known of the phenomena of congestion of the cord as differentiated from inflammation. It is a well-known fact that active hyperemia may partly disappear after death. Congestion of the vessels is found under so many conditions that a diagnosis of inflammation based on this finding alone would not be justifiable.

ANEMIA of the cord has been studied clinically and experimentally. The phenomena of paraplegia which succeed profuse hemorrhages as of the uterus *postpartum*, and from the stomach, are fairly ascribable to anemia of the cord.

This is confirmed by some experiments of Stenson, who compressed the abdominal aorta of an animal with the effect of causing almost immediate paralysis of the extremities; and of C. A. Herter, at Johns Hopkins Hospital, in which paraplegia supervened a few minutes after the application of a ligature to the aorta, followed more slowly by paralysis of the sphincters. Within thirty-six hours there were marked changes in the ganglion cells of the anterior horns in the lumbar segment, and, later, signs of myelitis. Within fourteen days contracture of the limbs set in with atrophy of the muscles and with fibrillar twitchings. Similar results have followed the experiments of others on animals. Obstruction of the aorta by thrombi and emboli has been followed by similar clinical phenomena, but it is questionable whether the results of these experiments can be applied to man, as ligation of the abdominal aorta in man may be done without causing paralysis. In intense degrees of general anemia, such as is found in pernicious anemia, the cord is not so rarely affected. Observations showing that the posterior and lateral columns are involved in pernicious anemia are numerous.

Embolism and thrombosis of the spinal arteries have been produced experimentally, with resulting *choreiform movements*. Embolism of the smaller vessels possibly occurs in connection with endocarditis. *Endarteritis* or its results are frequently found postmortem in syphilitic subjects as a nodular periarteritis or endarteritis, sometimes associated with gummy tumors of the meninges; and as an *endarteritis obliterans* with thickening of the intima and consequent narrowing of the lumen, involving chiefly the arteries of medium and larger size. *Miliary aneurysm and aneurysm* of the larger vessels of the spinal cord are very rare.

HEMORRHAGE INTO THE SUBSTANCE OF THE CORD.

Etiology.—Hematomyelia is at most a rare event. That it ever occurs primarily independent of disease is reasonably questioned. Its possibility must, however, be admitted, at least, as the result of traumatic causes, such as falls. Great physical exertion is another possible primary cause; so are cold and exposure and tetanic and other convulsions. Repeated coitus is mentioned by Gowers as having been followed by hemorrhage in the gray substance at the top of the bulbar enlargement, and this cause may have

operated in a patient of my own who was suddenly seized with a paraplegia during one of a number of closely repeated acts of coition and while in vigorous health. Secondary hemorrhage is more frequent.

Morbid Anatomy.—The cord may be distended, infiltrated, or lacerated by the hemorrhage escaping into the meninges; if not too copious, the bleeding may be limited to the gray matter and may extend up and down the cord to a considerable extent. The blood undergoes the usual changes after effusion, *i. e.*, coagulates, becomes darker hued, then yellow, and, finally, at times, the seat of the hemorrhage is occupied by a cyst, while numerous hematoidin crystals will be found in the residue. The blood may remain liquid for a long time.

Symptoms.—If the hemorrhage is in the lumbar enlargement or the thoracic region of the spinal cord, the effect is, as a rule, *sudden paraplegia*. If the cervical part of the cord is the seat of the hemorrhage, the arms as well as the legs are involved, and there may be embarrassed respiration, and possibly *sharp pain* in the extremities supplied by the nerves passing to the cord at the seat of the effusion. *Loss of sensation* follows later, while the reflexes also disappear. Myelitis is often developed as a consequence of the irritative presence of the clot, and there follow its usual symptoms, including *trophic changes* and *fever*.

Diagnosis.—This is based upon the suddenness of the consequent events—acute pain and paraplegia—under the etiological conditions described, *viz.*, trauma, and other causes. *Hemorrhage into the spinal meninges* is, of course, equally sudden or nearly so, but the symptoms of injury to the cord are less prominent, and there is little or no fever. In meningeal hemorrhage the pain is more severe and symptoms of irritation are more apt to precede the paralysis, while the paralytic symptoms are less persistent.

Prognosis.—The accident is rapidly fatal in the severest cases. In others paralysis may exist for a long time or may be permanent. In others there is slow but persistent improvement, and the patient may even recover. Hemorrhage into the cervical region of the cord is more serious because the center of the phrenic nerve which innervates the diaphragm is apt to be invaded. The presence of trophic changes renders the prognosis as to recovery more unfavorable.

Treatment.—This is identical with that for hemorrhage into the membranes. Absolute rest is the primary essential condition. Ice may be applied to the spine over the seat of the hemorrhage, and leeches or wet-cups by the same locality, although the benefit obtained by these measures is somewhat doubtful.

If the case is not immediately fatal, improvement is apt to follow the contraction of the clot, as in cerebral hemorrhage. Then, from the theoretical standpoint, ergot is indicated. Full doses, 1-2 dram (2 c. c.) to one dram (4 c. c.), of the fluid extract, or from three to five grains (0.2 to 0.32 gm.) of ergotin, repeated in two or three hours with a view to producing a profound effect early, should be given. Later muscular nutrition should be kept up by massage and electricity.

CAISSON DISEASE.

SYNONYM.—*Diver's Paralysis.*

Definition.—A paraplegia and sometimes general paralytic affection which happens to workers in caissons after their return to the surface from the compressed atmosphere of the caisson.

Pathology.—This is not thoroughly determined. That it is, however, a spinal lesion a study of the symptoms goes to show. It is ascertained that the pressure about the body required to produce it must exceed three atmospheres, that the symptoms do not come on until the patient returns to the surface, and that they are more prone to occur the longer the exposure. Under these circumstances it has been suggested that the symptoms are due to the escape from the blood of gases, especially oxygen and nitrogen, with which it has become charged in breathing in the highly compressed air—gases, which, under ordinary circumstances, escape gradually by the lungs. Gas escaping in the more rapid manner exerts a pressure which arrests the function of the nervous system for the time being. At one time local hemorrhages were supposed to be the cause, but in the few autopsies which have been made nothing has been found which would explain the symptoms from that standpoint. In a case dying on the fifteenth day Leyden found small, irregular fissures in the middorsal region, chiefly within the posterior and in the hinder part of the lateral column, filled with round cells, but containing no blood-corpuscles. It has been suggested that the fissures were produced by the sudden escape of gas, and were finally occupied by wandered-out round cells. In a case dying at two and a half months Schultzer found these fissures, together with signs of myelitis. Leyden suggests that the dorsal region suffers because of its relative softness as compared with other parts of the nervous system. Andrew H. Smith, of New York City, who had excellent opportunities for studying the disease in connection with the building of the Brooklyn Bridge, ascribed the phenomena to a congestion followed by stasis, supposing that under the high pressure the blood is driven from the periphery into internal organs, especially the cord and brain, dilating and paralyzing the blood-vessels. When the pressure is removed, the blood rushes to the periphery. Smith supposes that within the cord, when the pressure is relieved, the circulation is retarded and a stasis results. Is it not possible that the anemia resulting in the cord from the sudden withdrawal of blood from the brain and cord may cause the symptoms? It should be stated that in three fatal cases studied by Leyden, Schulze, and Van Rensselaer, diffuse parenchymatous myelitis with degeneration was found in the posterior and adjacent lateral columns.

Symptoms.—These come on, as stated, not during exposure to the abnormal conditions, but on return to the normal atmospheric pressure, often immediately, always within a half-hour. *Paraplegia* or *hemiplegia* is characteristic and essential, although the onset is usually preceded by *pain in the ears and joints*, especially in the larger joints. The latter may be affected without paraplegia after shorter periods of exposure, and there may be *tenderness in the limbs*. There may also be *dizziness* and *headache*. The onset of the paraplegia is sudden. Sensation may also be impaired, though the impairment is imperfect and irregular. In severe cases the *sphincters* are affected. Monoplegia and hemiplegia are rare, and when present, they

are apt to be transient. The *cerebral symptoms* may be more severe, amounting to sudden loss of consciousness and continuing as coma. *Abdominal pain* and *vomiting* may be present. Severe cases are usually fatal in a few hours. Those who are less accustomed to the work are the most liable to suffer, but the power of resistance also varies in different individuals.

Diagnosis.—The diagnosis is not usually difficult, the history of the case furnishing the conditions and explaining the symptoms.

Prognosis.—The prognosis is usually favorable, the symptoms generally passing away in the course of a few days, although in severe cases they may last for weeks or months, and may even be permanent. In fatal cases death may occur in a week, or as late as the end of two or three months, with the symptoms of myelitis. Of 110 cases occurring in connection with the building of the Brooklyn Bridge, three died.

Treatment.—None of an active character is usually required. Morphine may be needed to relieve pain. The prophylactic treatment is of greatest importance. This consists in avoiding too long continuance of work under pressure, and care should be taken to make the transition from the higher to the lower pressure gradually. Dr. Andrew H. Smith advises that in passing through the lock, from the low to the high pressure, at least five minutes should be taken.

DIFFUSE MYELITIS (ACUTE AND CHRONIC).

SYNONYMS.—*Myelitis; Transverse Myelitis.*

Definition.—The line of demarcation symptomatically between acute, subacute, and chronic myelitis is not sharp, but the term *acute* is applied to that form of inflammation in which the symptoms come on suddenly. When requiring from two to six weeks for their development, it is called *subacute*. When a still longer time elapses before the symptoms reach a decided degree of intensity, it is *chronic*. At the same time it is plain that no very sharp line of demarcation can be drawn between these forms. When the whole thickness of the cord is involved to a small vertical extent,—a common form,—it is said to be *transverse*; if an extensive area, *diffuse*; when one small area, *focal*; when many foci, contiguous or distant, it is *disseminated*. Inflammation of the gray matter around the central canal, extending into the intermediate gray substance, is called *central* myelitis, which may be parenchymatous and interstitial.

Etiology.—The cause is often undiscoverable. There is an occasional hereditary tendency to it. It may occur at any age, but is more common in adult males. It may result:

1. From repeated exposure to wet and cold, or from overexertion, or from both combined.

2. Rarely from the infectious diseases, as smallpox, typhoid fever, or puerperal fever.

3. From syphilis, either as the direct result of primary infection, or secondarily from invasion of the cord by syphilitic tumors; the former appears within a few months or several years after the primary inoculation, the latter as a late manifestation, but a macroscopic gumma of the spinal cord is a very rare finding.

4. From tumors other than syphilitic.

5. From injuries to the spinal column, especially fractures, and from caries of the vertebræ. It is extremely difficult, nay, often impossible, to distinguish the inflammatory results of tumors and caries from those of compression; and, indeed, the symptoms due to tumors and caries are chiefly the result of pressure.

The seat of invasion varies, the upper half of the dorsal cord being most frequently involved, but there may be cervical myelitis and rarely lumbar myelitis. There may be a central focus and numerous small foci in the vicinity. The extent of the involvement varies at different levels. The softer reddish conditions indicate the more acute stage; the harder, grayer, and more contracted, the chronic stage—sclerosis.

Morbid Anatomy.—Considerable experience is necessary to be able to recognize the changes in many cases of myelitis. The separation of the process into different stages is difficult or impossible. To the untrained naked eye the cord often appears quite normal. The expert examiner may recognize by touch that over a certain extent the cord may be either softer or harder and firmer. On section, the substance of the cord rises up more than in the normal state, the contour of the gray matter is less distinct, and sometimes has a hyperemic, reddish coloring, while the white matter is reddish-gray. There may be minute hemorrhages. The consistence may be diffuent, constituting red softening. These foci of hemorrhage may give place to cavities. The gray matter may be involved throughout considerable extent. The meninges may be affected.

These changes become much more evident if the cord is allowed to remain from eight to ten weeks in Müller's fluid,* and only after hardening can the lesions be satisfactorily studied.

Microscopic examination of the fresh cord recognizes numerous granular fatty cells. *Blood discs* and *leukocytes* may be present, the latter rarely in quantity to justify the name of pus or abscess. Thin sections stained by carmine give a very different picture even to the naked eye, the diseased tissues taking on the darker staining because of their greater richness in neuroglia. By the microscope it is found that in these portions the normal nerve tissue has partly or almost wholly disappeared. In some places axis-cylinders remain, possibly much swollen, and having lost only their medullary sheaths; in others the nerve tissue has disappeared. The *changes in the ganglion cells* are also definite; they have lost their processes and are rounder, or are entirely destroyed, while the *increase of neuroglia* goes on *pari passu* with the destruction of the proper nervous matter. The former occupies the enlarged meshes caused by the disappearance of the latter. The cells of the neuroglia increase, and Dieters' spider cells may be numerous. The granular fatty cells may also be recognized, provided no alcohol has been used in hardening. The blood-vessels are dilated and distended, and their walls are hyaline.

In localized acute myelitis affecting the white and gray matter after injury the cord is swollen, the pia injected and soft, and on cutting the membrane an almost diffuent fluid may escape. In less degree the appearances first described are present. It is these cases which arise particularly by invasion from without or from compression in which the white matter is involved. In extensive involvement the membranes are often invaded, producing myelomeningitis.

* Potassium bichromate 2½ parts, sodium sulphate 1 part, water 100 parts.

Localized areas of softening with blood accumulation constitute *red softening*. Abscess of the substance of the cord exists, and at least nine or ten cases have been reported. Pus forms in the cord in considerable quantity only in purulent meningitis.

Symptoms.—The distinctive symptoms of myelitis may be preceded by constitutional disturbance, including *headache* and general *malaise*, and even *chill*, *fever*, and *delirium*. A temperature of 107° to 108° F. (41.7° to 42.2° C.) has been noticed. These symptoms are, however, unusual.

The characteristic symptoms vary greatly with the part of the cord involved, and no picture can be drawn to suit such differences of locality. I prefer, therefore, following Strümpell, to describe the symptoms more or less common to all localities, and, after this, such modifications or peculiarities of these as enable us to locate more precisely the process. The former include:

1. *Symptoms of Motor Paralysis.*—They are the most conspicuous and commonly the first recognized sign of developing transverse myelitis. Beginning with a tired feeling in one or both legs, followed by evident weakness and then dragging, the paresis continues to grow until the patient is totally unable to make any active movement with his legs. This implies that the lateral columns of the cord, and especially the posterior part of the lateral columns, carrying the lateral part of the pyramidal tract, are involved, cutting off the motor impulses. The motor paraplegia can occur in every form of myelitis—lumbar, thoracic, or cervical; but in the first two the upper extremities are intact. In the cervical, however, paralysis of the upper extremities also takes place. If one side of the body is involved more than another, it implies that one-half of the cord is more intensely affected.

2. *Symptoms of Motor Irritation.*—These consist in spontaneous twitchings of the muscles of the paretic limbs, either rapid and short or slow and persistent. They occur at the beginning and during the course of the disease, and are variously severe. It is not always easy to distinguish them from increased reflexes, hence their diagnostic value is not great. Ataxia and intention tremor may occur in connection with involvement of the upper extremities and in the convalescence of acute cases, but they are very rare.

3. *Disturbances of Sensibility.*—These occur in marked degree much later in the disease than the motor phenomena. At the beginning there may be numbness, formication, tingling, and even girdle sensations, but severe pain is rarely present. When pain is present, it is an evidence of involvement of the vertebræ or meninges. There may be slight impairment of sensibility, but, on the whole, *sensibility* is normal in all except advanced stages. In such advanced stages, in addition to anesthesia, there may be paresthesia and even striking hyperesthesia. The involvement of sensibility probably means that the whole transverse area of the spinal cord is intensely affected.

Disturbances of sensibility are useful in determining the segment of the cord involved because the lesion corresponds very nearly, or sufficiently so for practical purposes, to the level of the seat of the modified sensibility. Thus, in myelitis of the lumbar region the altered sensation extends nearly to the umbilicus, in the lower thoracic to the ensiform cartilage, in the upper thoracic to the level of the axillæ, while in the cervical the sensibility of the upper extremities is impaired, but total anesthesia is very rare.

4. *The Reflexes.*—The effect of myelitis on the reflexes varies greatly with the seat of the disease and the degree and extent of the lesion. In the very incipency of an inflammation of the cord we may expect all the reflexes,

cutaneous and tendon, centering in the part involved to be increased, but with the progress of the disease the effect varies greatly and must be discussed in detail.

(a) *Skin Reflexes*.—The reflex arcs of the cutaneous reflexes are not definitely determined. Their connection with reflex inhibitory fibers from above is to be remembered, irritation of which fibers possibly diminishes, and interruption of which possibly increases the sensitiveness of the reaction. In extensive lumbar myelitis the reflex path is broken and the cutaneous reflexes of the lower extremities are diminished, running about *pari passu* with altered sensibility. In thoracic and cervical myelitis the arc for the lumbar reflexes is intact, and if the reflex inhibitory influence is removed, these skin-reflexes may even be increased. Experience shows, however, that the skin reflexes in the leg may be diminished even in dorsal or cervical myelitis, in which event there must be loss of irritability in the fibers. The cremaster reflex has its arc at about the level of the first lumbar nerve, hence its loss means disease there. The lower abdominal reflex corresponds to the lower thoracic cord and the upper to the level of the fourth to the seventh thoracic vertebra. There is much need for careful study on the behavior of the cutaneous reflexes, as this subject is far from being fully understood.

(b) *Tendon Reflexes*.—The reflex arc of the patellar reflex lies at about the level of the second to the fourth lumbar segment. Hence the knee jerk fails in disease of the lumbar cord involving the lateral part of the posterior columns and the anterior cornua of the gray matter. The ankle clonus probably has its reflex arc at the level of the first sacral segment. It is always absent in extensive disease of the posterior columns and gray matter of the sacral cord in this vicinity. *The absence of deep reflexes of the lower extremities is, therefore, one of the most valuable signs of myelitis of the lumbar cord.* In almost all inflammations *above* the lumbar cord—that is, of the thoracic and cervical portions—there is a decided *increase in the tendon reflexes of the lower extremity*, because these lesions destroy the reflex inhibitory influence. When, therefore, alongside of this it is remembered that the fibers which influence the condition of the tendon reflexes run chiefly in the *lateral* columns of the cord, we may conclude that the lateral columns are involved. In cervical myelitis the tendon reflexes of the upper extremities are often increased. It should be remembered that complete or nearly complete, transverse lesion of the cord in the thoracic or cervical region may cause a loss of the deep reflexes of the lower limbs.

5. *Disturbances of the Bladder and Rectum*.—These are common in myelitis. There is, first, delay in micturition, finally accomplished by extra straining, but later all power to empty the bladder is lost—the *detrusor urinæ* is paralyzed. Still later the *sphincter vesicæ* is paralyzed, and then there is incontinence of urine. These symptoms occur in connection with paralysis in any part of the cord. The ultimate effect is almost invariably a cystitis, the result partly of decomposition, induced by germs introduced through repeated catheterization, even when most cautiously conducted, partly by the entrance of germs through the patulous sphincter. Such cystitis has also been ascribed to trophic influence. To the cystitis may succeed pyelitis and purulent pyelonephritis.

In myelitis there is at first obstinate constipation, followed by paralysis and incontinence of feces. This symptom does not give any information as to the seat of the myelitis. Defecation and micturition are sometimes reflexly aroused in abnormal degree when there is increased reflex irritability.

Sexual functions, the centers of which probably reside in the sacral cord, are also often deranged in myelitis.

6. *Trophic Disturbances*.—These are most important symptoms, and valuable also in diagnosis. In cervical and thoracic myelitis the trophic centers in the lumbar cord are intact. The paralyzed muscles, therefore, do not atrophy, though they may be somewhat softened from want of use. They retain their normal electrical excitability, or at least the reactions are not qualitatively altered, although they may be quantitatively. On the other hand, genuine atrophy and the presence of the reaction of degeneration show that the anterior gray cornua or the fibers of the anterior roots of the lumbar cord are involved; in the upper extremities they show that the same portions of the cervical cord are involved. Bed-sores are among the trophic phenomena, the possibility of the occurrence of which should always be vividly present. They are among the most unpleasant and most unmanageable symptoms, yet they may be guarded against; for, although favored by the deranged trophic influence, they require an exciting cause such as pressure, the irritation of secretions, or foreign substances to originate them. They occur over the sacral and gluteal regions, more rarely on the feet and inner sides of the knees. The total anesthesia often associated with advanced stages of the disease co-operates to permit the action of the exciting causes.

Other trophic effects often met are drying and hardening of the skin; glossy skin, also thick and brittle nails. Vasomotor disturbances also occur, producing congestion and mottling, and there may be slight edema of the paralyzed parts; also sweating, which may be localized. The temperature of the affected limbs may be lowered, and multiple arthritis may occur.

7. Disturbances in the area of distribution of the *cranial nerves* almost never occurs, though bulbar symptoms are met in rare cases of cervical myelitis, when the process has extended to the medulla oblongata. Optic neuritis and pupillary changes, vomiting, hiccough, slow pulse, diminishing to 20 or 30, dysphagia, dyspnea, and syncope, have been observed in cervical myelitis.

Further, in *cervical myelitis* there is paraplegia of the legs, along with various degrees of deranged function in the arms, especially if the lesion is in the lower part of the cervical cord, when the arm paralysis is more or less complete. Ultimately there may be loss of sensation. Sometimes the muscles of the shoulder are spared, this depending on the location of the lesion. In rare instances the arms only are involved, the so-called cervical paraplegia, but it is questionable whether the lesion in such cases is merely myelitis. In most the lower limbs are affected in the early stages of the affection. There may be atrophy of separate muscle regions in the arms, without atrophy of the muscles of the legs, but if the lesion is an extensive one, the legs are also paralyzed on account of the destruction of the central motor tract. The tendon reflexes are usually increased in the legs and often in the arms, while there may be spastic symptoms in each. Cutaneous reflexes are retained in the legs, often increased. Disturbances in the bladder and rectum are present.

In *thoracic myelitis* the arms are intact, but there is motor and possibly sensory paraplegia of the legs, without degenerative atrophy. In some cases a transverse myelitis of the region involves the anterior horns above and below it, producing flaccid muscles, wasting, fibrillar contractions, and reactions of degeneration. Tendon reflexes are increased; skin reflexes are present, rarely increased; also disturbances of the bladder and rectum. The

pyramidal fibers below the lesion may undergo the secondary degeneration, and there may be ascending degeneration of the posterior median columns, as in cervical myelitis.

In *lumbar myelitis* the arms are intact; legs as in thoracic myelitis; tendon and skin reflexes diminished or absent; usually degenerative muscular atrophy with some reaction of degeneration; disturbances of bladder and rectum.

By uniting the symptoms detailed and their mode of manifestation we may draw conclusions with a certain degree of positiveness as to the portion of the cord involved. The following table by Morton Prince in Dermum's "Text-book" will be helpful:

	LUMBAR MYELITIS.	DORSAL MYELITIS.	CERVICAL MYELITIS.
Paralysis.	Paraplegia.	1. Dorsal, abdominal, and intercostal muscles, according to height of lesion. 2. Legs.	Neck muscles, diaphragm, arms, trunk, and legs.
Sensation.	Pains in legs, or girdle pains around loins; hyperesthetic zone around loins; anesthesia of legs, complete or uneven distribution.	Girdle pain and hyperesthetic zone between ensiform cartilage and pubes.	Hyperesthesia and pains in certain nerve distributions of arms; below this, anesthesia of arms, body, and legs.
Atrophy.	Of legs.	Of dorsal and abdominal (and intercostal muscles, not subject to examination) corresponding to height of lesion; sometimes mild and slow of legs.	Atrophy of neck muscles (rare) or more commonly of arms.
Electrical reaction.	Reaction of degeneration in atrophied muscles; or, in mild cases quantitative diminution.	R. d. in dorsal and abdominal muscles; slight quantitative changes only in legs when wasted.	R. d. in atrophied muscles.
Bladder.	Incontinence from paralysis of sphincter.	Retention, or intermittent incontinence from reflex action; later from overflow. Cystitis common.	Same as in dorsal myelitis.
Bowels.	Incontinence from paralysis of sphincter, disguised by constipation.	Involuntary evacuation from reflex spasm, or constipation.	Same as in dorsal myelitis.
Reflexes, superficial.	Lost.	Temporary loss, then rapid increase.	Same as in dorsal myelitis.
Reflexes, deep.	Lost.	Temporary loss, then slow increase.	Same as in dorsal myelitis.
Priapism.	Absent.	Often present.	Often present.

Diagnosis.—The difficulty of diagnosis is sometimes very great, because identical symptoms may be produced by other diseases, especially pressure diseases of the cord, such as are caused by tumors or hemorrhages, possible conditions which must be carefully sought.

Landry's acute ascending paralysis and *multiple neuritis* present some striking resemblances, and in some cases Landry's paralysis is due to myelitis. Both Landry's paralysis and multiple neuritis present rapidly progressive motor paralysis, but though sensory derangement may be a late development in myelitis, it is still a symptom belonging to it rather than to Landry's paralysis, which is a motor affection, while the trophic symptoms, the paralysis of the bladder and rectum, rapid wasting, electrical disturbances, and fever, pertain to myelitis. The resemblance to multiple neuritis is closer. In this, however, anesthesia is less complete, the wasting less rapid, and bladder and rectum involvement almost never present, and the parts affected are in nerve distributions.

Prognosis.—Almost all cases of myelitis are chronic after a more or less acute beginning, seldom lasting less than a year, often two or three years and even longer. The term acute is not therefore, applied in its ordinary meaning, implying rapid course and early termination, but it is used to indi-

cate cases which develop rapidly to their acme as contrasted with those that are slow. Even these cases become chronic. There are many who doubt the existence of a myelitis which begins in a chronic form. They hold that all so-called chronic cases of myelitis have an acute commencement. Rapidly developing cases passing to a fatal termination in from five to ten days may occur, but are rare. Moreover, recoveries are not impossible, though also rare. Certain cases, after reaching a given stage, remain as to symptoms *in statu quo*, by which it is understood that the local lesion has healed, while function has not been regained because of the impossibility of restoring the normal structure of the cord. Remissions and improvements are less infrequent. Death is usually the result of exhaustion, although it may result from intercurrent disease.

Treatment.—This is for the most part to be directed to the relief of symptoms, no curative means existing beyond what nature herself provides. In cases with acute onset and pain, cups may be applied to the back. Even in syphilis it is thought by some useless to give the usual remedies, but it is safer in cases of suspected disease to give iodid of potassium in ascending doses to the extent permitted by the stomach, while the mercurial effect should be brought about by inunctions, thirty grains (2 gm.) to a dram (4 gm.) of mercurial ointment being rubbed in daily in the armpits or inner surface of the thigh. Tonics, such as iron, quinin, and strychnin, are useful in this as in other prolonged affections.

The most painstaking attention must be given to the skin by bathing with alcohol and thoroughly drying after all washing, in order to prevent the excoriations which are often the beginnings of bed-sores, while the irritating effects of the excretions must be carefully watched, and if catheterization is necessary, it must be practiced with the closest attention to antisepsis. It may even be desirable to keep a soft catheter permanently in the bladder, to which a long tube is attached and the bladder thus kept drained. Should cystitis supervene, the bladder is to be washed out as directed on page 763. When possible, the rectum should be emptied by enema rather than by purgatives, which should be cautiously used.

Electricity is elaborately directed by the German authors, although they admit that in the majority of instances it is principally a diversion to the patient. In the later stages, however, of the forms in which there is atrophy of the muscles, some advantage may be expected. The constant current is most highly commended, by large electrodes placed over the vertebral column, and a moderate stabile current or slowly labile current is passed for four or five minutes through the supposed seat of the disease. Peripheral galvanization or faradization of the paralyzed muscles and nerves should also be employed. Massage is useful, perhaps more so than electricity. The bladder may also be treated by electricity.

The bath treatment is carried out to various degrees of elaboration. The simple tub-bath with warm water furnishes the easiest form and may be quite useful, at a temperature of 85° or 90° F. (24° to 26° C.), in the cases with spastic symptoms. The baths should be at first limited to ten or fifteen minutes three or four times a week, and if well borne, may be increased to an hour daily. The water may be impregnated with sodium chlorid, using either the sea-salt or common salt, from four to six pounds of the former or from five to ten pounds of the latter to the bath. When the patient is able to travel and avail himself of the actual sea baths, they may be expected to be beneficial. The Hot Springs of Arkansas and Virginia in

this country may be resorted to. In Europe the thermal waters at Rehme and Nauheim in Hesse, Ragatz in Switzerland, Teplitz in Austria, Wildbad in Württemberg, Gastein in Salzburg, Austria, and Wiesbaden in Baden are among those recommended; also the mud-baths of Carlsbad and Marienbad in Bohemia and Elster in Southern Saxony.

ACUTE ANTERIOR POLIOMYELITIS OF CHILDREN.

SYNONYMS.—*Myelitis of Children; Spinal Paralysis of Children; Atrophic Spinal Paralysis; Infantile Palsy; Essential Paralysis of Children.*

Definition.—An acute febrile disease of children, usually under three years of age, in which there is paralysis with rapid wasting of certain muscles.

Historical.—The clinical phenomena of this disease were described as early as 1840 by Jacob von Heine. The same physician twenty years later suggested that a spinal malady lay at the bottom of it, but it was reserved for Prevost and Velpeau, Charcot and Joffroy, to demonstrate the lesion which justifies the use of the term "spinal paralysis of children," for the older "essential paralysis of children."

Etiology.—Especially a disease of later infancy, it may occur at all periods of life, but is ten times more frequent in the first decade than in all the rest of life. It is more common in boys than in girls, and in the warm months, as pointed out by Wharton Sinkler, who ascertained that in Philadelphia four-fifths of the cases occurred in May to September. There seems to be a slight family tendency. It has appeared in epidemic form in Stockholm, where Medin reports twenty-nine cases from August 9 to September 23. A very remarkable epidemic in this country, occurring at Rutland, Vt., was reported by Caverly in the "New York Medical Record," volume ii., 1894, in which 190 cases occurred during the summer, of which 85 were under six years of age, and 18 died. Other epidemics have been recorded. Acute anterior poliomyelitis has been ascribed without foundation to dentition, to cold, and to overexertion, and is very frequently erroneously attributed by parents to falls and the carelessness of nurses. Most children are attacked while in perfect health, although previous exhausting diseases may reasonably be held responsible. It is probably due to bacterial invasion. Among predisposing diseases are typhoid fever, measles, and diphtheria. Strümpell, however, says that though the paralyzes arising after these diseases are of spinal origin, they cannot be identified with the idiopathic spinal paralyzes of children.

Morbid Anatomy.—The disease occupies more frequently the cervical or lumbar enlargement. The usual lesion found in old cases, which are those which commonly come to autopsy, is an *atrophy of one anterior cornu*, which is changed to a dense sclerosed tissue, whence the ganglion cells have almost or totally disappeared, often pierced by thickened and dilated vessels. A similar condition is found in the corresponding cornua of the cervical enlargement if the paralysis is in the arm, and of the lumbar if in the leg. If bilateral, both cornua would be involved. The corresponding anterior nerve-roots are atrophied and the muscles supplied by them are wasted, undergoing a fatty and sclerotic change. The white matter of the cord in the vicinity may be involved to some extent, resulting in sclerosis and slight reduction in size. Opportunities for autopsy in the earlier stages are rare,

but a condition of acute myelitis predominating in the gray matter, with degeneration and rapid destruction of the ganglion cells, has been found by a number of investigators.

Symptoms.—*Sudden onset* is characteristic of the disease, although there may be, and probably oftener than is noticed, slight previous indisposition with feverishness. A child, apparently perfectly well and lively, may be suddenly taken with *fever*, 101° to 103° F. (38.3° to 38.9° C.), sometimes reaching 105° to 106° F. (40° to 41° C.); *headache* and sometimes *pain* in the *loins* and *limbs* and *aching* in the *joints*, *drowsiness*, and even *stupor*. Rarely there may be *convulsions* and *loss of consciousness*. These initial symptoms do not often last longer than a couple of days, when *paralysis* sets in abruptly, reaching its climax usually in twenty-four hours. The extent varies, involving one or both arms, one or both legs, more rarely one arm and one leg, or there may be crossed paralysis, as of the right arm and left leg. Groups only of muscles may be affected, as those of the upper or lower arm, upper or lower leg, corresponding to the nerve-cells involved. Less

Fig. 104.—Section through the Cervical Enlargement in Anterior Poliomyelitis; the Left Anterior Column (*b*) is very much Contracted and is without Ganglion Cells—(from Charcot and Joffroy).

frequently the paralysis comes on more slowly, taking from three to five days to develop. It commonly also diminishes in extent after its first invasion, in rare cases even totally disappearing, but usually withdraws itself to a definite set of muscles, which remain more or less permanently affected. In the legs the tibialis anticus and extensor groups of muscles are more commonly affected than the glutei and the hamstrings; in the arm, the deltoid. The child, in the mean time, has regained its health in other respects.

At first the affected limbs remain natural, and hence the child, too, appears vigorous, especially as the face is not involved. This may be the case for some time, but usually in a few weeks *atrophy* sets in and progresses rapidly, producing a soft, flaccid, wasted limb. The *changes in the electrical reaction* of the nerve and muscle appear at the same time, commonly more rapidly than the visible atrophy. Usually as early as the first week the reaction of degeneration is present. Faradic excitability of both nerve and muscle is gone, and galvanic excitability in the nerve. In muscles there is at first increased responsiveness. To galvanism with a predominance of slow anodic closure contraction (An Cl C), while after two or three months

even galvanic excitability falls decidedly, though the muscular contraction maintains its characteristic quality of slow vermicular motion.

Often the growth of *bone* in the affected limb is delayed, and even arrested, and a stunted development results. After a time there also ensue *relaxation of the joints* and deformity from secondary muscular contraction. In the lower extremities the paralytic club-foot (*talipes varo-equinus*) develops, resulting from the paralysis of peroneal muscles and the tibialis anticus, permitting the point of the foot to drop, while a contracture develops in the antagonistic muscles of the calf. In paralysis of muscles of the calf there results, on the other hand, a moderate degree of *talipes calcaneus*, from contraction of the antagonistic muscles. In the arms and vertebral column numerous *contractures* and *deformities* arise, mainly due to the contracture of unparalyzed antagonistic muscles and to external mechanical conditions, such as weight and pressure.

Sensation remains intact, as also does, fortunately, bladder and rectum control. At the onset *micturition* is sometimes slightly deranged, but subsequently this disappears. The tendon *reflexes*, and almost always the skin reflexes, are *lost* in parts affected by the atrophy. The skin sometimes exhibits trophic disturbances, being cool and cyanotic.

Diagnosis.—This is usually easy. There are few diseases in which one can reason so soundly from characteristic symptoms to morbid states causing them. The paralysis of one or more limbs, the flaccidity, the rapid wasting, the reaction of degeneration, and the absence of reflexes, with integrity of sensibility and undisturbed mental state, point only to disease of the anterior cornua. The pseudoparesis of *ricketts* presents some similarity in paretic and muscle phenomena. There is not, however, in rickets true paralysis—simply pain on motion, to which are added the peculiar head-sweating and hyperesthesia, together with rachitic symptoms elsewhere.

Prognosis.—This is always unfavorable so far as recovery is concerned, but improvement, at first general, and afterward in groups of muscles, is often decided, so much so, indeed, as to be somewhat delusive. In protracted cases we must expect the superaddition of contractures, while deformities must be mentioned to parents as possible. The initial period passed, there is no danger to life, and subjects may live to old age.

Treatment.—Notwithstanding the unfavorable prognosis, treatment should not be ignored. Paralysis is established, of course, before the diagnosis is made, and atrophy nearly as soon. The early symptoms can, therefore, only be treated symptomatically. An aperient should be given and febrifuges ordered. Should an opportune circumstance favor an early diagnosis, cold applications may be made to the spine; it is doubtful whether they will accomplish much. Paralysis supervening, the little patient must immediately be put at rest in bed and wrapped in cotton. No active measures should be taken at this stage.

The acute stage passed, electricity is the most important therapeutic measure to be employed. It is used both for curative purposes and to keep up the nutrition of the muscles. In attaining the former, galvanism is preferred, a broad electrode being placed on the vertebral column over the spot supposed to be diseased,—on the cervical region, if the upper extremity is paralyzed, and over the lumbar if the lower,—while the other pole is placed over the paralyzed muscles and nerves. The latter is moved about, the current being at times reversed. Interruptions may also be made. While the galvanic current is commonly employed, faradization may be used.

The second purpose of the electrical treatment, keeping up the nutrition of the muscles, is more likely to be effectual. For this purpose massage and baths, after the method laid down under treatment of myelitis, are also useful. The electrical treatment must be persisted in for months and even years in order that the muscles may be in a condition to resume their function should the integrity of the cord be restored. Both massage and electrical treatment may be carried out by members of the family after a little instruction.

Tonics are employed for the usual purposes, and orthopedic appliances may be necessary to overcome the effect of muscular relaxation on the one hand and of contractures on the other.

ACUTE POLIOMYELITIS IN ADULTS.

SYNONYM.—*Acute Atrophic Spinal Paralysis of Adults.*

The existence in adults under thirty of a disease with all the clinical manifestations of the one just described as comparatively frequent in children must be admitted, since an undoubted anatomical lesion of the same kind, associated with such manifestations, has been found by investigators. On the other hand, it must be conceded that the disease is very rare and that many of the cases so diagnosticated were really cases of multiple neuritis. Landry's paralysis in some cases may be the clinical manifestation of poliomyelitis. In view of the fact that the symptomatology is almost the same as that of the infantile form, no separate description is necessary. Among peculiarities may be mentioned the possible involvement of all four extremities, as contrasted with a monoplegia or a paraplegia at other times. Again, there may be the involvement of groups of muscles. Thus, in paralysis of the crural region the sartorius muscle often remains free. In the leg the tibialis anticus may be separately involved or the extensor digitorum. In the forearm the supinator longus supplied by the musculospiral nerve may remain free while all the other muscles on the extensor side of the forearm are paralyzed, furnishing "the forearm type" of E. Remak; or the supinators may be paralyzed alone or together with the biceps, brachialis anticus, and deltoid, furnishing "the upper arm type" of Remak. The latter form is said to correspond to a lesion at the level of the fifth and sixth cervical roots, and the former to a lesion of the eighth cervical and first thoracic roots.

Diagnosis.—This is mainly from *multiple neuritis*, in which the palsy is symmetrical instead of irregular in distribution, pain is more characteristic and persistent, while the nerve trunks are inflamed and painful.

Prognosis and treatment are similar to those of the same affection in children, except that the prognosis is rather more favorable, recovery being reported, though such cases may have been multiple neuritis.

SUBACUTE AND CHRONIC POLIOMYELITIS.

SYNONYMS.—*Subacute and Atrophic Spinal Paralysis; General Anterior Spinal Paralysis, Subacute of Duchenne.*

All that was said of the probable confounding of acute poliomyelitis of adults with acute multiple neuritis may be said of the subacute and chronic form. Yet it would seem that undoubted cases have been studied. Oppenheim especially studied a case—in which the anterior cornua of the cord

were found markedly diseased at necropsy. There were, clinically, paralysis and atrophy of all four extremities without sensory disturbance. The cases differ from the acute form in the absence of the severe initial symptoms, fever, headache, somnolence, delirium, and vomiting.

ACUTE ASCENDING SPINAL PARALYSIS.

SYNONYM.—*Landry's Paralysis.*

Definition.—A disease first described by Landry, in 1859, characterized by an advancing paralysis beginning in the lower extremities, passing upward to the trunk and arms, and finally to muscles supplied from the medulla oblongata, including those of respiration, sensibility and bladder and rectum control remaining intact.

Etiology and Pathology.—It is most common in men between 20 and 30, and usually those who are strong and healthy. Cases have, however, been seen in children and old persons. No anatomical lesions pathognomonic of the disease have been shown to be associated with it. Hence attempts have been made to classify it elsewhere, and H. Oppenheim, James Ross, Neuwerk, Barth, and others regard it as a form of peripheral neuritis, Ross having found an interstitial form confined to nerve roots, while Neuwerk and Barth described a case confined to peripheral nerves. Other carefully studied cases failed to disclose such lesion. In some cases myelitis, especially poliomyelitis, is the cause. A toxic cause seems not unlikely. It is quite consistent with such cause that it should leave no local lesion, as well as that it should always seek the same spot. Gowers is especially disposed to ascribe the disease to such a cause. Some cases have, however, followed trauma.

Symptoms.—The characteristic symptoms are commonly preceded by a prodrome, in which *loss of appetite, general malaise, moderate fever, headache, backache, and tingling in the extremities* are conspicuous. These symptoms vary in severity and last from a few days to several weeks, when a *paresis* suddenly sets in, first of one leg and then of another, increasing rapidly, so that in a few days, sometimes in a few hours, an almost total motor *paraplegia* is developed. The paresis next extends to the trunk; in a few days or even less the arms are paralyzed. The muscles of the neck are next involved, and ultimately those of respiration, deglutition, and articulation, producing bulbar symptoms. Finally, facial paralysis and other disturbance of facial muscles may ensue. The paralysis is a flaccid one, and there is no tendency to spasm or resistance to passive motion. There is not usually a change in electrical reaction, although there is sometimes a rapid loss of faradic muscular excitability. The *reflexes are diminished* or absent, but the *muscles do not waste*, because death usually occurs before atrophy has had time to develop.

There is *no definite loss of sensation*, but in addition to the primary tingling referred to there is sometimes *hyperesthesia* and *muscular tenderness*. In other characteristic cases sensation is intact. More rarely there is a *blunted* and *delayed sensation*. The special senses are not affected, nor are the bladder and rectum. Sometimes there are *vasomotor edema* and *sweating*. The spleen has been found enlarged and slight albuminuria has been observed.

Diagnosis.—This is not always easy, the disease being simulated by *multiple neuritis*, *acute anterior poliomyelitis*, and *ascending myelitis*. All these may cause difficulty, and sometimes a distinction clinically and pathologically is impossible. The rapid motor paralysis, advancing from below, in the feet and hands, instead of from above, the absence of anesthesia, of wasting, and of electrical changes, are characteristic of *Landry's paralysis*.

Prognosis.—This is grave, and the possibility of a rapidly fatal termination, even in a few days, is to be remembered, the danger being from interference with the cardiac and respiratory functions of the medulla oblongata. Other cases terminate similarly in three or four weeks. If, on the other hand, the acute stage passes off, the symptoms of paralysis may cease to extend, and recovery is possible and has occurred in some cases.

Treatment.—The patient should be put to *bed* immediately, and *counterirritation* should be applied to the back by dry cups, and maintained by gentler means, as by a mustard plaster. The thermocautery has been recommended, but is of doubtful value. Paquelin's cautery is, at least, harmless.

Of internal remedies the apparent results from *ergotin* and *mercury* justify their further use. Gowers relates a remarkable case of recovery under the use of the former drug, twenty grains (1.32 gm.) having been given in the course of a night in divided hourly doses. Likewise cases of syphilitic origin have been reported, in which the *iodid of mercury* has seemingly proved of service. The *biniodid* may be given in doses of from 1-50 to 1-30 grain (0.003 to 0.006 gm.). The *salicylates* have been advised. Both remedies are indicated if its toxic origin be admitted. *Perchlorid of iron* is recommended in traumatic cases, especially when there is evidence of septic poisoning.

If *swallowing is difficult* the patient must be nourished by the rectum or through the nasal tube, and if symptoms of respiratory failure come on, electrical stimulation of the phrenic nerve and respiratory muscles may be used. If the acute symptoms pass away and paralysis persists, the usual application of galvanism and faradization may be made for restoring muscular and nervous power.

Chronic Affections of the Spinal Cord.

SPASTIC SPINAL PARALYSIS.

SYNONYMS.—*Primary Lateral Sclerosis; Spasmodic Tabes Dorsalis.*

Definition.—A chronic disease of the spinal cord, characterized by stiffness and weakness of limbs with greatly exaggerated tendon reflexes, but without atrophy or sensory or vesical derangement.

History.—In 1875 Erb, and independently Charcot, called attention to a form of paralysis characterized by "a gradually increasing paresis and paralysis, usually advancing from below upward, with muscular tension, reflex contractions and contractures, with marked increase of the tendon reflexes and *complete absence of sensory and trophic disturbances of vesical and sexual weakness, and of any cerebral disturbance.*" Both observers agreed on a "primary symmetrical sclerosis of the lateral columns" as the anatomical condition of the disease. Since then numerous cases have been observed corresponding in clinical features, but while the anatomical features described as essential have been found, they have, with one or two exceptions, been accompanied by other lesions, which are not alike in different cases. A few cases have been described, which seem to show the possibility of the occurrence of primary lateral sclerosis, without complications, but most foreign writers discard the name of lateral sclerosis, and some speak of it by its most prominent symptom, spastic paraplegia.

Etiology.—The etiology is not always apparent, although the causes are probably many. The cases mostly begin between the 20th and 40th years. It may occur in children. It has been traced to syphilis, several times to trauma, after acute infectious fevers, lead poisoning, and to the puerperium; the diagnosis in such cases usually has been without anatomical confirmation. Strümpell has called attention to hereditary family type, found in male members, between the 20th and 30th years, and in some families the symptoms are first manifested in early childhood. A form closely related, but resulting from arrested development rather than from atrophy of the central motor tracts, is the spastic paraplegia occurring in children born prematurely, and sometimes classed as one type of Little's disease.

Morbid Anatomy.—The lesion which would be expected in spastic spinal paralysis is degeneration of the pyramidal tracts. In point of fact this condition is found, but it is apt to be part of a mixed lesion which may include that of myelitis, meningomyelitis, multiple sclerosis, compression of the cord by tumors or by caries of the vertebræ. In a few cases, however, the lesion almost uncomplicated has been found by Munkowski, Strümpell, Dejerine, and Sottas.

Symptoms.—The conditions may begin with a sense of *fatigue* and *weariness* in the legs, but the two essential and predominating symptoms are *increase of the tendon reflexes and motor paresis.* The first is the more unmistakable, constant, and characteristic. In decided degrees of this increase the contractions come on even with that amount of tension on the tendons which is produced by the weight of the limbs or any active or passive movements, while the reflex muscular tension or rigidity opposes any attempt at motion. The muscles feel rigid and firm, and the legs are found in almost permanent extension, while the feet are in plantar flexion. Any attempt, especially if sudden, to flex the leg at the knee or the foot dorsally meets with resistance. Yet if slow effort is made, flexion may generally be accomplished, the leg, while undisturbed, remaining in the position assumed,

wilence the graphic term of Weir Mitchell—"lead-pipe contraction." If the thigh be placed over the edge of the bed, the traction of the leg on the quadriceps extensor may be sufficient to excite vigorous extensor tetanus and a convulsive tremor of the whole leg, like that of ankle clonus. If the patient is examined in a bath, the spasms are less violent because the effect of the weight of the legs is diminished. The superficial reflexes are also increased.

Walking is interfered with in two ways, first by the *stiffness* in the legs, and second by the *paresis*. The legs are only partially, if at all, flexed at the knee, and the foot is not raised, but is pushed along the floor in short, difficult steps. Owing to the contraction of the calf muscles the toes are brought to the ground, and thus the patient walks on his toes; sometimes an ankle clonus is developed by contact of the toes with the ground. The legs are kept close together, the knees touch, and in certain cases adductor spasm may cause cross-legged progression. Stiffness is not always so marked. The effect is the so-called *spastic gait*. In some cases there is no paresis, and the peculiarity of the gait depends purely on the muscular spasm. The effect is what Strümpell calls *pseudoparesis*, or spastic pseudoparesis. The absence of actual paresis is shown by the fact that, notwithstanding the stiffness in the gait, the patient can still walk some distance, even miles. With all this, the *patient is well nourished* and there is no wasting of muscles, which may even be hypertrophied, and outside of these symptoms he may enjoy excellent health. Nor is there vesical disturbance.

There is no *sensory disturbance*. Ocular symptoms are rare. The tendency is to grow gradually worse, but very gradually; finally the patient cannot walk at all, nor can he stand. Rarely the muscles of the trunk and arms become involved, presenting also a paresis with decided increase in the tendon reflexes without disturbance of sensibility or muscular atrophy. Such is the picture of spastic palsy, rarely, perhaps, seen in an uncomplicated form.

Diagnosis.—As stated at the outset, there is absence of sensory and trophic disturbance. The onset may be sudden, but is never so in typical cases, with numbness in the extremities, progressive loss of strength, but no emaciation. Spastic symptoms, with increased knee-jerk, appear, followed by gradually developing paresis. The arms are often affected, but less so than the legs, and may escape. The course of the disease is slow, and mental symptoms similar to those of dementia paralytica may be present at the close; also amyotrophic lateral sclerosis in some of its symptoms, but it differs in the absence of muscular atrophy.

Hysterical spastic paraplegia may furnish in the most striking manner the symptoms detailed. Every symptom to be mentioned may repeat itself more or less identically. It is, therefore, not necessary to name them. Moderate wasting is sometimes added. It occurs more commonly in women, and usually careful examination will reveal some distinct stigmata of hysteria.

Prognosis.—Spastic paraplegia of all forms except the hysterical is of long duration with little prospect of recovery. The upper extremities are tolerably free from derangement, and the mind is usually clear. Hysterical spastic paraplegia may end in recovery, if properly managed. When the cause is transient, also, recovery may be expected with removal of pressure, as in caries.

Treatment.—If *caries* is present, mechanical measures should be used to remove pressure. If *sypphilis* is suspected, treatment by *iodids* and *mer-*

curials should be persevered in. Mercurial inunction is the most ready way of bringing about mercurialism. *Galvanism* and *faradization* are less useful in spastic conditions of the muscle than in those in which nutritional changes are more decided, but in hysterical spastic disease they are of signal use for their moral effect. The electrical brush is here the most useful instrument. It should be associated with *massage* and *passive motion*, and early attempt at locomotion should be encouraged and a positively favorable prognosis made. These, at least, tend to defer the immovable stage.

In any case friction, massage, and forcible flexion may be of benefit, but should be used cautiously, as the irritation produced in this way may possibly hasten premature contracture. Hydrotherapy is commended. The effect of the prolonged warm bath at 90° to 95° F. (32.2° to 35° C.) is often an amelioration of the spastic symptoms. The bath should be kept up for half an hour and manipulation practiced during it.

TABES DORSALIS.

SYNONYMS.—*Posterior Spinal Sclerosis; Duchenne's Disease; Locomotor Ataxia.*

Definition.—A disease especially characterized clinically by loss of co-ordinating power, and by sensory and trophic symptoms; anatomically it is pre-eminently a disease of the posterior spinal roots and posterior columns of the cord, although the cerebrum does not always escape, and the optic nerves are commonly affected.

Historical.—Inco-ordination of movement in cases of spinal cord disease was noticed in the first third of the last century, but the cases in which it was present were not separated from those with loss of power. The association of this distinctive symptom with disease of the posterior columns was first announced by Stanley in 1840, and the first accurate account of the disease was published by R. Bentley Todd in 1847. He distinguished inco-ordination without weakness from paraplegia, inferred involvement of the posterior columns, and confirmed his inference by autopsy. In 1851 Romberg described the disease and the lesion in the posterior columns, but failed to eliminate loss of power from the symptoms. In 1855 Russel Reynolds accurately described the symptoms and ascribed ataxia to muscular anesihesia, giving thus the first correct explanation of this symptom. Türck first recognized with the microscope the wasting of the fibers in the posterior columns of the cord. In 1858-59 Duchenne, without adding anything essential to the symptomatology or pathology of the disease, published a monograph which so attracted attention that the disease has come to be called by his name, although, as Gowers correctly says, if the name of any man should be associated with tabes dorsalis, it is that of Todd.

Etiology.—The etiology of tabes dorsalis is not a satisfactory chapter. The disease is more common in cities, affects ten men to one woman, is rare in the negro, and is pre-eminently a disease of middle life, about one-half the cases beginning between thirty and forty, one-fourth between forty and fifty, and less than one-fourth between twenty and thirty. It has been met as late as sixty-six, and occasionally before the age of twenty. Direct inheritance, independent of inherited syphilis, is almost unknown, but a slight tendency is found in neurotic families.

Of the direct causes, syphilis is believed to be the most frequent. From 50 to 90 per cent. of cases have been ascribed to it by different authors, Erb and Strümpell leading with the latter figure. Möbius even believes that all cases of tabes are due to syphilis. Yet there are difficulties in tracing the relation growing out of the facts, first, that the pathological product is not

anatomically a syphilitic one, and, second, that it does not respond to the treatment of syphilis. A reasonable explanation ascribes it to a toxic cause analogous to that of the paralysis which follows diphtheria, acting especially on the centripetal sensory fibers.

Prolonged exposure to cold and wet, such as belongs to certain occupations, as lumbering, is a commonly admitted cause, but simple overexertion, physical and mental, especially sexual excesses, formerly held responsible, are probably not causes. Alcoholism is also held responsible less commonly than formerly. On the other hand, Tuzcek has shown that in

Fig. 105.—Lumbar Region. *g g*, degenerated posterior roots. *h h*, normal anterior roots. *f f*, degenerated posterior columns. *e e*, ventral fields of the posterior columns intact—(after Spiller).

chronic ergot poisoning symptoms like those of tabes develop, and with them a lesion appears in the posterior columns of the cord.

Traumatism affecting the spine has been believed to be a cause in a few instances, but this relation has not been established.

Morbid Anatomy.—Tabes dorsalis is pre-eminently a disease of the posterior spinal roots and posterior columns, although the cerebrum does not always escape, and the optic nerves are usually affected.

Directing our attention to the spinal cord, in which are found the most manifest changes, we find that, at times, even when inclosed in the membranes, its smallness and thinness are noticeable, while through the pia we may see the *posterior columns* distinctly as a gray band throughout the length of the cord. The pia is, however, commonly thickened and opaque, especially on the posterior surface, sometimes more firmly adherent than is natural, while the blood-vessels also show signs of arterial sclerosis. The contraction of the posterior columns is more conspicuous on section. They are flattened instead of convex, while the gray translucent appearance of

the posterior column is also evident, being due to the fact that the nerve-fibers have been substituted by neuroglia tissue. Hence, also, the name "gray degeneration." In the cord hardened in Müller's fluid the difference in hue is even more striking than in the fresh state. The posterior cornua and the posterior nerve-roots are small and gray.

On minute examination, in transverse sections stained by carmine or other staining fluid, the affected areas are more conspicuous, because of the deeper staining of the sclerosed tissue, while all parts of the posterior columns are not equally affected. In the *lumbar cord*, which, with the lower thoracic region, is usually the most frequently and seriously involved, the change affects chiefly the middle and posterior parts of the columns, while

Fig. 106.—Thoracic Region. *dd*, degenerated posterior roots, *cc*, degenerated posterior columns, *bb*, degenerated columns of Clarke. *a*, small group of normal fibers from one or more posterior roots, lower in the cord, which were not entirely degenerated. *e*, normal anterior root—(after Spiller).

the extreme anterior portion, the so-called ventral fields, remains intact. The sclerosis is commonly most intense in the part adjacent to the posterior cornua, into which the posterior roots enter, also near the surface of the cord. Ascending into the *thoracic cord*, the intensity of the disease gradually diminishes in the external parts of the posterior columns, and increases in their median portions. It presents also the distribution of an ascending degeneration, which in fact it is, receding from the commissure in the upper cervical region.

In the *cervical cord* the columns of Goll are chiefly affected, sometimes with the fibers in the root zones—that is, those portions of the columns of Burdach in which fibers enter directly from the posterior nerve-roots, and from which fibers may be traced further into the gray matter of the posterior

cornua; but two anterolateral areas in the columns of Burdach remain free from disease, at least for a long time.

Figure 108 shows how the beginnings of the disease are localized in the posterior columns. It is in consequence of involvement of the *posterior roots* that the corresponding posterior cornua into which they enter are also affected. The same is true of the medullated *fibers of Clarke's columns* (Fig. 106), which are also direct processes of the posterior roots, while the cells of the columns remain normal. Lissauer's tract, a narrow strip at the periphery of the posterior cornu, is early involved.

In advanced cases, in the *larger peripheral nerve trunks*, such as the sciatic, and in the finer branches of the sensory nerves, many degenerated fibers can be recognized. Some of these atrophies may be secondary; but modern clinicians are disposed to regard the peripheral degenerations of tabes as independent and primary, especially since, in addition to these, decided degenerative processes sometimes occur in the trunks of certain

Fig. 107.—Cervical Region. The degeneration of the posterior columns is now nearly limited to the columns of Goll, *e e*. *b*, normal fibers from roots lower in the cord which were not entirely degenerated—(after Spiller).
Figures 105, 106 and 107, from an advanced case of tabes.

cranial nerves, such as the optic and oculomotor, and more rarely the vagus and auditory. They will be referred to in treating the diseases of special nerves.

Finally, there are even *cerebral changes* of various kinds. While the spinal ganglia on the posterior roots have been found invaded in a few cases only, it is the disposition of some observers to place the initial changes of the morbid process constituting tabes dorsalis in these ganglia, and thence the fibers ascending into the posterior columns. Thus considered, tabes dorsalis would be a general disorder of the central and peripheral nervous system, but limited mainly to sensory tracts though motor ganglia and nerves do not altogether escape.

Symptoms.—The characteristic symptoms of tabes are easily divisible into three sets: *motor*, *sensory*, and *reflex*. In addition to these there are

others not essential, but striking, including modifications of *special sense* and certain *visceral symptoms* characterized by pain and known as "crises." The special sense modifications include especially that of vision, while of "crises" the gastric is most striking.

The *motor phenomena* are usually the most prominent, whence the disease takes the name of locomotor ataxia, but this symptom may be absent

Fig. 108.—Lumbar Region. *h h*, posteromedian root zones (Flechsig) only slightly degenerated. *i j*, middle root zones (Flechsig) degenerated. *g*, normal ventral fields. This section represents the earlier lesions of tabes.

Figure 108 should be compared with Figure 105—(after Spiller).

for years, and hence the inappropriateness of the term. The distinctive symptom is a *loss of co-ordinating power* in the legs, having its simplest illustration in the unsteady gait of a drunken man. It is intensified when the patient attempts to walk with his eyes closed—that is, when the guiding sense is removed, and, indeed, in its early development does not appear except when the eyes are closed. It is usually *unaccompanied* by a *loss of power or muscular wasting*, but the latter may be extreme. On the other hand, *inco-ordination is by no means always the earliest symptom* and it may, indeed, never be developed, while there is usually a preataxic stage in most cases of tabes. The inco-ordination may be shown sometimes, before otherwise evident, by directing the patient to place the heels and toes together and then to close the eyes, when a swaying appears, as though the patient were going to fall—*Romberg's symptom* or "tabetic

swaying.”* In health a slight unsteadiness under these circumstances is present, which varies in different persons. Higher degrees develop the “sway” even when the eyes are open. The symptom often exists for a long time before being recognized by the patient, but is sometimes discovered quite early through an accidental production of the favoring conditions. Soon the peculiar gait is noticeable. The foot is thrust forward too far, and brought down suddenly, with the heel first on the ground, with a stamp. This is the typical tabetic or “heel” gait. The patient cannot walk in a straight line, and the staggering becomes worse when the eyes are closed, because the power of orientation through vision is lost. The movements of the lower limbs are excessive and unnecessary. Ultimately, he can walk only with the aid of a cane or by keeping the eyes fixed upon the floor. He rises from the sitting posture with difficulty, often after three or four efforts. The loss of co-ordinating power may also be shown in the recumbent posture when the patient attempts to touch the knee with his heel, when he will carry it around and in front and behind without accomplishing his purpose. The tabetic gait is not confined to tabes, but may occur in disseminated sclerosis and cerebellar disease. In the latter closure of the eyes may not increase the ataxia of the gait.

Inco-ordination also develops in *the hands*, but much more rarely, and late in the disease, though it may appear in them first. It is shown in connection with more delicate acts, such as picking up a pin, buttoning, and writing. It may be demonstrated also by asking the patient to bring the ends of two of his fingers together with his eyes closed, or to touch the end of his nose with one, which he may not be able to do. With all this ataxia the *muscular power remains intact*. The patient lying in bed can kick out with great force, and resist successfully any effort to flex the extended leg, while the grip of the hand is strong.

The *sensory symptoms* are less distinctive, especially at first. The most frequent of these—indeed, among the most frequent of all symptoms—are *pains* of a darting, shooting, or stabbing character, whence they are called *lightning-pains*. They are said to occur in nine-tenths of all cases. They resemble closely those of neuralgia, lasting but a second or two. They are most common in the legs, and are often accompanied by burning or tingling, especially in the feet. They may be felt in the trunk, arms, and even in the head. Commonly they do not correspond with nerves or affect joints. They are often considered by the patient as rheumatic pains. A *sensation of cold* is felt, also a feeling as though the limb were immersed in cold water. The pains are induced by fatigue or excesses or by temporary ill health from other causes, and are apt to come on at night. They may last hours or a day or two. There may be areas of *hyperesthesia and anesthesia*. A very curious sensation is felt in the soles of the feet when walking, a feeling as though *soft carpet or cotton were interposed* between them and the floor. A painful sense of constriction about the limb or waist or around the entire trunk—*girdle pains*—is regarded as characteristic.

There are other disturbances of sensation, such as retardation of tactile sensation, wherein the prick of a pin, instead of being instantaneously felt, is *delayed* for several seconds. Another sensory symptom is difficulty in

* This symptom is classed by Strümpell among those of impaired sensibility in the soles of the feet and the muscles, whence follows defective control of muscular movements necessary to equilibrium.

localization, manifested, for example, in referring a pin-prick to the right foot when it is made in the left,—allochiria,—or it may be felt in both feet—polyesthesia. In advanced stages the *muscular sense* is also impaired, and the patient is unable to indicate correctly the position of a limb. There may be other perversions of sensibility. The sense of pain may be lost or perverted; also the temperature sense—that, too, without derangement of the pain-sense or common sensibility. All varieties of sensation may be lost in the most diverse parts of the body and most irregularly.

Visceral pains, known as tabetic crises, among which the gastric is the most common, are also among the sensory phenomena. They may be laryngeal, rectal, nephritic, urethral, and are sometimes exceedingly severe. The gastric crises are sometimes accompanied by vomiting of strongly acid gastric secretion. On the other hand, the vomited matters may be alkaline, the result of a reflux of the intestinal contents into the stomach. Nor are gastric crises limited to tabes. They may occur in other cerebrospinal disease, including general paralysis, *sclerose en plaques*, and subacute or chronic central myelitis. The laryngeal crises may be associated with spasm and dyspnea, with noisy breathing. Death is a possible termination from this cause. Rectal crises consist in paroxysmal pain and tenesmus, with a sensation as of a foreign body in the rectum.

The *reflex symptoms* consist in *impairment in reflexes*, both tendon and cutaneous. The loss of the knee-jerk is one of the most frequent and early of these, occurring sometimes years before ataxia appears. Of itself it is not diagnostic, as it may be absent in healthy persons, but in association with lightning pains and ocular symptoms it is almost conclusive evidence of the disease. In by far the greater number of tabetics—at least 70 per cent.—the patellar reflex is wanting, with or without the Argyll Robertson pupil. The skin reflexes fail *pari passu* with the loss of tactile sensibility, and it is doubtful whether they are ever present without this. The plantar skin reflex is that most frequently impaired, and after this are successively involved the gluteal, cremasteric, and abdominal. It happens rarely that in the early stages of the disease the skin reflex is increased, sometimes considerably, but even then the knee-jerk is absent or diminished.

Of the remaining symptoms the *ocular* are the most important. They include *ptosis* of one or both eyelids, producing a very striking appearance. It may be unaccompanied or associated with *external strabismus* and *double vision*. Rarely there may be paralysis of all the external muscles of the eye, producing *ophthalmoplegia externa*. The most remarkable eye symptom is, however, the *Argyll Robertson pupil*, in which there is loss of reflex contraction of the iris in response to light, while the contraction in accommodation remains. According to Gowers, the loss of this reflex occurs in five-sixths of all cases. The contraction in accommodation is, however, not always maintained. Very rarely the reverse of the Argyll Robertson pupil exists. Wendell Reber has made a clinical study of the correlation between the iris and patellar tendon reflexes, and finds that in non-specific cases of tabes they are both involved in 70 per cent., and in the specific cases in 77 per cent. He holds that the co-involvement of these distant reflexes is evidence in favor of the view held by Sachs, Trevelyan, and Hirt, that tabes is a secondary degenerative process in which the entire nervous system takes part, and of Nageotte that the three separate clinical pictures of general paresis, tabes, and cerebrospinal syphilis are only the result of the preponderance of the inflammatory process in different localities, the nature of the process

being essentially the same, the initial change being vascular starvation.* Often the dilatation of the pupil which takes place in health when the skin of the neck is pinched cannot be produced and coincident with this is often unnatural smallness of the pupil—spinal miosis.

Finally, there is sometimes *atrophy of the optic nerve, producing the amaurotic form*. When it occurs, it is often an early symptom, usually commencing before inco-ordination; and, what is more singular, the ataxia often does not supervene—that is, there seems to be a tendency for the spinal malady to become stationary when the optic nerve is affected early. The failure of vision usually begins with peripheral limitation and progresses slowly to total blindness, sometimes to a considerable extent before the patient notices it. Occasionally it ceases, and there may even be slight impairment. *Hemianopsia* may occur from disease at the optic chiasm.

Deafness may be present from disease of the auditory nerve; also, more rarely, *anosmia*, from atrophy of the olfactory nerve. Attacks of *vertigo* are common in these cases. Abnormalities in function of other cranial nerves may be due to similar involvement. Among these may be mentioned pain at one time and anesthesia at another in the area of the fifth nerve; also unilateral atrophy of the tongue.

There may be *delayed micturition* from weakness of the detrusor muscle of the bladder, or *incontinence* from paralysis of its sphincter, with partial evacuation of the bladder, and resulting cystitis. The anal sphincter is less frequently affected.

Vasomotor and trophic phenomena also occur, and may be predominant symptoms. They include local sweating of the palms and soles, or of half the head, edema, skin ecchymoses, herpes, and modified hair growth, loss of pigment from hair and skin, thickening of the epidermis of the sole, succeeded by blisters under it. Alteration in the nails, and onychia with ulceration, may be present; also decay of the teeth and the so-called *perforating ulcer of the foot*, which is almost peculiar to this disease. Only late in the disease may atrophy of muscles, sometimes associated with neuritis or involvement of the anterior cornua, occur. *Paroxymal diarrhea* occurs, and has been regarded as vasomotor in origin.

The so-called *arthropathies* are an interesting trophic symptom and are directly the result of the disease. The most common is that known as Charcot's joint, anatomically similar to chronic affections in which the disease begins in the bone as contrasted with the synovial membrane, resulting in atrophy and in the destruction of bone and cartilage, while brittleness of bones, attended with spontaneous fracture or luxation, may occur. If union takes place, there is a superabundance of callus, with ossification or calcification of adjacent structures and of any newly formed inflammatory tissue. The large joints are those commonly affected and are painless when the seat of arthropathy. There may be effusion and even pus in the joints. The arthropathies may even occur in the preataxic stage. They may be excited by injury. The joints may also become greatly relaxed, while changes in the tarsal bones and articulations may cause the foot to become flat, with projection backward or inward of the tarsometatarsal articulations and of the tarsal bones, producing the "tabetic club-foot."

Cerebral symptoms also occur, but are rare, and may resemble those of

* Reber's paper, published in the "Annals of Ophthalmology and Otology," vol. v. No. 3, July, 1896, showed also that in *non-specific cases* the patellar reflex alone was involved in 23 per cent., the iris alone in 77 per cent.; in specific cases, the patellar reflex alone in 7 per cent., and iris alone in 16 per cent.

dementia paralytica. It is not always easy to decide whether the dementia or the tabes is primary. The final stage of the disease, in which the patient is bed-ridden, is known as the *paralytic stage*.

Diagnosis.—The diagnosis, commonly easy when the characteristic symptoms are developed, may demand critical judgment in the early stage. The combined presence of lightning pains, absence of knee-jerk, early ocular palsies, including the Argyll Robertson pupil, ptosis or squint, and ataxia are conclusive. Lightning pains and ocular palsies should always stimulate to thorough examination. The same is true of severe attacks of gastralgia in middle-aged men.

Differential Diagnosis.—*Disease of the vertebral column* with resulting compression of the spinal nerves is also associated with lancinating pain and absence of the patellar reflex, but the later symptoms are widely different. The same is true of deep-seated tumors impinging on the spinal cord.

Peripheral *alcoholic neuritis* and *arsenical neuritis* also may be associated with diminished knee-jerk, a pseudotabetic gait, and sharp pains, but the gait differs from the true tabetic gait, the leg being lifted high in order that the *toes* may clear the floor. The pain also follows the course of the nerves, which are tender on pressure, and there is none of the shooting character. Nor is there reflex immobility of the pupils, and seldom bladder disturbance, while atrophic paralysis, always absent in tabes, also develops. *Multiple sclerosis* in rare instances presents similar symptoms, but defective speech, nystagmus, mental weakness, and ultimate apoplectiform seizures serve to distinguish it. In *diphtheritic palsy* and *ocular palsies* there is absence of knee-jerk, but the history of the case, the throat palsy, and all absence of pain are distinctive. *Ataxic paraplegia* also displays ataxia, but here again eye symptoms and pain are absent. In *cerebellar disease* there is also loss of co-ordination, and the knee-jerk may be absent, there may be headache, optic neuritis, and vomiting, but no lightning pains or sensory disturbance. Occasionally neuritis may present a clinical picture closely resembling tabes, known as peripheral pseudotabes. The rapidity of development, the absence of the Argyll Robertson sign, and of implication of the bladder, and in some cases recovery, are the most important differential features.

General paresis and *tabes* sometimes merge, the latter developing on the former, and the former on the latter toward the end. Rapidly developed ataxia with mental symptoms often resolves itself into general paresis. Yet acute involvement of the posterior columns may be possible, producing ataxia.

Finally, there is the *nicotin* tabes of Strümpell, who has twice met, in men long working in tobacco factories, a set of symptoms consisting in painful sensation, absence of patellar reflex, contracted pupil, with reflex immobility and uncertain gait, differing, however, from tabes in the presence of tremor and marked increase in the skin reflexes, especially in the lower extremities.

Course and Prognosis.—It is generally conceded that no case of thoroughly developed tabes has ever recovered. The disease may, however, be arrested. This happens especially if optic nerve atrophy has set in early, after which ataxia rarely develops further, while the other symptoms subside. In most cases of the disease, however, the advance is slow but irresistible. The duration of the first stage, characterized by absence of knee-jerk, and by the presence of the Argyll Robertson pupil and of lancinating

pains, lasts from a few months to twenty years. The second stage,—that of ataxia,—from which, indeed, the patient often dates the disease if the initial symptoms were slight, may then supervene gradually or suddenly. Finally, the paralytic stage supervenes, to be soon followed by death. Tabes is believed by some to assume a mild type more commonly now than was the case twenty or twenty-five years ago.

Treatment.—While recovery from tabes dorsalis probably never occurs, much may be accomplished by treatment in arresting progress and relieving symptoms. There is no specific treatment, although this effect has been claimed for more than one remedy. *Nitrate of silver*, first recommended by Wunderlich, has probably had most reputation, but has latterly fallen into comparative disuse, and coincidentally the number of cases of chronic argyria has diminished. The dose administered is from 1-6 to 1-4 grain (0.011 to 0.0165 gm.) three times a day. A proper question is as to the length of time the remedy may be used without danger of producing this unfortunate result. Professor E. Harnock asserts that in no recorded case of argyria were less than 450 grains (30 gm.) of the salt taken before the discoloration appeared. To consume this much in 1-4-grain doses three times a day would take six hundred days. If, therefore, it is given in the usual doses for a month and then suspended for one week, as commonly directed, it does not seem possible that unpleasant effect can result. In this manner, then, it may be kept up indefinitely; or it may be alternated with *arsenic*, of which last Gowers at least says that it does distinct good more frequently than any other remedy. The favorite preparation in this country is Fowler's solution, of which five minims (0.3 c. c.) are given three times a day for an adult. The edema beneath the eyes, which results from its accumulated effect, is a sign that the dose should be reduced or the drug temporarily suspended. Arsenious acid in doses of from 1-30 to 1-20 grain (0.0022 to 0.0033 gm.) or sodium arsenite in doses of from 1-30 to 1-10 grain (0.002 to 0.006 gm.) may be substituted. Sometimes a smaller dose only is borne. Gowers has also found the *chlorid of aluminium* useful in doses of from two to four grains (0.132 to 0.264 gm.) three or four times a day. More recently it has been recommended in doses of five to ten grains three or four times a day.

The supposed frequent causal relation between syphilis and tabes renders the antisyphilitic treatment appropriate in all cases in which such relation can be traced. To this end *mercurials* are to be administered until the specific effect is produced. This is best accomplished by inunction, a dram to a dram and a half being rubbed into the armpit or inner surface of the thigh daily, to be discontinued when the gums are affected. After this the *bichlorid* may be given in doses of 1-24 grain (0.0027 gm.) three times a day, in association with the *iodid of potassium* in ascending doses if well borne, or the *binioidid of mercury* may be given in doses of 1-24 grain (0.027 gm.) three times a day. If this treatment is found effectual, the iodid should be continued in the minimum doses, which will keep up the effect. *Calabar bean* in doses of from 1-10 to 1-5 grain (0.0064 to 0.0128 gm.) three times a day and the fluid extract of ergot in doses of from five to thirty minims (0.3 to 1.6 c. c.) or more are recommended, but the results have not been such as to give them a permanent reputation. Iodid of potassium may be tried apart from the indications of syphilis. The *rest treatment*, originally suggested by Weir Mitchell, has been found useful in arresting the disease, but I do not know that it has been followed by permanent

results. *Extension of the spinal column* and presumably of the cord by suspension of the body for from one to three minutes daily was used for a time, among others by Mitchell, but it has been discontinued, perhaps too soon, for instances of undoubted improvement have been reported under its use: *vide* one reported by Charles S. Potts in the "University Medical Magazine" for September, 1891, and several by De Forest Willard and Guy Hinsdale in the "Medical News," November 24, 1894.

In Germany *electricity* is still a popular remedy, and failure with it in this country may be due to imperfect and too brief trial. Erb's directions for galvanism are to place a moderate-sized anode in the vicinity of the sympathetic in the neck, and a large kathode on the side of the vertebral column for four or five minutes, moving it at intervals from above downward. Severe pain and vesical weakness are treated by galvanization and the faradic brush. The latter, as recommended by Rumpf, should be brushed over the skin of the back and extremities for five or ten minutes, using a strong current. Counterirritation by blisters is of no use, although simple rubefacients may relieve slight degrees of pain.

Hydrotherapy likewise maintains its popularity in Germany, although claimed by some authorities to be sometimes harmful, especially in the shape of hot baths and vapor baths and wet packs. The *tepid bath* is entirely safe and often symptomatically useful. Its temperature should be from 80° to 90° F. (26.6° to 32.1° C.), accompanied by gentle rubbing. *Wet compresses* upon the abdomen or legs at night sometimes relieve the pains. In Germany, too, there are numerous water-cure establishments in the hands of experienced directors, to which patients may be advantageously sent, but, unfortunately, there is nothing of the kind in this country which can be recommended. Oeynhausen-Rehme in Minden has the best reputation for its carbonic acid thermal salt baths, but the baths at Nauheim in Hess are similar. Mud and iron baths are found at Pyrmont, near Brunswick; Driburg, in Westphalia, Prussia; Elster, pleasantly situated in Saxony; Karlsbad, Marienbad, and Frazenbad, in Bohemia.

The *painful attacks* are often not relieved by the measures thus far suggested, and require more powerful treatment. The first to be used should be *phenacetin*, *acetanilid*, *exalgin*, *salophin*, *aspirin*, and *antipyrin*, while *morphin* should be deferred as long as possible. It may, however, be necessary, when it should be used hypodermically. *Cocain* used in the same manner in doses of from 1-6 to 1-4 grain (0.011 to 0.165 gm.) is also sometimes efficient, while *cannabis indica* in doses of 1-4 to 1-2 grain (0.0165 to 0.033 gm.) of the extract may also be tried. Bandaging with a broad flannel bandage from toes to thighs has been recommended for the sciatic pain and pressure for the relief of painful spots. Massive doses of strychnin have been suggested for the same purpose.

Fatigue of all kinds as well as anxiety of mind should be *avoided*, while moderate exercise may be encouraged. Excesses in smoking, and especially in the use of alcohol, are harmful, as is also sexual indulgence. Over-eating and the use of indigestible articles of food should be avoided, as gastric crises are invited by them.

Great benefit has been claimed for the so-called Fränkel movements. They are "based upon the education of the central nervous system by means of repeated exercises, whereby it is enabled to receive sufficiently distant stimuli from the limbs as to their position and so on, although the available quantity of sensation is rather small. It is necessary, of course, that the

movements be attempted and carried out repeatedly and with great attention." They are too complex to be repeated here, and the student is referred to Fränkel's book.*

HEREDITARY ATAXIA.

SYNONYMS.—*Hereditary Ataxic Paraplegia; Friedreich's Disease.*

Definition.—A disease whose clinical features are especially ataxia and paraplegia, occurring in families and at an age much earlier than ordinary tabes, from which it differs also in the addition of peculiar symptoms associated anatomically with lesions in the posterior and lateral columns.

Historical.—Friedreich reported in 1861 six cases of this disease and a further number in 1870, whence the association of his name with it, but as the name Friedreich's disease is also applied to *paramyoclonus multiplex*, confusion results. On the other hand, the term hereditary ataxia is scarcely correct, because while sometimes it is hereditary and even congenital, it is not always so. It usually occurs in families, several brothers and sisters being, as a rule, affected. Yet isolated cases occur. In one case of William Osler's three generations were involved. A neurotic tendency is sometimes noticed. Alcoholism and syphilis were present in parents in a few instances, consanguinity of parents in a very few only.

Etiology.—Its etiology is unknown. It is more common in males than in females, affecting 86 males and 57 females out of 143 cases collected by J. P. C. Griffith. Strümpell makes the opposite statement as to sexes, but other observers agree with Griffith. Of Griffith's cases, 15 occurred before the age of two, 39 before the age of six, 45 between six and ten, 20 between eleven and fifteen, 18 between sixteen and twenty, and 6 between twenty and twenty-four.

Morbid Anatomy.—There is decided degeneration of the posterior and lateral columns, and the degeneration in the posterior columns may extend throughout the cord, leaving a narrow band of normal tissue near the posterior cornua. Different opinions are held in regard to the condition of the posterior roots. The degeneration of the lateral columns involves the area of the pyramidal tracts, but it is disputed whether the pyramidal fibers are actually diseased. The degeneration is found also in the direct cerebellar and Gowers' tracts as well as in the column of Clarke. As yet no changes have been found in the cells of the posterior horns. The pia mater over the posterior columns is sometimes thickened.

The disease seems to consist of a double morbid process, consisting in early degeneration of nerve elements, associated with a tendency to overgrowth of interstitial or neuroglia tissue. According to Dejerine and Letulle, it is a gliosis of the posterior and lateral columns, due possibly to defect in development.

Symptoms.—The essential symptoms are *ataxia with paraplegia*. Initial pains are rare. The ataxia is, however, peculiar. As in tabes, it begins in the legs, but it is swaying and irregular, more like that of drunkenness. The feet are not often raised too high, and while there is stamping, as in true tabes, it is less marked. Tabetic swaying—Romberg's symptom—may or may not be present. The ataxia of the arms occurs early and is striking, the movements being choreiform, jerky, irregular, and swaying. The hand first moves an object in its efforts to secure it and then pounces

* "The Treatment of Tabetic Ataxia by means of Systematic Exercise," Freyberger's Translation, Philadelphia, 1902.

upon it. There seems to be a superabundance of effort in voluntary movements, action is overdone, and prehension is claw-like. Again, the fingers may be spread out or overextended. The first manifestation of the disease in children is often a tendency to fall.

As the disease advances, irregular, *jerky movements* affect the *head* and shoulders, sometimes tremor-like. In most cases there is *nystagmus* when the eyes are moved laterally or upward, usually a late, sometimes an early, symptom. *Atrophy of the optic nerve* is rare, and the pupils are normal. *Speech* is sometimes impaired, generally as a late symptom—three, five, or ten years after the initial symptoms. Syllables are elided,—the speech is *scanning*,—with occasional movements of the tongue, but no twitching of the lips.

The *paresis* is at first slight,—indeed, the power of the muscles is at first unimpaired,—while there is rarely ever total paralysis. Some patients, however, never walk. The nutrition of the muscles is good. The *knee-jerk* generally disappears early, or is at least absent when the cases come under observation. In a few this symptom appears late, while in some atypical cases this reflex has been reported increased. *Sensory* symptoms are *not* usually *conspicuous*. There may be none, even in bad cases. At times there is delayed sensation or impaired sensibility to pain and temperature. Increased sensitiveness may be present. *No visceral crises occur*.

While trophic lesions of the usual kind are rare, there occur peculiar *deformities*, especially of the *feet*. There is talipes equinus or equinovarus, and the patient walks on the outer edge of the foot. The *great toe* is overextended or dorsally flexed, and occasionally this is the first sign of the disease. There may be *lateral curvature of the spine*.

Diagnosis.—This is not difficult, although sometimes the disease is confounded with *chorea*, with the hereditary form of which it has certain points in common. The ataxia in early life, the club-foot, overextended great toe, spinal curvature, lost knee-jerks, nystagmus, and scanning speech form a complex of symptoms not found in any other disease.

It resembles *ataxic paraplegia* in more than its symptomatology, but the increased knee-jerk, foot clonus, and spasm of the latter disease are wanting. In cases of combined lateral sclerosis and posterior sclerosis in which the knee-jerk is absent the family history and youth of the subject can alone settle the question. The loss of iris reflex in children points to tabes, the result of inherited syphilis. *Disseminated sclerosis* presents inco-ordination, nystagmus, and defective articulation, but the knee-jerks are almost always exaggerated, and intention tremor is characteristic.

Prognosis.—This is invariably bad, so far as recovery is concerned, although the disease lasts many years.

Treatment.—There is no treatment except such as will overcome tendency to deformity. The remedies used in locomotor ataxia may be tried.

CEREBELLAR HEREDITARY ATAXIA has been described by Marie, Sanger-Brown, Klippel, and Durante. It starts after twenty years of age. There are ataxia, disordered speech, nystagmus, and heredity, but the knee-jerks are normal or exaggerated, there is Argyll Robertson pupil, optic nerve atrophy with limitation of the field of vision, while there is no scoliosis or club-foot. The opposite is true of hereditary ataxia. Many do not recognize the cerebellar hereditary ataxia as a distinct symptom-complex.

PROGRESSIVE INTERSTITIAL HYPERTROPHIC NEURITIS OF CHILDHOOD is also a family disease. The symptoms are a combination of those of tabes

dorsalis with those of neurotic muscular atrophy (peroneal type of progressive atrophy). There are hypertrophy and hardening of peripheral nerves. It was first described by Dejerine and Sotas.

TOXIC SCLEROSIS, especially of the posterior and lateral columns, results from such diseases as pellagra, ergotism, and pernicious anemia

ATAXIC PARAPLEGIA.

SYNONYMS.—*Combined Sclerosis; Progressive Spastic Paraplegia; Combined Lateral and Posterior Sclerosis.*

Definition.—A chronic disease of the spinal cord, characterized by symptoms which point to lesions of both lateral and posterior sclerosis, including, therefore, both spastic and ataxic features, the symptoms of one lesion being more or less modified by the other.

Etiology.—This is obscure. It is more common in males, is a disease of adult life in which overexertion, exposure, spinal traumatism, and sexual excess each have been antecedent events. Less frequently than tabes does it follow in the wake of the syphilitic taint. It is always associated with general paralysis of the insane. Hereditation has been observed in one-tenth of the cases, and the neurotic constitution seems to favor it. It is probably most frequently associated with anemia.

Morbid Anatomy.—As the name suggests, lesions are found in both posterior and lateral columns. In the posterior columns they resemble those of uncomplicated tabes dorsalis, and are most intense in the cervical and thoracic portions of the cord, variously distributed, sometimes equally, at others preponderating in one or the other. The changes in the posterior root zones are less pronounced than in true tabes. In the lateral columns the crossed pyramidal tracts and in the anterior columns the direct pyramidal tracts are chiefly involved, though the mixed zones of the lateral columns, the lateral limiting layers, and the direct cerebellar tracts may also be invaded. The gray matter and membranes remain intact. In most cases the lesions are diffuse and the apparent systemic degeneration is usually the result of secondary degeneration.

Symptoms.—The symptoms are slow in their development, though occasionally a more rapid course is pursued, the only modification in this being that occasionally months instead of years are sufficient to develop the distinctive features. Those of either lesion may predominate at first. More usually those of ataxia are the first to appear, including fatigue and even pain after comparatively slight exertion, unsteadiness of gait, increased with the eyes closed, though an associated stiffness, may prevent the typical gait of tabes. There is also more or less paresis. There may be dull pain or numbness in the lower extremities and in the back or sacral region, but the lightning pains of tabes are rarely present; nor is the girdle sensation, while visceral crises very rarely occur. The Argyll Robertson pupil is, also, commonly absent, but nystagmus is not infrequent. The most striking difference in the symptomatology of ataxic paraplegia, as contrasted with true tabes, is the presence of *exaggerated reflexes in the former*, including knee-jerk and ankle clonus. Simple tapping of the patella or the belly of the quadriceps extensor brings out the former. The upper extremities are also often involved, and the chief symptoms here are weakness, inco-ordination with exaggerated wrist- and elbow-jerks.

Sensibility is also diminished in combined sclerosis, but less so than in pure tabes. Electrical reactions are unaltered, at least in the early stages of the disease. With advance of the disease the features of a purely lateral sclerosis become very pronounced; those of tabes less so. Muscular paresis and rigidity become marked, and the patient is unable to leave his bed. There is no localized *atrophy* of the muscles, although general wasting is not uncommon in the late stages of the disease. Very rarely there may be atrophy of the optic nerve, the ocular muscles remaining intact. The sphincters of the bladder and rectum are sometimes involved; at others not, those of the bladder more frequently, producing difficult micturition. On the other hand, by rest and tonic treatment the spastic symptoms may be diminished, while ataxia remains unchanged and the symptoms of this condition become more pronounced. The mind remains normal.

Diagnosis.—This is usually easy, enough of the symptoms of each lesion being present to show the existence of a combined disorder. The *absence of co-ordination on the one hand and increase of knee-jerk on the other* are the two antipodal symptoms around which others of each lesion cluster. Then, as to differential diagnosis, *myelitis* may present similar symptoms. On the other hand, myelitis is usually a disease of sudden development, characterized by a rapid increase of symptoms as contrasted with the slower course of the disease under consideration. *Friedreich's ataxia* resembles ataxic paraplegia closely in its pathology, but the exaggeration of the tendon reflexes and the spasticity are absent in the former. *Cerebellar tumor* may be mentioned with better reason as a disease which may be confounded, but in this disease headache, optic neuritis, and vomiting are peculiar, and while there is ataxic gait, it is the reel of a drunken man, and not the inco-ordination of tabes. So, too, there may be spastic symptoms in cerebellar disease, but they are less decided than in combined sclerosis. *Disseminated sclerosis* is a disease with which combined sclerosis may be confounded, and although it is the less pronounced forms of each which give rise to doubt, it is important to remember that the former has been found postmortem in cases which presented the clinical symptoms of spastic paraplegia during life. Whence it is not impossible that it may also present in its earlier stages symptoms of ataxic paraplegia.

Prognosis.—This is unfavorable as to recovery, but the disease is so slow in its development that death commonly results from intercurrent disease or from complications favored by the disease itself, such as diseases of the urinary organs, bed-sores, and septic complications. It does happen also that the disease is arrested for a time.

Treatment.—The treatment is mainly symptomatic: warm baths and a warm climate for the spastic symptoms; massage and exercise for the ataxic symptoms. Electricity and spinal stimulants like strychnin are contra-indicated as calculated to increase the spastic symptoms, while bromids and belladonna may be of service in controlling these. If a specific history can be traced, the disease should be appropriately treated by iodids or mercurials, and when anemia is present the treatment should be directed to the improvement of this condition.

SYRINGOMYELIA.

Definition.—A term applied to all cavities in the spinal cord, most of which are surrounded by an overgrowth of neuroglia.

Etiology and Morbid Anatomy.—The cavities are formed by defective closure of the central spinal canal or by the breaking down of residual embryonal tissue or of gliomatous tissue. The cavity of a syringomyelia is usually in the posterior part of the cord, extending toward the posterior cornua. It may prevail throughout the entire extent of the cord, but in most cases involves only the cervical or thoracic regions or more limited areas. The transverse section is oval or circular, but it may be fissure-like or quadrilateral, even irregular. On the other hand, a primary hemorrhage of traumatic origin, or even without trauma, may be the starting-point of a syringomyelia, and it has been supposed that such a hemorrhage into the spinal cord, occurring at birth from difficult labor, may later in life cause the symptoms of syringomyelia. So, also, compression of the cord due to fracture or dislocation may furnish the condition which will result in dilatation of the cervical canal of the cord. The cavities may be multiple. The term hydromyelia, applied to the forms in which the cavity is merely the dilated central canal, is falling into disuse, and there is no real difference between this and the other varieties. It is probable that hydromyelia may change into syringomyelia.

Symptoms.—The milder degrees are without symptoms and are often overlooked. Symptoms usually make their appearance about the period of adolescence. They are mostly gradual in development, and are partly the result of the secondary processes of distention which derange natural function. The symptoms are influenced also by the situation of the cavity, which is found most frequently in the cervico-thoracic region, whence the arms and neck are correspondingly affected. They depend also on the greater involvement of the gray matter of the cord.

The essential symptoms are modified *sensibility*; chiefly to *pain*, *temperature*, and to a *less degree* simple touch; also muscular *atrophy*, the latter progressive in development; and *trophic disturbances*. The sensory symptoms are the earlier and more constant. The sense of tactile impression is lost by involvement of its path, which, as has been said, is not precisely known after it enters the posterior roots, though it is possibly, partly in the posterior columns. The comparative rarity of this involvement may be said to be due to the difficulty in destroying this path completely. Derangement of the sense of pain and thermal sense is probably due to implication of the central gray matter, since it is through it that these impressions probably radiate to the white conducting tracts of the opposite side. The extension of the process to the lateral columns probably explains the derangement of these senses in portions of the body below the level of the cavity in the spinal cord. There may not only be a loss of thermal sense, but it may be reversed in that heat is felt as cold, and vice versa. So, also, subjective sensations are felt, including heat and cold, or, in their absence, pain, which may be neuralgic in character and irregular.

The muscular atrophy is the result of injury to the motor cells of the anterior cornua from compression or destruction of these cells. This causes degeneration of the nerves and wasting of the muscles, and along with it is a lowered electrical irritability. There is also *muscular weak-*

ness, involving the trunk muscles, and possibly to this is due the lateral curvature. If the legs are affected, it is generally from simple spastic paralysis from pressure on the pyramidal tracts, but sensory changes in the lower limbs occur. Great wasting of the legs indicates lumbar involvement, and the presence of ataxic symptoms points to involvement of the posterior columns. The remaining symptoms are not essential, but may be incidentally present from the action of the causes which usually produce them. The *reflexes* may or may not be increased, and *myotatic irritability* may in rare cases be lost, while *tremor* of the limbs has been noticed in some cases.

Trophic symptoms are not rare in the parts affected by sensory loss. The skin may be glossy and thin, or thick and horny, while there may be eczema, herpes, bullæ, and even ulceration and gangrene. The nails may become fissured and drop off. There may be deformity and absence of the end phalanges and lingual hematophy. *Vasomotor* disturbances are more common, including coldness, lividity, or redness with swelling and heat. There may be sweating, brittleness of bone, and joint changes like those of tabes.

The area of the *cranial nerves* may be invaded when there is involvement of the medulla oblongata. The phenomena may include paralysis of one vocal cord, the tongue and face, difficulty in swallowing, of breathing, and embarrassed heart's action. The eyes may be disordered, and the pupils unequal, but the other special senses escape.

Diagnosis.—This is based upon the sensory symptoms, and of these thermo-anesthesia and analgesia rather than tactile insensibility, together with muscular atrophy succeeding after some interval. *Cervical pachymeningitis* causes like symptoms similarly distributed. J. Hendrie Lloyd, in an important paper,* has also called attention to certain traumatic affections of the cervical region of the cord simulating syringomyelia. Cervical pachymeningitis runs a more rapid course; the anesthesia includes all varieties of sensation and corresponds more nearly in its distribution to that of the muscular atrophy, pain is more conspicuous, and the reaction of degeneration is commonly present in the wasting muscles, and later, signs of compression of the cord are observed.

The symptoms of syringomyelia are sometimes simulated by the anesthesia and wasting of *anesthetic leprosy*, but in the latter disease the trophic changes are more marked, the phalanges often drop off, while the sensory symptoms include all varieties of sensation.

Progressive muscular atrophy differs in the absence of altered sensation. An intramedullary *spinal tumour* in the same situation as a syringomyelia furnishes almost identical symptoms, and may have an identical origin if it starts from the neuroglia, but the symptoms may be more rapid in their development.

The diagnosis of syringomyelia is sometimes exceedingly difficult to make, as the characteristic disturbances of sensation may be absent.

Prognosis.—This is ultimately fatal, although the course is slow, extending over a period from fifteen to twenty years. Toward the end the course is more rapid, death resulting from exhaustion or interference with the functions of the medulla oblongata.

Treatment.—This can only consist in measures to combat symptoms and tendencies to them, such as cystitis, bed-sores, and the like.

* Read before the Philadelphia Neurological Society, March 26, 1894.

MORVAN'S DISEASE.

SYNONYMS.—*Analgic Panaritium; Analgesic Paresis with Panaritium; Painless Whitlows.*

Definition.—This term is applied to a chronic affection described in 1883 by a Breton physician named Morvan, which is characterized by neuralgic pains, tactile and thermal anesthesia, analgesia, and painless destructive felons (paronychia). The disease is probably in most cases the same as syringomyelia; in some instances it is leprosy. Twenty cases were recognized in a population of 50,000 in Brittany. One or two cases have been reported in America.

Zambuco, of Constantinople, found in the broken-down matter of the syringomyelic cavity of what seemed a typical case, Hansen's lepra bacillus. In two well-studied cases reported by Marinesco and Jeanselme to the Société Médicale des Hôpitaux de Paris, February 12, 1897, the typical lesions were found, but no bacilli.

COMPRESSION OF THE SPINAL CORD.

SYNONYMS.—*Compression Myelitis; Pressure Paralysis of the Spinal Cord.*

Definition.—Under this head are included all forms of paralysis due to gradual compression of the cord from whatever cause.

Etiology.—A large number of causes may operate in the way indicated, among which are tumors or inflammatory new formations, including syphilitic products either in the membranes or outside of them, caries of the vertebræ, especially the form known as Pott's disease or tuberculosis of the vertebræ, cancer of the vertebræ, echinococci and cysticerci in the vertebral canal. Extraspinal causes may also produce erosion of the vertebræ and compression of the cord; among these are aneurysm of the aorta, retroperitoneal sarcoma, lymphadenoid growths, and suppurating kidney; also retropharyngeal abscess. Pott's disease is by far the most frequent cause.

Morbid Anatomy.—The changes in the cord as the result of compression are best studied in the compressions due to dislocation of the vertebræ in the breaking down of the bodies of one or more from tubercular infiltration, or as the result of intrusion into the spinal canal of foci of cheesy pus from the posterior surface of the bodies of the vertebræ. Macroscopically, the cord is often smaller, softer, and sometimes bent. In old cases it may be harder. The term myelitis has been applied to the changes thus produced in the cord, but careful examination fails in some cases to find any of the usual histological products of inflammation. In the early stages the axis-cylinders are swollen, and fatty granular cells may be present. The nerve-cells suffer more or less alteration depending on the degree of pressure. At a later stage may be seen a secondary overgrowth of neuroglia, replacing the destroyed nervous tissue, first loose, later firm and fibrillated. After a certain duration there may be ascending and descending secondary degeneration of certain systems of fibers in the spinal cord.

Symptoms.—When tubercular disease of the spine is the cause, the resulting deformity—kyphosis—is usually seen long before the symptoms

of compression of the cord are present. On the other hand, when the erosion is due to aneurysm or growths within the thorax or abdomen, the subjective symptoms appear before the deformity, or more frequently without external deformity. The first of these symptoms is usually *pain* at the seat of the compression, which often does not amount to more than a dull ache, while at another time it is extremely severe. It is also aggravated by bending or straightening the body. Again, the pain is distributed along the course of the nerves, when the compression is exerted on the nerve-roots. Previous to such pain and associated with it are *paresthesias* of various kinds, such as numbness, tingling, and formication. More rarely there is *impaired sensibility*, the same degree of pressure which deranges the function of motor fibers having often no effect on the sensory. Marked anesthesia is rare, and then only in the last stages.

With the foregoing soon become associated *motor symptoms*, which may consist in *stiffness*, giving rise to difficulty in moving arms or legs, with peculiarity of gait, or there may be simple weakness or *paralysis*, increasing to complete motor *paralysis*. These symptoms rarely affect both arms or legs at once, but rather first one and then the other.

The seat of the more pronounced sensory and motor symptoms varies with the segment compressed. Thus, when the caries is in the *upper cervical region*, between the axis and the atlas, or between the latter and the occipital bone, there may be *spasm of the cervical muscles*, the head may be fixed, and movements may either be impossible or extremely painful. Retropharyngeal abscess may be the cause of such a symptom, as in a case in the Montreal General Hospital mentioned by Osler, where movement was liable to be followed by transient instantaneous paralysis of all four extremities from the compression of the cord, the patient dying in one of the attacks.

If in the *lower cervical region*, there may be *dilatation of the pupils* from interference with the ciliospinal center or nerve-fibers arising in this center. There may be *flushing* of the face and ear on one side or *unilateral sweating*, *rigidity of the muscles* of the neck, while the sensory and motor symptoms described, if present, will be found in the arms. The deformity of tuberculous caries is not always marked in this locality, but after recovery evidence of its presence may be found in a conspicuous *callus*, which may cause permanent rigidity of the neck. The cortical inhibitory influence being suspended, both tendon and cutaneous *reflexes* are increased, sometimes so markedly as to produce in the lower extremities a pronounced type of the spastic paralysis, with increased patellar reflex and ankle clonus. The increase of the skin reflexes is less marked than that of the tendons.

When the *thoracic* and *lumbar* segments are involved, only the *lower extremities* suffer from the effect of compression: commonly the paresis is late, though rarely it may appear before the deformity of Pott's disease. When the lesion is confined to the thoracic region, there may be *girdle sensation* and *pain* in the course of the intercostal nerves. Here, as elsewhere, motion is affected before sensation. As to the reflexes, since the reflex arc for the lower tendon reflexes is in the lumbar region, compression of the *thoracic* cord should produce an increase in them, and this is usually the case. On the other hand, they are diminished when the *lumbar* cord is compressed. If the lower thoracic and lumbo-sacral region is affected, the sphincters are apt to be involved, and there is, first, difficulty in micturition, then retention, and finally incontinence with cystitis, but the sphincters may

also be involved from lesions higher in the cord. Yet all these symptoms may disappear, and recovery take place after many months' duration of the disease.

Trophic symptoms may be present in the paralyzed parts. These may include herpetic eruptions in the course of the nerves, at other times derangement of nutrition, manifested by bed-sores forming on slight irritative provocation, rapid shedding of the epidermis, and brittleness of the nails. With the involvement of their trophic center the muscles may waste.

Diagnosis.—This is easy when there are evident signs of caries of the spine, manifested by prominence of spinous processes of the vertebræ and by tenderness on pressure. Repeated examination of the spine should be made. Nerve-root symptoms, or symptoms resulting from pressure of nerve-roots, as they pass out between the vertebræ, are always significant. They include radiating pains, girdle sensation, and hyperesthesia or anesthesia, spasm and wasting. Stiffness on motion in separate parts of the spinal column is also significant. Root symptoms are said to be more common in cancer than in caries, but any of the symptoms named have increased diagnostic value if there has been cancer elsewhere, especially of the breast, and if the age exceeds forty. There is much more pain attending the paraplegia of cancer—whence the term *paraplegia dolorosa*, and when the pain is referred to areas anesthetic to tactile and painful impressions, *anesthesia dolorosa*. Such is the case whenever erosion is wrought from the abdomen outward, as by retroperitoneal growths or aneurysm.

Prognosis.—This is unfavorable in all cases except tuberculous spondylitis, which often terminates in cure, for, sooner or later, especially with suitable treatment, the tuberculous process may cease and the symptoms of paralysis disappear, although, of course, the kyphosis remains. Some cases perish from miliary tuberculosis, others from the exhaustion incident to bed-sores, cystitis, and pyelonephritis.

Treatment.—Only when tuberculous spondylitis is responsible is there hope of cure. The treatment is general, by the usual measures found useful in tuberculosis, such as cod-liver oil and creasote or creasotol, with such tonics as iron and iodine, good food, fresh air, and mechanical appliances suggested by the orthopedic surgeon. These should be so adjusted as not to produce pain. Their object is to produce extension and thus relieve compression, and if this is not accomplished, they are useless. The method of extension by suspension, originally suggested by the late Dr. J. K. Mitchell, and more recently revived by Weir Mitchell and extensively practiced of late years, has again fallen into comparative disuse, partly because of the difficulties in carrying it out, and perhaps because there have been some unfortunate accidents. Good results have, however, followed its use. Especially may such results be hoped for if the extension is used early, although they have followed even after paralysis had supervened.

Along with the extension, rest in bed is a most important measure, and many cases are arrested by such rest. Local measures, like counter-irritation and the hot iron, are of no use—rather harmful than otherwise. The same may be said of electrical treatment and massage, except so far as they are useful to keep up the nutrition in the paralyzed muscles. On the other hand, warm bathing is useful in relieving pain and allaying discomfort.

Operative treatment—laminectomy—has lately been practiced with a good showing of result, and it should be considered, at least, after other

measures have failed. Treatment should be persevered in, as recovery takes place sometimes after paralysis has long persisted, and in no form of tuberculosis has the general treatment previously recommended been so useful.

In the incurable forms anodynes must be resorted to to relieve pain, including even the hypodermic use of morphin, which should never be used without bearing in mind the possibility of the patient acquiring the morphin habit.

TUMORS OF THE SPINAL CORD AND MEMBRANES.

Both the membranes and the substance of the cord may be seats of tumors, while the cord may also be invaded from the spinal column by enchondroma or sarcoma.

Varieties.—From the spinal column, enchondroma, sarcoma, and cancer may intrude into the canal. External to the dura mater in the extradural space occur fatty and malignant tumors, while parasites are also found in this region. The extradural tumors, all rare, may spring from the dura or from the tissue between it and the bone, or may arise outside and pass

Fig. 109.—Sarcoma of the Lower Cervical Cord—(Adamkiewics).

Fig. 110.—Sarcoma Compressing the Cervical Cord—(E. Long Fox).

through the intervertebral foramina. Within the dura are found myxomata, fibromata, lipomata, and neuromata on the nerve-roots. Subdural tumors may arise from the inner surface of the dura, the arachnoid, or from the pia, and may include sarcomata, syphilitic, tuberculous, and parasitic growths. The last two are rare, but both echinococci and cysticerci have been met, developing in the meshes of the arachnoid. Schlesinger collected forty-four cases of echinococcus disease. When the parasite is intradural it is round or oval and compresses the cord. The dura is not usually implicated, merely distended. Of the forty-four cases only five were intradural,

so that the extradural location is seven times more frequent than the intradural. They are usually on the posterior surface of the cord and in the thoracic portion of the vertebral canal, at least in the extradural variety. They may be the size of a pea, of a walnut, or even larger. Their contents are clear and they often contain daughter cysts. Their growth is usually slow. It is said that the hydatids are sometimes found in the substance of the bone.

Fatty tumors are also rare, but have been found and are probably congenital, because they were usually found associated with spina bifida. In the cord itself and attached to the pia occur tuberculous, syphilitic, and gliomatous tumors; sarcomata and myxomata have been found. Syphiloma and sarcoma are the most common. Most of these tumors spring from the pia mater, but tuberculous growths also develop in the gray matter. Some tumors are compound, as myxosarcoma, etc.

The size attained by tumors of the spinal cord and membranes is necessarily limited by the surrounding space. The largest do not exceed two inches (5 cm.) in diameter, and many are very small, not larger than a pea. They are usually single, rarely multiple, as seen in the instance of neuromata, and occasionally sarcomata. Tumors developing within the cord may lead to syringomyelia.

Symptoms.—These vary with the seat of the tumor and the degree of pressure exerted. When the latter increases slowly, the growth may reach quite a large size before serious mischief is done. *Pain* is a frequent and conspicuous symptom, and is apt to be maintained by pressure on nerve-roots which are in the way of the growth. The seat of pain varies with the course of the nerves impinged upon, and may be of every variety, such as "burning," "tearing," "stabbing," "aching," "girdle sensations," and the like. It may be unilateral or bilateral, and is worse, according to Horsley, when the tumor presses forward. Sometimes the pain is in the spine itself, which may also in rare instances be tender to pressure. When the growth is in the lower lumbar region, the pain may be referred to the soles of the feet, and may ascend from this seat. In other cases there is hyperesthesia of the skin, which may be associated with pain felt at the level of the tumor, or pain may be felt in anesthetic areas. Very rarely pain is absent, chiefly in extradural lipoma.

Muscular spasm is also frequent, especially when the tumor springs from the membranes, when it may be very decided. There may be rigidity at the seat of the growth, most marked when the disease is at the more mobile parts of the spine, as the cervical region. Then there is apt to be pain in the vicinity, increased by motion. Spasm in the abdominal muscles may also be associated with *girdle pains*. *Contractures* may arise in the limbs, both those supplied by nerves directly irritated by the tumor and by those given off lower down. It is important to note the seat of the rigidity and its character, which may aid us in diagnosing the seat of the tumor, whether it is on the nerve-roots or conducting tract of the cord. Thus, a tumor in one-half of the cord, in the cervical region, may cause persistent contraction of the arm and leg on the side of the growth, and in the early stage of thoracic tumors one leg only may be rigid at a time or one may be more so than the other. In the dorsal region the level of the pain is apt to correspond accurately with the level of the growth, and the reflexes centering at this level may be lost, but retained in the legs.

Paralysis occurs sooner or later as constantly as pain, increasing grad-

ually with the pressure. Paraplegia is more common, but all four limbs may be paralyzed by a tumor in the cervical region, one limb being usually affected before the other, though when the tumor is exactly central, both sides are affected simultaneously. Loss of sensation follows paralysis sooner or later. It corresponds in distribution to the motor palsy when the tumor is below the middle of the dorsal region, but if higher and on one side, the sensory loss may be greater on the opposite side; especially is this the case when the tumor is within the cord, when the symptoms may be those already described under the head of Brown-Séquard's paralysis.

Atrophy follows involvement of the anterior cornua, and *vasomotor* disturbances may be marked. In cases of prolonged interruption *ascending and descending degenerations* may occur. Tumors not infrequently cause subacute or acute myelitis, whose symptoms may mask the clinical picture.

Diagnosis.—The characteristic symptoms are slow development of severe and constant unilateral root symptoms, later bilateral, at the level of the growth, and a progressive paralysis, motor and sensory. The radiating pain is usually at the level of the tumor or below. Pain in the spine itself is an important sign. Rigidity of the muscles of the spine, muscular contractions in the limbs, early and marked exaggeration of reflex action when the cord itself is involved, are also important signs, especially when associated with the history of syphilis or tuberculous disease. *Caries of the spine* may produce the same symptoms, but the radiating pains are less severe and the effects of compression of the cord are more likely to be bilateral, either from the first or soon after their commencement. Tenderness of the spine may generally be elicited by careful examination, while irregularity of surface, from the breaking down of the bone, sooner or later makes its appearance. When the *tumor is in the bone itself*, the symptoms at first scarcely differ from those of caries, though the pain on motion is usually worse in the former.

The symptoms of *cervical meningitis* also closely resemble those of tumor. They are, however, usually bilateral from the first and have considerable vertical extent. Central tumors covering a like area may produce identical symptoms. Pain and muscular atrophy in the arms without wasting occur in both, but are usually less severe in tumor, while the early and localized impairment of all forms of sensation is less.

Chronic transverse myelitis also closely simulates tumor in its radiating pain, sense of constriction, progressive paralysis, and a differential diagnosis is sometimes impossible. The symptoms here, too, are from the first bilateral, while the radiating pain is commonly not severe in myelitis, which invades also larger areas of the cord.

As to the exact seat of the tumor, in general terms it may be said that *when within the cord*, the symptoms are those of a gradually increasing paraplegia or of a Brown-Séquard's paralysis, while vasomotor disturbances are marked, and reflexes are bilaterally influenced, according to the law explained. Atrophy means involvement of the ventral cornua. Acute or subacute myelitis may be associated and complicate the clinical picture. Tumors in the *membranes* are characterized by early "root symptoms," including radiating pains, girdle sensation, and hyperesthesia or anesthesia. Irritation of motor nerves may cause spasm or wasting, with paralysis late in the disease.

The nature of the tumor may be inferred only from the history of the case, syphilis and tuberculosis giving the most valuable assistance. Its seat

is suggested by the level of the transverse symptoms. It is never below these, while it may be a distance of three or four vertebræ above the nerves corresponding to the highest level of anesthesia or pain. The diagnosis of tumor from other transverse lesions of the cord may be at times impossible.

Prognosis.—Only when the tumor is syphilitic may any relief be expected from medical treatment. In all other forms the symptoms gradually increase until paralysis results, unless operative interference produces a more favorable termination—a practice which modern methods are rendering more frequent and justifiable.

Treatment.—When there is reason to believe syphilis is present, the antisyphilitic treatment may be used with reasonable expectation of success. Beyond this, symptoms must be met as they arise. Attempts made of late years to formulate the laws governing surgical operations in these cases have been more or less successful, but wider experience is necessary before they can be thoroughly relied upon. I may, however, close this subject with the advice of Victor Horsley, whose studies on surgery of the nervous system entitle his opinion to the highest respect: “If it is clear that the growth is not syphilitic, and that no good can be done by other treatment, delay in an operation can only cause harm—can only result in a less favorable state for the proceeding, less chance of recovery, longer and greater suffering, and should, on every ground, be avoided.”

LESIONS OF THE CAUDA EQUINA AND CONUS MEDULLARIS.

The *cauda equina* is the bundle of nerves coming off from the lower cord and occupying the spinal canal from the second lumbar vertebra downward. At this vertebra the cord itself terminates in the *conus medullaris*, prolonged into the thread-like *filum terminale*. Fractures and dislocations in the lumbosacral region may impinge on these parts, while the filaments of the nerves of the cauda equina may be invaded by tumors or compressed by cicatrices.

Symptoms.—*Compression* of the *conus* and of the *last sacral nerves* given off from it, such as may be caused by a dislocation of the first lumbar vertebra, produces paralysis of the bladder and rectum and loss of sexual power, whence it has been inferred that the anovesical center and the center for the sexual function are seated in this part of the cord. This paralysis may be the only symptom or it may be associated with disturbance of sensation about the anus and in the perineum and external genital organs except the testicle, the latter being supplied with sensation from a higher segment of the cord.

When the *lumbar nerve-roots** are involved, from the *second to the fourth* inclusive, there is paralysis embracing all the muscles of the thigh and leg except the outer rotators of the thigh the flexors of the knee and of the ankles, the peroneal muscles, the long flexors of the toes, and the small foot muscles. There is also loss of sensation in the front, inner, and outer parts of the thighs and the inner side of the leg and foot.

Involvement of the fifth lumbar and first and second sacral produces

* Of the lumbar nerves, the first root appears between the first and second lumbar vertebræ, the fifth between the last lumbar and the base of the sacrum. The four upper sacral nerves pass from the spinal canal through the sacral foramina, the fifth between the sacrum and coccyx.

paralysis of the muscles just excepted, and loss of sensation in the outer and posterior part of the leg, foot, and sole of the foot. *Lesion of the third, fourth, and fifth sacral and coccygeal nerves* causes paralysis of the perineal muscles, the bladder, rectum, and of the external genitals, the coccygeus, with loss of sensation in the back of the thigh, anus, perineum, genital organs, and skin about the anus and coccyx.

SPINA BIFIDA.

SYNONYMS.—*Split Spine; Hydrorrhachis; Myelocele; Meningocele.*

Definition.—A name applied to a congenital defect in the closure of the spinal canal, through which protrudes a sac-like portion of the dura containing cerebrospinal fluid, at times a part of the cord, either normal or altered, and forming also, as a rule, an external prominence of tumor covered by skin.

Description.—The tumor is found commonly in the lumbar and sacral portions of the spine, rarely in more than one place, very rarely throughout the whole column. Its size ranges from that of a small nut to that of an orange, and occasionally it is so large as to interfere with the birth of a child afflicted with it. On section of the skin the protruding sac of the dura is seen and beneath this the arachnoid. Barely is the dura cleft so that the sac is formed by the arachnoid only. There may be a dilatation of the central canal,—hydromyelia,—when the substance of the cord is found more or less atrophied, while the central canal communicates directly with the cavity of the spina bifida. At other times the cord is normal, while its lower end may be adherent to the sac. A tumor of similar character is occasionally seen protruding through the skull.

Symptoms.—At first there are usually no clinical symptoms. By pressure the contents of the tumor can often be forced into the spinal canal, causing expansion of the fontanels and increase of cerebral pressure with its consequences—viz., somnolence, with changes in the pulse and breathing, which may be fatal if the pressure is continued. The absence of such symptoms goes to show that communication of the tumor with the spinal cord is cut off.

With the lapse of time the tumor usually grows slowly, and the effects of pressure on the spinal cord or cauda equina appear. These are paralysis, atrophy, anesthesia, bed-sores, vesical derangements, talipes varus, and trophic phenomena, of which perforating ulcer of the foot is one. The sac may burst, or the walls become inflamed, converting the contents into pus.

Prognosis and Treatment.—Unless removed by surgical interference, the child dies sooner or later of exhaustion. The tumor has been rarely obliterated by gradually increasing pressure or by injecting the cavity, after evacuation of the fluid, with iodin, producing obliteration through an inflammatory process. Other surgical measures may be found in text-books on surgery.

PROGRESSIVE BULBAR PALSY.

SYNONYMS.—*Polioencephalitis inferior chronica*; *Glossolabiolaryngeal Paralysis*; *Paralysis of the Tongue, the Soft Palate, and the Lips*; *Duchenne's Disease*; *Atrophic Bulbar Paralysis*.

Definition.—Bulbar palsy is a progressive paralysis invading the lips, the tongue, the palate, the pharynx and larynx, and in more advanced cases the lower face muscles, due to lesion of the motor nuclei in the medulla oblongata (or bulb), whence arise the nerves distributed to those parts.

Historical.—Bulbar palsy was first completely described in its clinical aspects by Duchenne in 1860, but the exact seat of the disease was not determined until 1870, when Charcot in France and E. Leyden in Germany confirmed the earlier suggestion that it was a progressive degeneration and atrophy of the nuclei in the medulla oblongata.

Etiology.—Primary progressive bulbar palsy is difficult to account for. It is more frequent in men, and sometimes heredity or family tendency is noted. It has been ascribed to the overuse of the muscles of the mouth, as

Fig. III.—Situation of the Cranial Nerves—(after Edinger).

Cranial nerve nuclei, oblongata, and pons represented as transparent. Motor nuclei, black; sensitive nuclei, red.

in the blowing of wind-instruments; to a tumor in the medulla oblongata or vicinity; while syphilis, to which so many of the unaccountable lesions of the nervous system are ascribed, is less commonly held responsible for this affection than for some others. Cold, emotional excitement, and extreme fatigue have all been named as causes. Most frequently, however, no cause is traceable.

Morbid Anatomy.—Most writers concede that the lesion starts in the nuclei of the medulla oblongata. It may be that the entire motor apparatus from the muscular fiber to the ganglionic cell is invaded simultaneously. Certain it is that bulbar paralysis is often associated both with progressive spinal muscular atrophy and amyotrophic lateral sclerosis, the symptoms now of one and now of the other preceding. There can be no doubt that these three conditions are closely allied. The nature of the lesion is the same in

each, the motor cells in each are involved, the muscles are wasted in each, though the particular ones involved vary as the situation of the motor cells is different.

The anatomical lesion is an *atrophy of the motor cells of the medulla oblongata*. The nucleus of the hypoglossus, the nucleus of the pneumogastri- c, to a less degree, that of the facial and that of the glossopharyngeal are all involved, while the *sensory nuclei are intact*. Very rarely the nuclei of the ocular nerves, third, fourth, and sixth, are involved. From these nuclei the degeneration extends to the *nerves* which have their origin in them, and thence to the *muscles* to which they are distributed.

The nature of the degeneration is a more or less complete destruction of the motor cells. In addition, there is an overgrowth of neuroglia tissue and a thickening of the walls of the blood-vessels. The nerve-fibers of the pyramidal tract may undergo degeneration.

Symptoms.—The symptoms of progressive bulbar paralysis are exceedingly gradual in their development. The first symptom noticeable is usually a *difficulty in the pronunciation of words* containing letters which require the use of the tongue in their formation, such as E, R, L, S, G (hard), K, D, T, and N. Still later there is difficulty in pronunciation of words requiring the aid of the lips, as P, B, F, V, O, A (long), and the sound of O in tool, while whispering becomes impossible.

Concurrently with these symptoms the *tongue and lips* are observed to *waste*, the tongue becomes thinner and narrower, the lips thin and compressed in appearance, the loss of power being commensurate with the degree of wasting. *Fibrillar tremors* are usually seen in the tongue, and the mucous membrane may be thrown into transverse folds. Finally, the *tongue cannot be protruded*, or can be brought only to the edge of the teeth, while the *mouth cannot be closed* because of complete paralysis of the orbicularis oris muscle. In more advanced stages other muscles of the face become involved, the labionasal fold is less distinct, and the face becomes expressionless.

Before this degree has been attained, however, the muscles of the *palate* have commenced to fail in their action, and thus a further difficulty in the articulation of words is added, while the *voice is nasal*. Fluid begins to pass through the nose when swallowing is attempted. The difficulty in swallowing is increased by growing *paralysis of the pharyngeal muscles*, and is further aggravated by the inability of the tongue to carry the bolus of food backward. Feeding the patient is a troublesome and disgusting process, the food being scattered all about and sometimes thrown to a considerable distance, by the act of coughing facilitated by absence of power in the lips to retain substances in the mouth. By this time, too, the *laryngeal muscles* are involved, and the patient's efforts to speak result in mere grunts.

Thus he cannot talk, he cannot swallow, he cannot close his mouth; he cannot expectorate, yet the saliva flows from his mouth because he can neither swallow nor close his lips, and the term "driveling idiot" well covers the impression caused by his appearance. Yet his mental powers are unimpaired, and may remain so until the last. The motor electrical phenomena in the muscles involved may be altered, and the reaction of degeneration may be present.

To these symptoms are to be added complications due to the paralysis. From the difficulty in swallowing, particles of food may enter the larynx, be

insufflated to the deeper parts of the lungs, and there cause a pneumonia which may be fatal, or the fragment which enters the larynx may be so large as to cause death by suffocation.

In rare cases the lower distribution of both facial nerves is involved, producing *diplegia facialis*; but the upper distribution usually escapes. Or there may be paralysis of the ocular nerves to which it may be confined (anterior bulbar paralysis or progressive *ophthalmoplegia* of von Graefe). Even the muscles supplied by the spinal accessory and the motor branch of the trifacial may be invaded. In all these instances the nuclei of the corresponding nerves are affected.

Diagnosis.—The diagnosis is generally easy, the symptoms are so characteristic and so evident. For a typical case they must be purely motor; they must be disassociated from other muscular involvements which would go to make them a part of *progressive spinal muscular paralysis* or *amyotrophic lateral sclerosis*. If there are disturbances of sensation, invasion of the upper division of the facial, of nerves of special sense, the disease is not true bulbar paralysis. There must be some general involvement of the medulla, thrombosis, or embolism, a tumor developing near it or diffuse sclerosis through it.

There is a *glossolabiopharyngeal paralysis* of cerebral origin known as "pseudobulbar paralysis," in which there is complete paralysis of the tongue and lips, due to bilateral and possibly even unilateral cerebral lesions. Close examination will, however, detect, sooner or later, deviations from the typical course, which include absence of fibrillary tremor, and of atrophy, and of reaction of degeneration. The symptoms tend, too, to occur first on one side and later on the other. Mentality is much affected, and the reflexes may be exaggerated. Bulbar tumors run a like chronic course, but almost always presents unilateral symptoms.

Prognosis.—This is invariably sooner or later fatal, although it is said that the progress of the disease may be delayed by treatment.

Treatment.—If there be any suspicion that syphilis is the cause, *iodid of potassium* should be used, but the treatment which has been found most effectual is electrical. *Galvanism* is recommended, electrodes being applied to the two mastoid processes daily for two or three minutes, the current often reversed. The sympathetic nerve and the affected muscles of the lips and the tongue may be similarly treated, faradization being also substituted for galvanism in the case of the muscles. Deglutition may even be excited by galvanism when it begins to be impaired. This is accomplished by placing the anode on the nape of the neck and the cathode on one side of the larynx. At every cathodal closure, or every time that the cathode is carried across the side of the larynx, there is a reflex act of deglutition. When deglutition becomes very difficult, the stomach-tube should be used and nutrient substances thus introduced. Great care should be exercised in feeding the patient without the tube, lest the food pass into the trachea and cause suffocation. Hence, too, the use of the tube should not be too long deferred.

In addition to *iodid of potassium*, *nitrate of silver* and *ergot* are also recommended. The first should be given in such doses as the stomach will tolerate, while salivation may be controlled by atropin—1-100 to 1-60 grain (0.00066 to 0.0011 gm.). Silver should be given in the usual doses of 1-6 to 1-4 gr. (0.0106 to 0.016 gm.); ergot in usual doses.

ACUTE BULBAR PALSY.

Etiology.—Besides the chronic or progressive form of bulbar palsy, there is an acute variety which is caused by hemorrhage into the pons and medulla, or possibly by thrombosis or embolism of the vessels supplying these centers—viz., the anterior spinal, vertebral, and basilar. Inflammation of the medulla oblongata is also a cause. Thrombosis may occur in any of the vessels, and is commonly due to atheromatous or syphilitic endarteritis. Inflammation is a rare affection, but does occasionally occur.

Hemorrhage, thrombosis, and embolism are subject to the same causes here as elsewhere in the brain, but the cause of the inflammatory form of acute bulbar palsy is unknown. It is probably infection or intoxication.

Symptoms.—In any event the symptoms are sudden. They are those already detailed in connection with progressive bulbar paralysis, but others are added. There is usually no loss of consciousness, though there may be. There may also be deranged cardiac action and respiration, including irregular and frequent pulse, vasomotor derangements, and Cheyne-Stokes breathing. The temperature, normal at first, may rise to 105° to 107° F. (40.5° to 40.71° C.) and higher as a fatal termination is approached. Sensation is rarely affected. Most characteristic of all is the so-called *crossed paralysis*, described on page 844, which attends most hemorrhages into the pons, in which there is paralysis of the face on one side and of the extremities on the other; but the motor tract may not be involved, and in that case paralysis is not observed.

Diagnosis.—Suddenness of occurrence of the symptoms named indicates one of the accidents previously mentioned, while a crossed hemiplegia is conclusive. When inflammation of the medulla oblongata is present, the phenomena of bulbar paralysis do not occur quite so suddenly. They may be several days or even a few weeks in developing, and may be preceded by prodromal symptoms such as vertigo and painful sensations in the back of the neck.

Treatment.—The treatment is the same as for similar lesions elsewhere in the brain.

PSEUDOPARALYTIC MYASTHENIA.

SYNONYMS.—*Bulbar Palsy without Discernible Anatomical Changes; Asthenic Bulbar Paralysis; General Profound Myasthenia; Erb's Disease; Hoop-Goldflam Symptom Complex; Myasthenia Gravis.*

Definition.—A disease beginning usually with weakness of the muscles of the tongue, lips, larynx, and eyes, followed by rapid exhaustion and temporary paralysis of the muscles of the extremities; by temporary recovery of power after rest; occasionally terminating in persistent paralysis. It is more common than the true bulbar palsy.

History.—The disease was first described by Wilkes in 1877 as "an unusual form of glosso-labio-laryngeal paralysis." In 1879 Erb reported three cases which he described as a new syndrome, probably of bulbar origin. It, however, attracted little attention until the publication of Goldflam's paper in 1891. In 1891 and 1892 Jolly,

and in 1892 Hoopé published reports of cases; also in 1892 Goldflam published his paper in which were collected all cases published up to that date with four new cases. In 1896 Strümpell collected twenty cases. In 1900 Harry Campbell and Edwin Bramwell made the most complete study of the cases so far as published—in all about seventy. They give the details of sixty. In a later paper* Edwin Bramwell says up to the present time only some eighty or possibly ninety cases have been reported.

Etiology and Pathology.—The disease occurs usually in those from twenty to forty years of age, and in both sexes alike. It is believed to be due to an autogenetic toxin. Congenital defect or abnormality either in the construction or mode of functioning of the neuro-motor apparatus rather than in the muscles, has been suggested by E. Bramwell, and especially the lower motor-neuron. It has followed the infectious diseases, and in about one-fourth of the cases neuropathic heredity has been noted. At necropsy no lesion has been found which would account for the symptoms.

Symptoms.—These include ptosis, paresis of the facial muscles, difficult mastication, and difficulty in swallowing and talking. They are due to fatigue of the muscles involved, and the patient can talk a few sentences quite glibly, but his speech soon grows indistinct and ultimately incomprehensible. So with chewing and swallowing so far as the first mouthfuls are concerned, but these acts soon become impossible. The muscles of the extremities and trunk, as well as those innervated by the cranial nerves are involved, the same rapid fatigue supervening on effort. Thus one of Strümpell's patients could ascend a flight of stairs very well once, but in making a second effort had to invoke the aid of a bannister, while the third and fourth efforts were ineffectual. Such a condition is known as the *myasthenic* state. At times the abnormal fatigue and consequent symptoms are limited to the lower extremities. A similar effect succeeds on continued faradization of the muscles, first detected by Jolly, and is called the *myasthenic reaction*. Almost equally characteristic is the disappearance of fatigue after the muscles have been put at rest for a time.

Diagnosis.—In well-marked cases this is easy, but when the symptoms are less pronounced, there may be difficulty. Cases are often met, especially in hysterical women, who complain of inability to hold up the head, which clearly do not belong to this class. But it is to be remembered that true myasthenia gravis is something very different from hysteria. An ability to use the muscles at first, followed rapidly by an opposite state, must always be looked for, and these conditions must be applicable to the muscles of the lower extremities, as well as to those of the bulbar nerves. The absence of muscular atrophy is essential to myasthenia gravis; there is more apt to be ocular and upper face paralysis as contrasted with bulbar palsy. The myasthenic reaction should be sought. The muscles respond normally to galvanism.

Prognosis.—This is not always unfavorable, but one must not be misled by the apparent improvement succeeding rest, which is often temporary.

Treatment.—It is evident from what has been said that rest is most important. Prolonged rest and the avoidance of mental excitement, and the use of massage and mild galvanization of muscles are recommended, and even central galvanization of the spinal cord and medulla oblongata. Since faradization excites the myasthenic state, it should not be used.

The nourishment, or mode of nourishment, is most important, in view

* "Scottish Med. and Sur. Journal," May, 1901.

of the fact that the muscles of mastication and deglutition are at fault. The food, therefore, should either be liquid, or very finely minced, and unless deglutition is natural and easy, the stomach tube should be used.

The drugs recommended are the usual ones: strychnin, arsenic, phosphorus, and other tonics, but no direct results have been traced to them.

AMYOTROPHIC LATERAL SCLEROSIS.

SYNONYM.—*Charcot's Disease.*

Notwithstanding the similarity of the clinical phenomena, and, to a certain extent, of the morbid anatomy of amyotrophic lateral sclerosis to those of the so-called progressive spinal muscular atrophy, to be next considered, there appears to me sufficient difference to justify a separate consideration.

Definition.—Amyotrophic lateral sclerosis is a systemic degeneration of the pyramidal tracts of the spinal cord, with atrophy of motor cells in the anterior cornua and medulla oblongata, and consequent wasting of muscles, depending upon these cells for their trophic influence.

History.—The confusion which has long existed between this disease and progressive spinal muscular atrophy was first cleared up by Charcot and his pupil, Joffroy, who published a fairly accurate account of the disease in 1869 and a complete description in 1874. Such description became possible, however, only after Flechsig's studies of the paths of motor conduction in the spinal cord. That there are, however, certain common features in the two affections appears not only from the clinical history, but also from the morbid anatomy.

Etiology.—The causes of this condition are still essentially unknown. *Severe muscular exertion* has been assigned as a cause, as it has also of the allied affection, progressive spinal muscular atrophy. As in it, too, the *male sex* suffers most. It is a disease of *young adult* life and *middle age*, from twenty-five to forty-five. It is probably due to the degeneration of an imperfectly formed central motor system.

Morbid Anatomy.—A *sclerosis of the crossed pyramidal tracts* in the two lateral columns and the *direct pyramidal tracts* in the anterior columns is essential to the morbid anatomy in a typical case. As important is *atrophy* of the corresponding *large ganglion cells* in the anterior cornua and medulla. The degeneration has been traced in the pyramidal tracts from the sacral cord upward to the pyramids in the medulla oblongata, sometimes even through the pons and crura into the internal capsule and central convolutions, in which, too, the large ganglion cells have been found atrophied. The nerve nuclei which are affected in the medulla oblongata are especially those of the vagus and hypoglossal nerves. The motor cranial nerves are sometimes degenerated.

The changes in the motor ganglion cells of the cord and the nerve nuclei in the medulla oblongata are analogous and produce corresponding results in the *muscles* supplied by the motor nerves originating from them. These results are an atrophy present in various degrees, some fibers disappearing almost entirely, others partially. The process is by fatty metamorphosis and absorption of resulting fat, leaving a residue of connective tissue.

Symptoms.—The clinical phenomena are in strict accord with what would be expected from the pathological lesions, consisting in *muscular*

wasting and *corresponding paresis*. Before the muscular wasting appears, a *sense of fatigue* succeeding slight effort may be manifested, followed by a positive weakness, primarily almost always in the *upper extremity*, first one and finally both. This is followed by *wasting* of the muscles of the *same* extremity, usually first seen in the thenar and hypothenar eminences, the interossei and the muscles of the extensor side of the forearm, while the flexors of the hand and fingers remain longer uninvaded. The atrophy is particularly well seen in the deltoid, and to a less degree in the triceps, still less in the biceps and shoulder muscles. Usually symptoms do not appear in the lower extremities until some time after they have appeared in the upper, but occasionally the disease begins in the lower limbs.

When the lower limbs are affected, the patient tires easily in walking, the gait becomes unsteady and stiff, and rising from the chair becomes difficult. *Tremor* may appear in the legs. The paresis in both extremities is proportionate to the destruction of muscle, though first, at least, it is independent of the atrophy. Associated with muscular atrophy, sooner or later, is a *diminished electrical excitability*. Some excitability, however, remains as long as the muscles are intact, diminishing as their destruction spreads. A reaction of degeneration may also develop in the muscular fibers still intact. The excitability remains for the most part *intact* in the *nerve-trunk* because in any event a large number of fibers are preserved in their normal state.

A distinctive feature of amyotrophic lateral sclerosis is found in the *reflexes*, which, in strong contrast to progressive muscular atrophy, are *markedly increased*. Even in the early stages of the disease vigorous contractions are obtained by gently tapping the tendons of almost any of the muscles in the extremities. Always most conspicuous is the patellar reflex, while more rarely ankle clonus may be obtained. The same is true of the masseter reflex. In the arms the biceps and triceps and the flexors of the hands may be excited to strong contraction.

Contractures may take place in the later stages of the disease in the *arms and hands*, but not always. In the lower extremities, where the atrophic symptoms develop some months later and are less marked, *spastic* symptoms are a more prominent feature. The legs become rigid and some strength is required to flex them, though the muscles themselves are paretic. A typical spastic paraplegia may be produced, which is due mainly to the increase of the tendon reflexes, and a spastic paretic gait is common—that is, at first.

Later on in the disease *bulbar symptoms* may present themselves, manifested first by defects of speech, difficulty in retaining the saliva and in swallowing; and later still the lips and tongue may be seen to be atrophied, and ultimately there is difficulty in taking food, whence nutrition is impaired, and the patient gradually sinks. In some cases the disease may begin without bulbar symptoms.

Throughout, *sensibility* remains *normal* in the upper and lower extremities, and the superficial reflexes are not much altered. The *sphincters* are, as a rule, *unaffected*. Micturition is natural. Only in the event of involvement of the reflex center in the lumbar cord may there be incontinence at night when the inhibitory power is in *abeyance*. There may be constipation, but no actual paralysis of the bowel. Sexual power may be lost.

The successive involvement of the upper extremities, the lower extremities, and the bulbar centers marks quite well-defined stages of the disease.

Death comes ultimately from exhaustion, or more frequently through an inspiration pneumonia, caused by entrance of foreign matter into the air-passages as a result of defective deglutition.

Diagnosis.—The disease is distinguished from *progressive spinal muscular atrophy* by the invariable increase in the tendon reflexes, even in the early stages, as contrasted with their absence in the latter disease.

Prognosis and Treatment.—The prognosis is very unfavorable and the disease cannot be arrested. By rest in bed, massage, electricity, and hot bathing we may be able to defer the end somewhat. (See, also, Treatment of Progressive Spinal Muscular Atrophy.)

PROGRESSIVE SPINAL MUSCULAR ATROPHY.

SYNONYMS.—*Wasting Palsy; Progressive Muscular Atrophy, Type Duchenne-Aran; Duchenne-Aran's Disease; Cruveilhier's Atrophy; Chronic Anterior Poliomyelitis; Chronic Degeneration of the Motor Nuclei.*

Definition.—Progressive spinal muscular atrophy is a *progressive wasting* of more or less limited *groups of voluntary muscles*, associated with *degenerative atrophy of the corresponding portion of the motor nerve tract*, including the ganglion cells of the anterior cornua, but *unaccompanied by disease of the pyramidal tracts*. The existence of this condition has been disputed, but degeneration of the cells of the anterior horns without degeneration of the pyramidal tracts has been seen by most reliable investigators. It is well to include the word spinal in the description of this disease, as thereby the disease is distinguished from progressive muscular atrophy from other causes.

Historical.—The history of the development of our knowledge of this disease is very interesting. A few facts only can be given here. Although a number of isolated cases were described at an earlier date, Duchenne's memoir on "*Atrophie Musculaire avec Transformation Graisseuse*," published in 1849, and Aran's "*Recherches sur une Maladie non encore décidée du Système Musculaire*," published in the next year, contained the first accurate description of this malady. Cruveilhier's studies were commenced in 1832, but were not given out until 1853. All of these observers believed at first—Cruveilhier reluctantly—that the disease was purely muscular. In his third case, however, Cruveilhier found atrophy of the anterior roots of the spinal nerves, and in his fourth, lesion of the gray matter of the cord, whence the anterior roots take their origin, and first asserted the belief that the disease of the gray matter in the spinal cord was the special anatomical lesion of the disease. The researches of Lockhart Clarke in 1866 and 1867 and of Charcot in 1869 may be said to have established the spinal nature of the disease; while Friedreich in 1873 still maintained its muscular nature, and Gowers and Leyden regard it as identical with amyotrophic lateral sclerosis. Strümpell also separates the two diseases of progressive spinal muscular paralysis and amyotrophic lateral sclerosis, and it appears to me there is quite enough reason for doing so. The close relation of these two diseases cannot be disputed, but most unquestionable proof has been furnished by Dejerine and others that they are not identical.

Etiology.—In the majority of instances we fail to find a sufficient cause. *Heredity* has been regarded as playing an important rôle in its causation, but Strümpell considers the cases thus originating as instances of the juvenile myopathic variety of atrophy—that in which no nervous lesion is traceable. On the other hand, *excessive muscular exertion* seems to be more than an accidental coincidence. Exposure to cold, especially to very cold water, and the *infectious diseases*—typhoid fever, influenza, diphtheria, and syphilis—have all been held accountable, but it is likely that some of

the atrophies thus resulting include other forms than the true progressive spinal muscular atrophy.

It is a disease commonly of adult males, most supposed cases among those who are younger being probably, as held by Erb, instances of the juvenile form of muscular dystrophy, although a very rare family form of progressive spinal muscular atrophy has been observed in children.

Morbid Anatomy.—The *anterior horns of the gray matter* are wasted and reduced in size; their ganglion cells wholly or partially destroyed; the neuroglia is proliferated and is intercalated in places with spider cells. The *anterior nerve-roots* passing from the horns are *atrophied*, as are also the motor nerve filaments in the peripheral nerves. But the crossed pyramidal tracts in the lateral columns containing the crossed motor fibers descending from the brain to the cells in the anterior cornua are intact. A slight degen-

eration may be seen in some cases in the anterolateral columns about the anterior horns. The *muscles* seen to be *wasted* before death are found converted into fat and connective tissue, a remnant of true muscular tissue remaining. At times also they are the seat of waxy change, at others still, narrowed but retaining their transverse striation.

As to the *relation of the nervous changes to the muscular atrophy*, the conspicuous symptom of the disease, there is more than one possible explanation. As in bulbar palsy, according to one view, the atrophy of the anterior cornua is primary, the result of chronic poliomyelitis anterior, the degeneration of the peripheral nerves and muscles being secondary to it. According to another view, the muscular atrophy is primary, possibly due, as Friedreich sought to prove, to a myositis, followed by fatty metamorphosis of the sarcous substance and subsequent absorption of fat, or to a simple primary fatty metamorphosis. In such event it may be inferred that

the nerves atrophy from want of use. According to a third, the degeneration begins in the last terminal branches of the motor nerves and extends upward along them to the spinal cord. Finally, it is held that there may be a simultaneous degeneration of the whole motor system involved, including muscle and nerve, and nerve cell. It is more in accord with the office of the spinal cord as a nutritive center, as well as with its morbid anatomy, to suppose the disease is a chronic poliomyelitis anterior, the essential infantile paralysis of Relliet and Barthez being an acute form of the same disease. Very important is the anatomical fact that the pyramidal tracts are quite normal.

Symptoms.—One of the most striking features of the disease is its *slow development*. Like its congener, amyotrophic lateral sclerosis, it begins most frequently in the *upper* extremities, 7 out of 9 times in Aran's cases. Of the upper extremities, the right was first invaded in 37 out of 62 of Sandahl's cases, the left 14 times, while the involvement was simultaneous in 11. The disease may begin in the *lower* extremities, as shown by Friedreich's statistics, according to which these were first invaded 27 times out of 146, the upper extremities 111, the lumbar muscles in 8.

The atrophy usually begins with the short muscles of the thumb, the abductor pollicis brevis first, then the opponens and the abductor. The consequent flattening of the ball of the thumb and its persistent approximation to the second metacarpal bone produces the so-called "ape-hand." Simultaneously, or almost simultaneously, the interossei begin to waste, producing conspicuous depressions between the metacarpal bones, associated with loss of power to extend completely the terminal phalanges of the fingers. Atrophy of the lumbricales follows, producing a flattening of the hollow of the hand. The ultimate result is the characteristic *main en griffe* of Duchenne, in which the extensor tendons on the dorsum of the hand, and the flexors in the palm, become as distinct as if dissected out.

From the hand the wasting creeps up the forearm and thence to the arm, or it may skip the forearm and pass into the arm, sparing usually the triceps extensor. In the forearm the muscles on the extensor (external) side are usually first affected, then the abductor pollicis and extensor longus pollicis, and later the supinators and flexors. It may come to a standstill at either of these stages, or may involve the muscles of the shoulder, especially the deltoid, in which, indeed, it may begin, preferably in the right, passing thence to the scapular and trapezius muscles, the pectorals, the rhomboidei and latissimus dorsi, while a grotesqueness of effect is often produced by reason of certain adjacent muscles retaining their natural size or being even seemingly hypertrophied. This is particularly the case with the inferior part of the trapezius and platysma myoides, which are almost never involved. The disease may be arrested at almost any of these stages.

The lower extremities may escape altogether, and the atrophy always develops late. The small muscles of the foot would naturally be the first affected. Very rarely there may be exceptions to this rule. The muscles of the face are invaded late or not at all, but ultimately even the intercostal and abdominal muscles may be involved. The result, then, is a veritable living skeleton, instances of which are sometimes exhibited. Deformities, including lordosis or anterior curvature of the spine may result.

With all this, *sensibility* is unaffected in the vast majority of cases, but the patient may complain of a numbness and coldness of the affected limbs. Very rarely *pains* precede the wasting in the muscles, when they are some-

times regarded as rheumatic. The *galvanic and faradic irritability* of the muscles progressively diminishes and disappears with the complete destruction of the muscle, the galvanic persisting longer. The *reaction of degeneration* may, however, be elicited late in the disease in certain muscles, more especially in the modified form known as "partial reaction" of degeneration. If the disease runs a rapid course, it may occur earlier and be more typical. *Fibrillary* muscular contractions may be present, and idiopathic muscular contractions, or myoid tumors brought out by a blow, may be thus produced. The bladder and rectum remain intact, but sexual functions may be lost.

Sweating and other *vasomotor* disturbances may occur in the affected muscles, such as pemphigoid bullous eruptions, thickening and fissuring of the skin, and curving and grooving of the nails. In certain places there is an overaccumulation of fat, producing an appearance of hypertrophy when there is actual atrophy.

Along with wasting there is a corresponding *paresis*, the result of the atrophy and not its cause. The arms are flaccid and toneless and hang loosely at the sides. The patient can no longer dress himself, and various devices are resorted to in order to accomplish certain acts. Especially characteristic is one of these—when the shoulders, being first affected, the arm and forearm retain their usefulness. Under these circumstances the power of lifting the arm from the side, and especially of raising it above the head, is lost, while that of the forearm remains. Hence, if the patient wishes to lay hold of anything, he swings the arm forward with a jerk until the object is brought within reach of his fingers, when it may often be caught by the pathologically hooked terminations of these. So long as the neck muscles remain effective, objects may be grasped by the mouth.

In true progressive spinal muscular atrophy the *reflexes* are entirely absent, at least in the wasted extremities, a natural result of the atrophy of the ganglion cells in the anterior cornua and of the centrifugal motor fibers of the reflex arc. The *special senses* and the *sphincters* remain normal.

Toward the close of the disease sometimes, and then only after it has existed for a long time, the phenomena of *bulbar* paralysis may present themselves after invasion of the ganglia of the medulla oblongata. These have been detailed in the section on that subject. They are by no means always present, even in advanced cases.

Diagnosis.—Muscular atrophy is not confined to the disease under consideration. It occurs in diffuse myelitis, in tumors of the cord and when cavities are formed in its interior, in multiple neuritis, and especially in amyotrophic lateral sclerosis. From all these named, except the last, it is easily distinguished by strict attention to the conditions and order of development of the symptoms—viz., insidious and progressive atrophy of groups of muscles to the exclusion of others, beginning usually in the hand or more rarely in the shoulder and upper arm; accompanied by a corresponding loss of power in the affected muscles and partial or complete reaction of degeneration in the same, by diminished reflexes and fibrillar twitchings.

Differential Diagnosis—From *amyotrophic lateral sclerosis* it is to be distinguished by its greatly *slower course* and *absence of the reflexes* and of *spastic symptoms*. It is also to be distinguished from *muscular dystrophy* in its various forms—the myopathic juvenile muscular atrophy of Erb, pseudohypertrophic muscular paralysis, and Duchenne's infantile hereditary palsy. In the *juvenile progressive muscular atrophy of Erb* there is also

slow symmetrical, and intermittent wasting, with weakness in certain groups of muscles, especially those of the shoulder girdle and upper arm, and later possibly the pelvis, upper thigh, and back, associated at times with true or false *muscular hypertrophy*, but usually unassociated with *fibrillar* contraction or reaction of degeneration. The average age, also, in the juvenile form is much less, Erb's cases ranging from seven to forty-six and one-half, or an average of twenty-six and one-half, while in the spinal form or true progressive spinal muscular atrophy the average age is much greater. Of Roberts' cases, all of which seem to be true cases of progressive spinal muscular atrophy, the youngest was twenty, while the ages of the remaining four were thirty-eight, thirty-nine, forty-seven, and sixty-seven.

While in the *pseudohypertrophic* form there are also great weakness and wasting of muscles, though the latter may be obscured by the fatty deposit, there are *no alterations in the spinal cord*. It is a disease of childhood, and strikingly *hereditary*, beginning in the lower extremities, while progressive muscular atrophy is a disease of adults, is not hereditary, and begins usually in the upper extremities.

Duchenne's hereditary infantile atrophy is characterized by onset at an *early age*, infancy or adolescence, and by *beginning in the facial muscles*. It is often hereditary. The distribution of the atrophy is very similar to that of Erb's form, when the disease has involved the muscles of the shoulders, but it begins in the face and may be confined to the face. The muscles of the hands and fingers are spared in Duchenne's form; *fibrillar tremors* are *not present*, and there is *no reaction of degeneration*.

Prognosis.—Many years are required to develop these symptoms in their entirety, and there may be spontaneous arrest, during which the patient may die of other causes. Sooner or later, if the patient lives, they recur, and their march is irresistible.

Treatment.—It has already been said that cure is impossible, although well-authenticated cases of arrest are reported. *Mercurials* and *iodid of potassium* should be used in cases of suspected syphilitic origin. Cooke reports a case of arrest under a course of mercury, after the disease had progressed for five years, during which many remedies were tried. In the main the treatment must consist of measures intended to *maintain the health and strength* of the patient and to counteract the muscular wasting. To the former end an abundance of nutritious food, fresh air, and outdoor life should be supplied, while tonics, including, especially, cod-liver oil, iron, arsenic, and strychnin, are indicated. The muscular wasting may be combated by *electricity* and *judicious massage*. *Both kinds of electricity* may be used, the faradic with rapid interruption to stimulate the circulation, or with slow interruption to excite individual muscles to contraction. The current should be of moderate strength, not too frequently interrupted, and continued for a few minutes only. Duchenne recommended, particularly, treatment of important muscles, like the diaphragm through the phrenic nerve, or the intercostal muscles and the deltoids before they are actually invaded by the disease. In evidence of its usefulness he relates the case of a man who had lost many of his trunk muscles, and who was beginning to suffer from dyspnea, on whom faradization of the phrenic nerves, repeated three or four times a week, was of great service, enabling him to walk considerable distances and to go upstairs without fatigue. Another patient, whose arms were much wasted, was again able to support his family. The direct current—galvanism—is useful in advanced stages of the disease, when the

strongest faradic currents fail to produce response. When galvanic currents fail to excite contractions, the treatment ought to be persevered in for a long time, using very strong currents at the onset, gradually reducing them as contractility returns. Remak, who especially advocated the use of the continuous current, advised placing the positive pole in the front of one mastoid process and the negative pole on the opposite side of the neck, near the spinous process of the vertebra, not higher than the fifth cervical, by which he produced the contractions already described as diplegic in the fingers and other paralyzed parts. Galvanization of the sympathetic has been apparently useful in the hands of some, Erb reporting a case of complete cure.

Massage is especially important, and should be used in connection with electricity, but at a different time of day. Eulenberg refers to a case said to have been brought to a standstill by it.

Hypodermic injections of strychnin, from 1-100 to 1-40 grain (0.0005 to 0.002 gm.), are said to have arrested the disease on the authority of Gowers.

In families in which a hereditary tendency exists prophylactic treatment should be used. It should include hygienic measures of the kind already referred to and the avoidance of undue fatigue and exposure, and in the selection of an occupation these matters should be kept in view. On the supposition that the disease is a purely local one, gymnastics involving the exercise of the groups of muscles prone to attack are indicated, but assume less importance from the standpoint that it is a spinal cord disease. At the same time the patient should have the benefit of any doubt in the pathogeny, and as gymnastics are eminently calculated to improve the general health and thus indirectly to avert disease, their use is indicated on these grounds.

DISEASES OF THE BRAIN

LOCALIZATION OF CEREBRAL DISEASE.

SYNONYMS.—*Cerebral Localization; Relation of Locality to Symptoms; Topical Diagnosis of Cerebral Lesions.*

Physiology.—The brain is the organ of consciousness and of perception of impressions and sensations—of memory, of thought, of origination of voluntary motion, and of speech. It is also the seat of the instinctive acts. It has been learned from clinical observation in connection with studies at the autopsy table and from experiment that certain parts of the cortex are concerned with corresponding offices, especially motion, speech, vision, and hearing, so that from the presence of given symptoms the involvement of corresponding localities may be inferred. Allusion has already been made to the subject of topical diagnosis, on page 842. Such diagnosis, it is important to remember, gives no information as to the nature of the lesion, the result being the same whether it be abscess, hemorrhage, or softening. We are simply informed that such and such area is involved.

Historical.—As early as 1825 Bouillaud asserted that derangements of speech are produced only by disease of the anterior lobes of the brain. In 1836 Marc Dax, also a French physician, pointed out that aphasia was caused only by lesions in the *left* half of the brain. In 1861 Broca announced that aphasia results from a lesion of the third left frontal convolution, which was accordingly called the convolution of Broca.

We can even point out separate regions which act as separate centers for various groups of muscles. The center for the movements of the facial muscles lies at the lower end of the central convolutions, and particularly of the anterior central convolution. (Fig. 115.) Near by and lower down is the center for movements of the tongue and vocal cords, while the center for the movements of the arm lies somewhat higher than that for the face—that is, about the middle of the anterior central convolution. From above downward the various segments are represented as follows: Shoulder, elbow, wrist, fingers—the index-finger and, lowest of all, the thumb. The center for the leg lies in the uppermost part of the central convolutions, but mostly in the paracentral lobule. Most anterior is the hip, next the knee and ankle, next the great toe, the center for the movement of which surrounds the upper end of the fissure of Rolando; still further back are the centers for the small toes. The centers for the trunk are situated in the paracentral lobule in the marginal gyrus just within the longitudinal fissure. The different regions are not sharply defined, but merge into one another.

Fig. 114.—Aspect of the Median Surface of the Cerebrum as it appears when the Two Hemispheres are Separated—(after Ecker).

The gyri and fissures are indicated by the lettering.

As to the so-called *muscular sense*, it has been believed that it resides also in the motor area, while there have been those who have claimed for it also a separate and different localization. M. Allen Starr and A. J. McCosh* have reported a case of injury with symptoms which go to prove the latter view and to show that the seat of the muscular sense is “a spot in the brain about at the junction of the superior and inferior parietal convolutions, clearly posterior to the posterior central convolution.” The so-called muscular sense is probably largely represented in the parietal lobe.

These *cortical motor areas* are united with spinal centers by nerve-fibers which proceed from cell to cell in each, without connection with intervening cells. Their route is through the white matter of the hemispheres, where they form the corona radiata, the fibers of which converge to the internal capsule which lies between the optic thalamus and the caudate nucleus on

* “Amer. Jour. of the Med. Sciences,” November, 1894, p. 520.

the inside, and the lenticular nucleus on the outside. The anterior portion of the capsule—the knee—is occupied by the fibers from the face, tongue, eye, and speech centers; behind these lie the fibers from the upper extremities, while those from the lower extremities occupy the middle of the posterior part. Thence the fibers of the motor path pass into the crus cerebri through its middle third, then through the pons, covered by the superficial transverse fibers of this body, into the medulla oblongata, of which they form the anterior pyramids. At the lower portion of the medulla oblongata a large portion of these pyramidal fibers cross over into the opposite half of the spinal cord, constituting the crossed pyramidal tract of the lateral column,

Fig. 115.—Lateral Aspect of the Brain—(after v. Monakow).

Lateral aspect of the human cerebral hemisphere. Motor fields (principal foci) after Allen Starr, W. W. Keen, Charles K. Mills, Victor Horsley, and the author's observations. γ , Spot on the posterior central convoluted whose isolated irritation causes thumb movements, and whose destruction in a case of cranial injury caused continued defect of motion of the thumb and finger; also derangement of the stereognostic sense. The lines 9-9, 10-10, etc., to 20-20 indicate certain planes of section in other figures in Monakow's monograph in Nothnagel's system—(after Monakow).

while a small bundle of fibers descends into the anterior column of the same side, forming the direct pyramidal tract, or Türck's column; some fibers probably pass to the lateral column of the same side. Both pyramidal tracts diminish in bulk as they descend, because they give off fibers which pass into the gray matter, dividing and subdividing, to come into contact with the protoplasmic processes which are continuous with the large nerve-cells of the anterior cornua.

These motor fibers form the *upper or cerebrospinal segment* of the motor system. Between the motor nerve-cells in the anterior cornua and the muscles to which the motor nerve-fibers are distributed is the *lower or spino-muscular segment*. In response to the law already mentioned as to

the nutritive independence of each neuron, each of these segments has a certain nutritional independence, depending for its integrity upon the integrity of its neuron, the upper or cerebral depending upon the cortical cells and the lower upon the large cells in the anterior cornua.

Lesions of the Upper Motor or Cerebrospinal Segment.—If, therefore, the cortical cells of the motor area degenerate, the fibers attached to them will waste as far as the beginning of the lower segment, and if the cells in the latter degenerate or are cut off, not only do the nerve-fibers below them waste, but the muscles to which they are distributed as well. Accordingly, all the cases of paralysis due to *destructive* disease in the motor cortical

Fig. 116.—The Motor Tract—(after Starr).

S, S. Fissure of Sylvius. NL, NL. Lenticular nucleus. OT, OT. Optic thalamus. NC, NC. Caudate nucleus. C. Crus. P. Pons. M. Medulla. O. Olivary body. The tracts for the arm, leg, and face gather in the capsule and pass together to the lower pons, where the face fibers cross to the opposite seventh nerve nucleus, while the others pass to the lower medulla, where they partially decussate, to enter the lateral columns of the cord. The non-decussating fibers pass into the anterior median columns.

region have been found associated with descending degeneration of the motor tract previously outlined, into the *direct* pyramidal tract in the anterior column of the cord on the same side, and the *crossed* pyramidal tract in the lateral column of the other side. At the same time the paralysis is accompanied by a *spastic condition*, manifested by an exaggeration of the tendon reflexes and an increase in the tension of the muscles, ascribed to a loss of the inhibitory control exerted by the cells of the cortex in the normal state. This explanation, however, is not entirely satisfactory. In other respects the paralysis due to cortical lesion does not differ from that due to focal disease lower down in the upper tract, except that the latter is apt to involve more muscles because of the compactness of the tract at this point. Atrophy has been observed in muscles paralyzed by disease of the upper segment, but

the reaction of degeneration does not occur. Lesions of the cortex are usually limited, causing correspondingly limited paralysis and even monoplegias, never, however, affecting less than a whole limb or a segment of a limb. A lesion may involve two centers lying close to each other, producing paralysis of the face and arm or of the arm and leg, but rarely of the face and leg without involvement of the arm. It may happen that the whole cortex is involved, producing paralysis of one side—cortical hemiplegia.

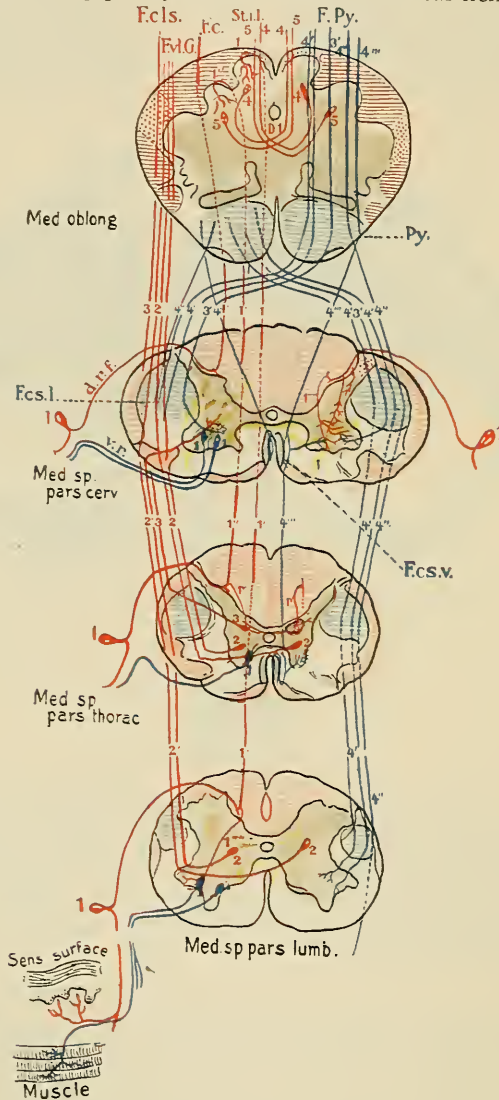

Fig. 117.—Sensory and Motor Paths in the Spinal Cord—(after Barker).

DESCRIPTION OF FIG. 117.

Black.—*Med. oblong.*, transverse section through the medulla oblongata at the level of the decussatio lemniscorum; *Med. sp. pars cerv.*, transverse section through the medulla spinalis pars cervicalis; *Med. sp. pars lumb.*, transverse section through the medulla spinalis pars lumbalis; *Med. sp. pars thorac.*, transverse section through the medulla spinalis pars thoracalis; *sens. surface*, sensory surface.

Red.—The areas of white matter in the spinal cord and medulla oblongata occupied by sensory axons are indicated by red lines or dots. The cell bodies and axons of sensory neurons are also colored red. *D. l.*, decussatio lemniscorum; *D. r. f.*, dorsal root fiber (central axon of peripheral centripetal neuron); *F. c.*, axon of fasciculus cuneatus; *F. cls.*, axon of fasciculus cerebellospinalis (direct cerebellar tract); *F. vl. G.*, axon of fasciculus ventrolateralis [Gowersi]; *St. z. l.*, axons of stratum interolivare lemnisci; *1*, cell bodies of peripheral centripetal neurons (situated in the spinal ganglia); *1'*, ascending limb of bifurcated central axon of peripheral sensory neuron extending from the pars lumbalis of the spinal cord to the medulla oblongata, being situated first in the fasciculus cuneatus, in higher levels of the cord in the fasciculus gracilis, and finally terminating in the nucleus funiculi gracilis. *1''*, ascending limb of bifurcated central axon of peripheral sensory neuron pertaining to the thoracic portion of the spinal cord. It enters the fasciculus cuneatus, and passing upward, approaches the medial border of this fasciculus without, however, entering the fasciculus gracilis. It is seen to terminate ultimately in the nucleus funiculi cuneati. *1'''*, ascending limb of bifurcated central axon of peripheral sensory neuron pertaining to the pars cervicalis of the spinal cord. It passes upward in the fasciculus cuneatus to terminate at a level higher than that indicated in the diagram. *1''''*, reflex collaterals extending from the central axons (or their subdivisions) of the peripheral sensory neurons to the ventral horns of the spinal cord, there coming into conduction relation with the cell bodies and dendrites of the lower motor neurons. *1*, collaterals from the axons of the fasciculus cuneatus to the nucleus dorsalis [Clarkii]; *2*, cell bodies in substantia grisea giving rise to axons of the fasciculus ventrolateralis [Gowersi]; *2'*, axons of fasciculus ventrolateralis [Gowersi]; *3*, cell body in nucleus dorsalis [Clarkii] giving rise to axon of fasciculus cerebellospinalis; *3'*, axon of fasciculus cerebellospinalis (direct cerebellar tract); *4*, cells of nucleus funiculi gracilis giving rise to axons of fibræ arcuatæ internæ which undergo decussation (decussatio lemniscorum) in the raphe; *4'*, continuation of axons of fibræ arcuatæ internæ after decussation. They run cerebralward in the stratum interolivare lemnisci. *5*, cells of nucleus funiculi cuneati which give rise to axons of fibræ arcuatæ internæ which undergo decussation (decussatio lemniscorum) in the raphe. *5'*, continuation of axons of fibræ arcuatæ internæ after decussation. Having had their origin in the nucleus funiculi cuneati of the opposite side, they now run forward in the stratum interolivare lemnisci.

Blue.—The areas of white matter in the spinal cord and medulla oblongata indicated by parallel blue lines correspond to the position of the fasciculi cerebrospinales (pyramidales). The cell bodies and axons of the lower motor neurons are also printed in blue. *F. cs. l.*, fasciculus cerebrospinalis lateralis or lateral pyramidal tract; *F. cs. v.*, fasciculus cerebrospinalis ventralis or ventral pyramidal tract; *F. Py.*, fasciculi pyramidales in the medulla oblongata; *Py.*, pyramis medullæ oblongatæ; *v. r.*, radix ventralis, nervi spinalis; *1*, cell bodies of lower motor neurons situated in the ventral horns of the gray matter of the spinal cord giving off axons which go to form the ventral roots of the spinal nerves; *3'*, axons of fasciculi pyramidales which undergo decussation in the decussatio pyramidum and pass down in the fasciculus cerebrospinalis lateralis of the opposite side of the spinal cord to terminate in the ventral horns of the cervical region. They throw the lower motor neurons which innervate the musculature of the upper extremity of one side under the influence of the pallium of the opposite side. *4'*, axons of fasciculi pyramidales which undergo decussation in the decussatio pyramidum and pass down in the fasciculus cerebrospinalis lateralis of the opposite side of the spinal cord to terminate in the ventral horns of the lumbosacral region. They throw the lower motor neurons which innervate the musculature of the lower extremity of one side of the body under the influence of the pallium of the opposite side. *4''*, axon of fasciculi pyramidales which does not undergo decussation in the decussatio pyramidum, but passes down in the fasciculus cerebrospinalis lateralis of the same side (homolateral fiber). *4'''*, axon of fasciculi pyramidales which does not undergo decussation in the decussatio pyramidum, but passes down in the fasciculus cerebrospinalis ventralis to terminate in the ventral horn of the same side. It would throw the lower motor neurons governing a portion of the musculature of one side under the influence of the pallium of the same side. It is probable that in addition to these fibers of the fasciculus cerebrospinalis ventralis, which terminate in the ventral horn of the same side, there are other fibers (not shown in the diagram) which, passing through the ventral commissure, terminate in the ventral horn of the opposite side. (See text.)

Yellow.—Cell bodies, axons, collaterals, and terminals belonging to the fasciculi proprii of the ventral and lateral funiculj—(Barker).

Such is the effect of destructive or negative lesion of the cortex. Quite different is that of *irritative* lesions. These produce convulsive seizures

known as Jacksonian or cortical epilepsy, characterized by convulsions beginning in a single muscle or group of muscles and proceeding in a definite order to the involvement of other muscles corresponding to portions of the cortex affected. Thus, the convulsions may begin in the face, and extend thence to the arm and thence to the leg. The convulsions may also be accompanied by sensory symptoms and followed by weakness of the muscles involved.

In point of fact most lesions of the cortex are both destructive and irritative, consisting in the destruction of nerve-cells in one center and increasing the activity of cells of neighboring centers.

Lesions of the upper segment include hemorrhages, tumors, abscesses, injuries, inflammations, and degenerations involving the brain and spinal cord.

Lesions of the Lower or Spinomuscular Segment.—Here, as in the upper segment, the *destructive* lesions produce motor paralysis. The added peculiarity is, however, a degeneration of the muscles as well as the nerve-fibers distributed to them from the motor cells of the anterior cornua, as evidenced by the wasting of the muscles, and further characterized by the presence of the reaction of degeneration described on page 857. In these lesions there is also a loss of reflex excitability in the areas supplied from the segments destroyed, the reflexes are lost, and there is reduced muscular tension. Lesions of the lower segment may also cause paralysis of limited groups of muscles when confined to limited areas of the cord.

Irritative lesions of the lower segment do not occur unless we regard as the result of such the slow atrophy of the ganglion cells of the anterior cornua in progressive spinal muscular atrophy, and consider the fibrillary contractions found in this affection as a result of the stimulation of these cells in their slow degeneration.

II. SENSORY AREAS OF THE CORTEX AND SENSORY PATHS.

Our knowledge of the sensory areas is much less definite than that of the motor. Beginning at the periphery, we learn that sensory fibers emanating from tactile surfaces, like the skin, promptly and for the most part become associated with motor nerve filaments in the lower motor segment, the union of both constituting a mixed nerve. The two sets of fibers, however, separate again within the spinal canal, the motor filaments are continuous with the anterior roots, and the sensory enter the cord by the posterior, on which is a ganglion. The areas whence the posterior roots gather their nerves will be found in Starr's table on page 979. The precise routes of sensory impressions to the brain are not determined, but experiment and clinical pathology show that probably a considerable number of sensory fibers cross at once and ascend to the brain in the opposite half of the cord. The following seems to be the results of the latest histological studies:

The sensory nerve-fibers, entering the spinal cord from the spinal ganglion on the posterior root, pass to the posterior columns and divide dichotomously, one branch passing upward, the other downward. From these longitudinal branches arise short transverse branches which penetrate the gray matter and end in the tufts or arborizations which characterize the *distributary* ends of nerve filaments. These tufts or arborizations in which the

sensory fiber ends in the gray matter are apparently in close contact, but possibly not in direct anatomical relation with the ganglion cells in the anterior and posterior horns and in Clarke's column. From these ganglion cells other nerve-fibers are projected, the course of which is not clear except as to those which pass into the anterior roots, and those from Clarke's column which pass over to form the ascending cerebellar tract. Some pass up the anterolateral columns, some decussate through the gray commissure with fibers from the opposite side. Many fibers from the posterior roots ascend in the posterior columns of the same side and decussate in the medulla oblongata to form the fillet or lemniscus. Further confirmation of this course is found in the fact that if a posterior nerve-root is cut, the ascending Wallerian degeneration is seen only in the posterior columns of the same side, and ceases in the nuclei of the *funiculus gracilis* and *funiculus cuneatus*, which are ganglionic bodies in the medulla oblongata beginning another stage of the sensory path. It is questionable whether there are separate strands of conduction for tactile, thermal, or painful impressions. The experiments of Gotch, Horsley, and Mott also go to show that mild sensory impressions pass up the same side in the posterior columns, while impressions made by pain, cold, and heat radiate into the gray matter of the cord, and through these probably again into the white conducting tracts of the lateral and, possibly, opposite posterior column. Hence pain and painful temperature sensations are only of different degrees, and excite a wider and more complex nervous mechanism than simple touch. Whence not only diseases involving extensively the gray matter, as syringomyelia, cause alteration in the temperature sense, but also diseases of peripheral parts, as pachymeningitis and neuritis. Many hold very different views from those just expressed and believe that different fibers exist for the conduction of the different forms of sensation.

Many investigators believe that all the sensory fibers of the opposite side of the body are collected in the posterior third of the posterior limb of the internal capsule, just behind the motor fibers of the upper segment. Dejerine utterly rejects this teaching, and holds that the sensory fibers are mingled with the motor in the posterior limbs of the internal capsule.

Much doubt exists as to the seat of the sensory areas in the cortex. Horsley suggested that the muscular and tactile senses are localized in the motor cortex, and that two of the three principal layers of cells in this region subserve these functions. The late experimental studies of Munk lead to the same conclusions—that the so-called "sphere of sensation" lies in the same region as the motor centers of the cortex. Dana also has shown that many lesions of the motor area, especially in the hinder part, are associated with anesthesia, while Ferrier considers the hippocampal convolution, and Schäfer the gyrus fornicatus, as the sensory center in the cortex. Clinical evidence on this point is not uniform. In some cases of motor paralysis there is undoubted simultaneous disturbance of sensation, in others not. By some the parietal lobe is considered an important part of the sensory area. The muscular sense is also sometimes impaired in paralyzed limbs, in consequence of which the patient cannot tell with his eyes closed the position of the affected limb.

Among the cortical areas covering sensation must be included those for sight, hearing, smell, and taste, which will be considered in connection with affections of the peripheral nerve. Suffice it to say, briefly, that the auditory center is located in the first temporal gyrus, the visual in the occipital lobe, the cortical visual center being on the mesial surface in the

cuneus, especially about the calcarine ("calcar," a spur) fissure, where are represented the opposite half visual fields.

LESIONS OF THE SENSORY TRACT.—These may also be *destructive* or *irritative*. *Destructive lesions* would, of course, destroy sensation in the part whence the nervous supply comes to the point of lesion. Most frequently it is an injury to a peripheral nerve, though loss of sensation is rarely complete in the part to which such nerve is distributed, because that area may receive sensory nerves from another segment of the spinal cord. Complete transverse section of the spinal cord itself causes complete anesthesia in the parts supplied from the segment below the injury. The effects of a lesion invading one-half of the cord are detailed on page 895.

Irritative lesions of the sensory path cause paresthesias, including formication, tingling, numbness, and finally pain corresponding to the degree of irritation. The last is commonly due to irritation in the course of a peripheral nerve, though it may also be caused by irritation to the sensory path within the central nervous system.

CORTICAL AREAS COVERING SPEECH.

THE VARIOUS FORMS OF APHASIA AND THEIR ANATOMICAL LESIONS.

It has already been stated that almost our first accurate knowledge of cerebral localization was the discovery by Broca, in 1861, that derangements of speech result from lesions of the third or inferior left frontal convolution. The loss of power to comprehend words correctly and to use them properly is covered by the general term *aphasia*. Further derangement consists in inability to articulate words, and is due to lesions of nuclei situated for the most part in the pons and medulla oblongata, regulating the action of the vocal cords, the tongue, and the lips, and is known as *anarthria* or *dysarthria*.

The study of the phenomena of aphasia will be facilitated by a brief review of the conditions of acquired language. Language is acquired by the child gradually through imitation. Thus, when the mother teaches it to say "cat" or "bell" or "papa," she names the word, and its sound impresses the distribution of the auditory nerve, *m* (see diagram, p. 118) whence it passes to the *acoustic* center, *x*, and thence to the sensory *speech* center, *a*, in the first or *upper temporal* convolution, where it is stored as a sound memory. From this it passes from behind forward along the association fibers to *b*, the motor speech center in the left inferior *frontal* convolution (Broca's center, propositionizing center of Broadbent),* whence the muscles of articulation are put into operation and the word is spoken. Thus, the speech mechanism consists of *receptive*, *perceptive*, and *emissive* centers.

The development of *voluntary* speech in the child continues through the accumulation of associated ideas in the perceptive and emissive centers, *a* and *b*. The *word image* or picture which is the foundation of every word is made up of the sum of a number of partial conceptions of memory pictures acquired by experience and stored for further use in the different sensory areas of the cerebral cortex. Thus, the memory of the *sound* of a

* That is, the center where thoughts are set in a framework of words, but through which utterance is not consummated; whence other cortical centers are necessary to motor speech, and these are found caudad of Broca's convolutions at the foot of the two central convolutions. This region Broadbent calls the *uttering center*.

word as spoken, the memory of the *appearance* of a word as written or printed, as well as the *muscular movements* needed to speak the word or write it, are distinct from one another and yet associated. Loss of one of these memory pictures or derangement in their association impairs the integrity of the word image and produces such defects in the use of the word as are covered by the different varieties of aphasia. These derangements have been arranged in two divisions, according as the defect is in (1) the receptive and perceptive and (2) emissive function of the brain, the former constituting the *sensory* aphasias, the latter the *motor*.

THE PHYSICAL BASIS OF THOUGHT—APRAXIA.

A *word* is a means of expression of a thought. Thus, when we say the word "bell," with a full conception of its meaning, such conception or mental picture is made up of as many distinct partial conceptions or memory pictures as there are special senses, these conceptions being seated in the most diverse parts of the brain. Especially concerned in the case of the bell is the acoustic conception, *c*, derived from its sound; the optic, *c'* from its appearance; the tactile, *c''* from what is learned by touch, united to form one conception, as shown in Figure 119, where the partial conceptions, *c*, *c'*, *c''* among others, taken together, give us the idea of a bell. In the blind, of course, the sensory perceptions are smell, taste,

Fig. 118.—Primitive Speech Apparatus of the Child in Mechanical Repetition of Words, according to Wernicke and Lichtheim.

a. Sensory speech center. *b.* Motor speech center. *x.* Acoustic center of pure sense of hearing. *m-x.* Route to acoustic center. *b-n.* Motor speech tract.

touch, and hearing only. The schema of conscious voluntary speech may be still further simplified by combining the partial conceptions, *c*, *c'* and *c''* into one single point, *C* (Fig. 120), as the sum of intellectual concepts, *m* representing any of the special senses—hearing, vision, smell, etc.

Broadbent has gone a step further, and suggested the existence of a center on the sensory side of the nervous system, to which converge sensory fibers from all the receptive centers and in which is combined all the

evidence respecting the nature of the object, which he called the *naming center*. He suggested a locality for this center in an unnamed lobule on the under surface of the temporal lobe near its junction with the occipital lobe. Charles K. Mills* has recently reported a case of glioma with autopsy which goes to confirm Broadbent's speculation and to locate the exact position of this center in the third temporal convolution. Its correlative center is the *propositionizing center* referred to on page 972, in which names or nouns are set in a framework for outward expression or utterance.

The loss of these memory pictures is known as *apraxia*, which may be defined as a state in which there is impairment or loss of the power to

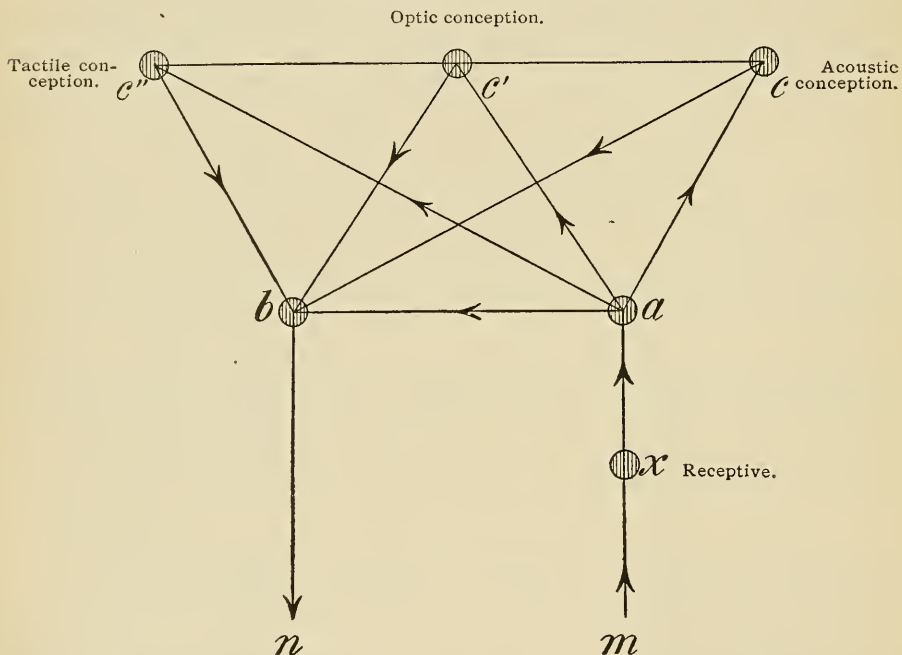

Fig. 110.—Wernicke's Schema, Showing the Association of the Various Partial Conceptions to Form the Whole Conception or Word Image of an Object.

For the sake of simplicity only three partial conceptions and three sensory areas are shown, instead of the many which go to make up our notions of complex objects.

The letters *a*, *b*, *m*, and *n* have the same application as in the previous figure, but *x* may indicate the seat of any of the special senses—hearing, vision, smell, touch.

recognize the nature and purpose of objects, and which is something apart from aphasia. In one form of it any object, such as a watch, a knife, or a spoon, may be taken up and handled by the patient, but all knowledge of its use or purpose is gone. Such a condition, when dependent on loss of the visual memories, was well named by Munk *mind-blindness*. A person formerly familiar with the tick of a watch or the sound of a bell no longer interprets such sounds aright; or is unable to follow melodies or appreciate music as he once did. Thus we have *mind-deafness*, or auditory amnesia, or in the case of music, *amusia*. Again, the odor of the rose and violet no longer suggests these flowers, giving *mind anosmia*; or the

*Dercum, "Diseases of the Nervous System" by American authors, 1895, p. 427.

taste of an orange, *mind ageusia*; or the soft feel of fur or velvet gives no notion of these substances, *mind atactilia*. For the sum of these defects the term *apraxia* is now used, but mind-blindness and mind-deafness are the most important subvarieties. Apraxia may occur alone, but it is usually associated with sensory or motor aphasia. In simple apraxia the patient may be able to read, but the words arouse no intelligent impression in his mind. Some observations go to show that the lesion in mind-blindness is in the *supramarginal and angular gyri*, or in the tracts posterior to these in the white matter beneath them; and possibly mind-blindness only occurs when this area in each hemisphere is injured, as pointed out by M. Allen Starr, in the left hemisphere in right-handed persons, and in the right hemisphere in those left-handed. Mind-blindness is, however, at times functional and transitory, and as such associated with many forms of mental disturbance. Starr also considers it probable from the association of psychical or *mind-*

Fig. 120.—Simplification of the Schema of Voluntary Speech by Uniting the Ideas into the point, C, and Omitting the Acoustic Center, x.

The letters have the same meaning as in Figures 118 and 119.

deafness with the form of aphasia known as *word-deafness*, to be considered presently, that mind-deafness may be due to lesion in the upper temporal convolution, though autopsies are wanting.

There are as many varieties of apraxia as there are organs of sense, but the most common appears to be psychical or mind-blindness, generally associated with the form of aphasia known as *word-blindness*.

APHASIA, OR LOSS OF THE FACULTY OF SPEECH.

Aphasia is sensory or motor according as it is caused by a loss of memory of words, or by an inability to enunciate,—according as it is the receptive or the emissive center which is at fault.

Sensory Aphasia. including **Word-blindness, Word-deafness, Amnesic Aphasia.**—By *word-blindness* is meant loss of the memory of the appearance of a word. In this condition the patient does not recognize words which he sees on the written or printed page, and although he may be able to pronounce them after hearing them or write them at dictation or copy them, he does not understand what he reads or writes. On the other hand, *figures* are sometimes recalled when words are forgotten, and the patient may even be able to solve mathematical problems and to recognize playing-cards. Word-blindness may occur alone or with *motor aphasia*. The lesion in most cases of word-blindness has been in the *angular* and *supramarginal gyri* on the left side, as located by Ferrier, but this area is not believed by all to be the center for word-seeing. *Alexia*, or inability to read, is a corollary growing out of this, as is also *agraphia*, or inability to write, so far as it depends on sight. It is often associated, as already stated, with *mind-blindness*, but may occur independently of it.

Word-deafness is a condition in which the patient has forgotten the significance of spoken words, although he hears them as sounds. The words

Fig. 121.—Situations of Lesions Causing Aphasia—(after Starr).

1. Lesion of word-deafness and deafness for musical sounds, according to M. Allen Starr. 2. Lesion of word-blindness, according to Ferrier. 3. Lesion of motor aphasia. 4. Supposed lesion of agraphia. F^1 . First frontal convolution. F^2 . Second frontal. F^3 . Third frontal. T^1 . First temporal. T^2 . Second temporal. T^3 . Third temporal. P^1 . First parietal. P^2 . Second parietal.

of his own language are as a foreign tongue which he does not understand, while there is deafness also to musical sounds—*amusia*, the “*Tontaubheit*” of the Germans. Word-deafness is commonly associated with other forms of sensory aphasia in various degrees, but cases of pure word-deafness occur in which the patient has been able to read and to speak, but is unable to recognize the meaning of a word when spoken. It is a rare variety of deafness whose *lesion* is placed by most students of the subject in the first *temporal convolution* or its posterior part, but Starr, basing his conclusion on fifty cases which he has collected with autopsies, places it, with Seppilli, in the *posterior half* of both the *first* and *second temporal* convulsions of the left side in right-handed persons, and of the right side in left-handed persons, as shown in the drawing.

A simple variety of sensory aphasia is *amnesic aphasia*, in which the patient simply forgets words—just as we are all, at times, at loss for a word. Such a person sees a dog or another animal, knows perfectly well what it is, but cannot recall its name. The moment, however, the word “dog” is suggested, he knows all about it. In disease usually a number of

words are thus lost. Such aphasia is called *amnesic*, because it is really a loss of memory for words. It may be partial, as when a patient forgets nothing but his own name and remembers all other words, or when he is able to express himself in another tongue. If permanent, it is probably due to a *break in the association tract*, to be later considered, and should be so limited. Word-deafness may be distinguished from amnesic aphasia by asking the patient to do some act, such as to touch an object, when he will respond correctly if he has simple amnesic aphasia, but will not if he is the subject of word-deafness.

Allied to amnesic aphasia is sensory or *amnesic agraphia*, in which a word cannot be written because it cannot be called to mind. A person thus affected may be unable to write voluntarily, but may be able to write at dictation if he is one who writes much. As already mentioned, agraphia also occurs as a part of word-blindness so far as it depends on sight.

MOTOR OR ATAXIC APHASIA OR APHEMIA—ALALIA.—In this condition the memory of the muscular action necessary to transfer the word image

Fig. 122.—The Left Hemisphere, with the Fissure of Sylvius Drawn Apart in Order to Show the Convolutions in the Island of Reil or 5th Lobe. The Island of Reil is covered in by the *pars opercularis* or posterior part of Broca's convolution, which is here drawn aside—(after Henle).

into speech is lost. There is disturbance of the emissive center, *b*, in which this transfer takes place. The patient knows perfectly well what he wishes to say, but cannot say it, though he may make the greatest effort to do so. Nor can he repeat a word after hearing it. The degree varies greatly. In complete cases he may be able to read, though not aloud, and understand what is said, but cannot say a word himself. More commonly, he can say one or two words, such as "no," "yes," while in mild cases he may simply misplace or omit letters, say "widow" instead of "window," or "wrestlers" instead of "wrestles." Singularly, too, when in a passion he may be able to say the right word or to swear. This is because such words are uttered, to a certain degree, involuntarily. A man acquainted

with the French and German languages may lose the power of expressing his thoughts in them while retaining his mother tongue, and if completely aphasic, he may recover one language before the other. This is the form of aphasia long ago recognized by Broca and localized by him in the third left frontal convolution, and since this is in contact with the center for the face and arm, there is not infrequently partial or complete *right-sided hemiplegia*. *Alexia*, or inability to read aloud, is a necessary corollary to motor aphasia so far as it depends on the power to speak.

Paraphasia, or *mixed aphasia*, and *monophasia* are allied to motor or ataxic aphasia. Paraphasia is a confounding of words, the wrong word being used instead of the right one, because of a confusion between the idea and the proper word. All degrees of this also occur, only a single word being sometimes erroneously used, while in others whole sentences are wrong. The patient may also use a wrong word which has a certain resemblance to the correct one, beginning, for example, with the same syllable, as "between" for "bewitch"; or the idea usurps the situation, as in the case of one of Strümpell's patients, who called a white handkerchief "snow." In these cases the *association* or *conduction tract* between the *perceptive* center and the *emissive* center is broken (see in Fig. 114), whence it was called by Wernicke *aphasia of conduction*. The lesion in paraphasia is usually in the island of Reil and in the convolutions which unite the frontal and temporal lobes. But any disturbance in the association processes of language, no matter where the break lies, may cause it. In *monophasia* the patient can command but one syllable or one word or a short phrase, which he repeats over and over again.

Motor agraphia must also be distinguished from sensory. Sensory agraphia is sometimes amnesic—that is, the patient cannot write the word because he cannot call it to mind; at others it is a part of word-blindness. Motor agraphia is quite independent of ability to read aloud—that is, of effort memories necessary to speech, the difficulty being connected with the movements of the hand; but when motor aphasia exists, motor agraphia is usually also present. In sensory agraphia he may still be able to write by dictation, in the latter not. Agraphia also varies greatly in degree. The patient may write one or two letters, or he may be totally unable to write voluntarily or from dictation. The seat of the *lesion* of motor agraphia is still unsettled. It was located by Charcot in the neighborhood of the middle of the anterior central *convolution*, but recent studies by Victor Horsley furnish some ground for locating it in the *posterior central (ascending parietal)* convolution. Both Charcot and Horsley therefore placed it in the motor area. According to some authorities the graphic center is located in the second frontal convolution of the left side, near the ascending frontal convolution. Starr locates it in the middle of the convolution (see Fig. 121). *Paragraphia* is a condition in which one word is written when another is intended. It is a corollary to paraphasia.

Aminia is the loss or impairment of the power of expression by signs when caused by cerebral disease. *Paraminia*, the misuse of signs in the attempt to express thought, is comparable to paraphasia for speech and paralexia for reading, and is dependent on a like cause—the *destruction or impairment of commissural or association tracts between sensory and motor centers*. It is not correct to suppose that the aphasic can substitute signs for words and thus express himself, for the two defects go hand in hand, even though he retain the power of moving his hands. A patient may,

however, regain pantomimic power before he regains speech. Loss of pantomimic power is found often associated with *destruction of the third left frontal convolution*, or destruction of the receptive speech centers or their connecting tracts. It may accompany verbal amnesia due to disease of these areas or disturbance of the association tracts. Just as the aphasic may say "yes" when he means "no," so he may use a sign which will be affirmative when he intends to be negative.

The following table may aid somewhat a review of the previous text, while Fig. 121, from Starr's book of "Familiar Forms of Nervous Disease," shows the situation of the lesions causing aphasia:

APRAXIA, inability to recognize the nature and purpose of an object.

Mind-blindness.

Seat of Lesion.

Supramarginal and angular gyri, or the white matter beneath, in the left hemisphere in the right-handed and right hemisphere in the left-handed.

Mind-deafness, including amusia, or auditory amnesia.

Upper temporal gyrus of left hemisphere in the right-handed.

Mind atactilia.

Gyrus fornicatus, hippocampal gyrus, præcuneus, and post-parietal (Mills).

Mind anosmia.

Uncinate gyrus (Ferrier) and hippocampal gyrus.

Mind ageusia.

Temporal gyrus (Ferrier).

APHASIA, inability to comprehend words correctly and to use them properly.

Sensory aphasia, inability to recognize word pictures and word sounds, loss of memory of word pictures and word sounds.

Word-blindness, in which memory of the appearance of a word is lost.

Angular and supramarginal gyri.

Word-deafness, in which memory of the sound of a word is lost.

Posterior part of first and second temporal gyri (Seppilli and Starr).

Amnesia, inability to recall a word.

Disturbance of association tract.

Motor aphasia, inability to utter words, though knowing well what to say.

Including *alexia*, or inability to read aloud.

Posterior part of third left frontal (Broca's convolution).

Paraphasia.

A confounding of words in speaking, in which the wrong word is used instead of the right one.

Island of Reil and any disturbance of the association tracts.

Amimia.

Loss of power of expression by signs.

Third left frontal convolution, receiving or concept center. Disturbance of association tracts.

Paramimia.

Misuse of signs to express thought.

AGRAPHIA, inability to write.

Sensory Agraphia.

Inability to write because (a) of want of idea as to what a word is or (b) looks like.

(a) Amnesic agraphia.
(b) A part of word-blindness.

Seat.

Association tract.
Angular and supramarginal gyri.

Motor Agraphia.

Inability to write because of want of motor power of writing, although the other movements of the hand may be excellent.

Not settled, but possibly middle of the ascending frontal convolution or ascending parietal — *i. e.*, in the arm center. Possibly posterior part of second left frontal convolution.

Availing ourselves of Wernicke's condensed schema (Fig. 120), most aphasic derangements met in practice are easily explained by it by supposing lesion and interruption of conduction in certain places. According as

the centripetal conduction m , a , C , or the centrifugal conduction, C , b , n , is interrupted we have sensory or motor aphasia, while the interruption of the line, a , b , produces the conduction aphasia of Wernicke. Lesions between a and b on the one hand and C on the other are called *transcortical*

Fig. 123.—Simplification of the Schema of Conscious Speech by Reduction of the Ideas to the Point, C , and Omission of the Acoustic Center, x . The letters have the same application as in previous figures.

aphasias; between a and b , *cortical*, and between a and b on the one hand and the periphery on the other, *subcortical*. These distinctions are schematic.

DERANGEMENTS OF SPEECH OF IRRITATIVE ORIGIN.

In addition to those due to direct lesion of the speech centers there are also derangements of speech due to irritation. Such are the different kinds of stuttering, the labio-choreic and gutturo-tetanic stuttering and choreic speech. The first two probably reside in the cortical speech centers, but the choreic spasms not necessarily, since the function of muscles concerned in their production may be disturbed from lesions in other centers as well.

Diagnosis.—The study of derangements of speech is by no means an easy matter, but it may be facilitated by pursuing a systematic method like the following, which is that of Starr, slightly modified:

- | | | | |
|----|---|---|--|
| A. | To determine whether apraxia is present. | { | (1) Test the power of recognizing the nature, uses, and relations of objects. |
| B. | To test integrity of the auditory speech area and association tracts between other sensory areas and the temporal convolutions. | { | (1) The power to recall the spoken name of objects seen, heard, handled.
(2) The power to understand speech and musical sounds.
(3) The power to call to mind objects named. |

- | | | |
|---|---|---|
| C. To test the condition of the visual word memories in the angular gyrus and of the connections between this area and the surrounding sensory and motor areas. | } | (1) The power to understand printed or written words.
(2) The power to read aloud and understand what is read.
(3) The power to recall objects whose names are seen.
(4) The power to write spontaneously and to write the names of objects seen, heard, etc.
(5) The power to copy and write at dictation.
(6) The power to read understandingly what has been written. |
| D. To test the integrity of Broca's center and its association tracts. | } | (1) The power to speak voluntarily; and if it is lost, the character of its defects.
(2) The power of repeating words one after another. |

When aphasia is associated, as is so often the case, with paralysis of the right arm, the writing test may be made with the left hand, when the patient may produce the so-called aphasic mirror writing, which can only be read by the use of a mirror; or if he cannot write with the left hand, as also happens, he may be asked to form words by letters cut out of printed pages, or with the letter blocks of children.

Prognosis and Treatment.—Aphasia is a symptom of a disease and not a disease itself. Yet it is a symptom which in its various phases informs us so precisely of the seat of the lesion that it sometimes suggests a point of operative interference comparatively easy of access. Where the symptoms of diffuse cerebral disease are wanting, and where the continuation of the symptoms and the addition of others suggest the presence of a possible circumscribed cause, such as abscess or tumor, operation is justified, and by it not only cortical, but also subcortical lesions and abscesses have been relieved. In cases of *sensory aphasia* the trephine should be applied over the upper parts of the *temporoparietal region*, in *word-deafness* over the posterior part of the first *temporal*, in *word-blindness* over the *angular gyrus*, in *word-deafness* and *word-blindness* combined over the *inferior parietal* and *first temporal gyrus*, especially if verbal amnesia be present. In purely *motor aphasia*, in which the understanding of language is preserved but the power of talking lost, the trephine should be applied over the posterior part of the *third frontal convolution*, or Broca's center. The lesion of simple *agraphia* is not sufficiently determined to warrant surgical interference.

When urgent symptoms do not exist, attempt should be made to re-educate the patient, and much may be accomplished in this way by perseverance, especially in the young. With adults, the prognosis is more unfavorable, especially in cases of complete motor aphasia associated with right hemiplegia. In them the patient may be taught to write with his left hand: *Sensory aphasia*, if it exist alone, is commonly transient.

CORTICAL AREAS WHOSE FUNCTION IS UNKNOWN OR UNCERTAIN.

After subtracting the motor, visual, and speech areas of the two hemispheres there remain extensive cortical areas, to which, as yet, no definite function can be assigned, and which are unexcitable. They include:

1. *The Frontal Region, Including all the Frontal Convolutions except the Posterior Half of the Third Frontal on the Left Side.*—Of this area the most that can be said is that, if injured, mental symptoms are quite likely to

be prominent—symptoms ascribable to a loss of self-control. It is to the greater development of the region of the frontal lobes in man as compared with the lower animals that his higher mental qualities are ascribed. Various forms and degrees of dementia have been observed after such lesions, and when such mental symptoms are present, it may with reason be inferred that there is lesion of the frontal lobes, especially of the left frontal lobe according to some investigators, more particularly when lesion elsewhere can be excluded. It should never be forgotten, however, that the intellectual development depends on the integrity of the entire brain.

2. *The Region of the Cortex Lying between the Ascending Parietal Convolution and the Occipital Convolution, Including all the Parietal Convolution except the Left Inferior Parietal Lobule.*—In these, it was at one time thought, might lie the centers of tactile sense, but the tendency at present is to make the sensory and motor areas of the cortex the same, although the sensory area is probably more extensive than the motor, since lesions of the posterior central convolution are found associated with anesthesia in the paralyzed part, and because the centers for the parts in which sensation is most acute—namely, thumb, fingers, and hand, toes and feet—lie in this region. The so-called muscular sense is, however, probably largely represented in this area.

3. *The Region Covering the Entire Temporosphenoïdal Lobe on the Right Side except the First Temporal, which probably has to do with hearing of ordinary sounds, and the temporosphenoïdal on the left side, excluding the parts not concerned in hearing of words, as well as ordinary sounds.* To the first temporal gyrus the function of hearing is assigned, but the remainder, so far as the cortex is concerned, appears unexcitable. Abscesses are common here after otitis media, and are sometimes reached with the trephine, the diagnosis being based on the presence of otitis with symptoms of brain disease.

4. *The Apex of the Temporosphenoïdal Lobe, including the uncinat convolution.* To this the olfactory sense has been ascribed with some show of reason.

5. *Of the Entire Median Surface of the Hemispheres, except the paracentral lobule, which is motor, and the cuneus, which is visual, and including the gyrus fornicatus and the hippocampal cortex, the function is unknown, although the hippocampal is probably a part of the olfactory area.*

TRACTS WITHIN THE BRAIN—CENTRUM OVALE, INTERNAL CAPSULE, CENTRAL GANGLIA, CORPORA QUADRIGEMINA.

CENTRUM OVALE.—In the centrum ovale, constituting the mass of white fibrous substance beneath the cortex and above the level of the basal ganglia, the fibers of the motor paths are more or less closely associated with other systems of fibers. They include three sets—*projection, commissural, and association* systems; the first connecting the cortex with nervous structures lying below it, the second joining the two hemispheres, while the third, or association fibers, join different parts of the same hemisphere. By these fibers adjacent convolutions, alternate convolutions, and more distant regions are connected, and through these as a physical basis the activities of the various cortical areas are harmonized and the different memories united.

The *diagnosis* of lesions involving this mass is exceedingly difficult.

We can only surmise in cases of *disturbance of association*, such as occur with aphasia and kindred disorders, that the *association fibers* have been destroyed. A break in the continuity of the fibers of the corona radiata must produce the same symptoms as if the corresponding center were destroyed. In like manner disease of the white substance of the *occipital lobe* may cause *hemianopsia*; of the *left temporal lobe*, *word-deafness*; and if the coronal fibers which proceed from the *third left frontal convolution* are diseased, *motor* or *ataxic aphasia* occurs. Yet quite extensive disease of the white substance of the frontal lobe has been found postmortem without any symptoms having been present during life.

INTERNAL CAPSULE.—Since in the comparatively narrow space in the posterior limb of the internal capsule is centered the pyramidal tract on its way from the cerebral convolutions to the crus cerebri, a very limited focal disease in this locality will lead to hemiplegia on the opposite side, while clinical experience shows that almost all cases of persistent hemiplegia are occasioned by disease in this spot.

According to the views of many neurologists, a purely motor hemiplegia, unattended by impairment of sensation, implies a lesion that does not involve the most posterior portion of the internal capsule, while such involvement is probable when there is sensory disturbance as well as motor

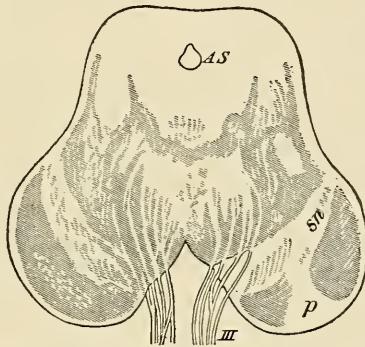

Fig. 124.—Transverse Section through the Crura Cerebri in Secondary Degeneration of the Right Pyramidal Tract—(after Charcot).

sn. Substantia nigra. *p.* The degenerated, and therefore translucent, pyramidal tract. *III.* Oculomotor nerves. *AS.* Aqueduct of Sylvius.

paralysis. Dejerine believes that disturbance of sensation in hemiplegia indicates involvement of the optic thalamus, and that there is no distinct sensory tract in the posterior part of the posterior limb of the internal capsule.

CENTRAL GANGLIA—*i. e., Caudate Nucleus, Lenticular Nucleus, and Optic Thalamus.*—In the writer's student days the corpus striatum was regarded as the great motor ganglion and the optic thalamus as sensory, while most hemiplegias were ascribed to lesions of the former, and hemianesthesia was ascribed to lesion of the optic thalamus. It is conceded to-day that the optic thalamus may have to do with the movements of mimetic or emotional expression, such as laughing and crying, which are lost in lesion of the thalamus, but which remain when the thalamus is intact, even though the half of the face is paralyzed and cannot be moved voluntarily. It is also likely that some of the fibers of the optic tract terminate in the posterior portion of the thalamus known as the pulvinar, while most of the fibers go to

the corpus geniculatum externum, and possibly some to the anterior colliculus of the corpora quadrigemina. Hence destruction of the hinder part of the thalamus produces complete hemianopsia of the opposite side, usually by destruction of the optic radiations. Focal disease of the thalamus has been supposed to cause posthemiplegic chorea and other posthemiplegic symptoms of irritation.

Beyond this, little definite is known of the effect of lesions strictly limited to the central ganglia, while disorganization of these ganglia has been found unattended by any symptoms during life.

CORPORA QUADRIGEMINA AND CRURA CEREBRI.—Lesions of the *corpora quadrigemina* are rare. Not much, therefore, is known of their function. The anterior tubercles are connected with fibers of the optic tract, but the extent of the connection in man is uncertain. Unilateral, or even bilateral, *paralysis of the oculomotor* nerve has been observed in connection with lesions of the quadrigeminal bodies, as have also *nystagmus* and *immobility of the pupil*. But this is because the nuclei of the motor nerves of the eyeball, except the sixth, lie very close to the tubercles, and may, therefore, be involved in such a lesion. According to Nothnagel, a staggering gait with oculomotor paralysis, associated with general symptoms of a tumor, points to the corpora quadrigemina as its site. The oculomotor paralysis is apt to be of irregular distribution, involving upward and downward movements of the eye, and should be an early symptom. Tumor of the corpora quadrigemina causes early optic neuritis.

If the *crus cerebri* is diseased, there often result characteristic symptoms,—viz., *paralysis of one side of the body* (arm, leg, and face), and on the side *opposite* the hemiplegia a *paralysis of the motor oculi*, or *third nerve*—crossed paralysis. An examination of Figure 124, from Charcot, will explain this. A lesion on the right side at *p* in the right pyramidal tract, might involve the oculomotor nerve, III, on that side, but would produce a hemiplegia on the left side. Since the crus contains sensory fibers from the opposite side, a lesion in one crus may also produce hemianesthesia of the opposite side of the body. Tegmental lesions should also produce sensory paralysis.

CEREBELLAR DISEASE.

The cerebellar hemispheres may suffer extensive lesions without producing symptoms, but if the central portion or vermiform process is injured, two symptoms result which are quite characteristic of cerebellar disease—namely, *uncertainty of gait*, known as cerebellar ataxia, and *vertigo*. The trunk and lower extremities alone are affected in cerebellar ataxia, standing, as well as locomotion, being interfered with. The patient can lie abed and move his legs almost as well as ever, but as soon as he rises he begins to sway back and forth with his whole body, even while standing. This tendency is increased if he brings his heels together, but is diminished while the legs are widely separated. In this respect cerebellar ataxia does not differ from the ataxia of posterior sclerosis. There may also be present the tabetic gait. On the other hand, closing the eyes usually does not aggravate it, because the cutaneous and muscular sensibility of the lower limbs remains normal. So, too, when he tries to walk, he totters, but there is none of the stamping gait of *tabes dorsalis*. It is more the true drunkard's reel, at one time forward,

and rolling now to one side and now to the other. Unfortunately, it is not so peculiar to cerebellar disease as to be pathognomonic of it, and we can only suggest that the cerebellum or its peduncles may be involved. The upper extremities are almost never implicated, but Hughlings Jackson has called attention to a paresis of the trunk muscles as the result of which the movements of bending, erection, and lateral flexion of the trunk cannot be performed.

The *vertigo* of cerebellar disease, if severe, is one of the most distressing symptoms with which one can be afflicted. It varies greatly and is not constant, while it may substitute the ataxia altogether. It occurs, however, under the same circumstances—that is, when the patient stands or moves about, disappearing when he lies down. The vertigo and ataxia are not associated, and one may be present and the other absent.

Headache is a frequent symptom in cerebellar disease, having been present in 83 out of 100 cases collected by W. C. Kraus. Most frequently it is occipital; more rarely there may be pain in the side of the head or in the forehead. *Vomiting* is also a result of chronic disorders of the cerebellum, being present in 69 of Kraus' cases. So is *visual disturbance* due to optic neuritis, which was found in 66 cases. None of these symptoms is pathognomonic, and each one may be a symptom of disease elsewhere in the brain. The most valuable, perhaps, is persistent occipital headache, especially if associated with the cerebellar gait. It might be expected that retained reflexes would be a distinctive sign as contrasted with their absence in tabes dorsalis; but, in fact, they are sometimes absent, this being the case no less than 12 times in Kraus' 100 cases.

Other symptoms which suggest cerebellar disease, but are not distinctive, are *neuralgic pains* in the region of the neck and occiput: blocking of the venæ Galeni and dilatation of the lateral ventricles producing hydrocephalus in children; pressure on the medulla oblongata, causing paralysis of the cranial nerves, glycosuria, or even sudden death, if a vital spot is impinged upon; finally, bilateral rigidity from pressure on the motor paths. On the other hand, there may be cerebellar disease without any symptoms whatever, especially as long as the middle lobe is not involved.

Form of Lesion.—By far the most frequent cerebellar lesion is *tumor*—in fact, some sort of tumor was found in 88 out of 100 cases, of which 10 were *abscess*, and there was one each of *softening* and *hemorrhage*. The remainder were: sarcoma and tubercle, each, 22; glioma, 18; nature of tumor unspecified, 13; cyst, 7; and one case each of softening, endothelioma, cyst and sarcoma, cancer, gumma, and fibroma. The tumor occupied one or the other hemisphere 32 times; the middle lobe, 17 times.

Disease of the middle cerebellar peduncles may be accompanied by the so-called *forced positions* and *forced movements*. As a result of the former, the subject may lie in bed upon a particular side, whether conscious or unconscious; and if put on the other side, may reassume his former position involuntarily. Sometimes this is accompanied by a corresponding forced position of the head and eyeballs, the extremities being seldom affected. The *forced movements* are less frequent. They consist either in oft-repeated rotations of the body on its longitudinal axis or, if the patient can walk, in involuntary circular movements. There is no guide by which to determine which of the two peduncles is affected under these circumstances, while in a few cases of brain disease the same symptoms have been observed without involvement of the cerebellum.

The following very convenient summary from Strümpell's "Text-book," American edition of 1901, contains the most important facts bearing on the localization of cerebral disease, and will be found useful for reference:

"1. The most frequent cause of ordinary hemiplegia is a lesion of the *pyramidal* tract in the posterior limb of the internal capsule. If the hemiplegia be persistent, then this tract is actually destroyed; if temporary, the tract has been functionally deranged for a time by focal disease in neighboring parts of the brain.

"2. Monoplegic cerebral paralysis is usually due to affections of the *cortex* of the brain—that is, the central convolutions and the paracentral lobule. Monoplegia of the face and tongue is the result of lesions in the lower extremity of the anterior central convolution. Monoplegia of the arm is referable principally to some lesion of the middle third of the anterior central convolution. Monoplegia of the lower extremity implies some affection of the upper portion of the anterior central convolutions and the paracentral lobule.

"3. Hemiplegia or monoplegia, if associated with epileptiform convulsions affecting either one-half or one particular portion of the body, is almost always caused by cortical lesions. These same symptoms of motor irritation without accompanying paralysis are likewise to be ascribed to some irritation of the above-mentioned regions of the cortex."

"4. Hemiplegia with crossed paralysis of the oculomotor nerve indicates a lesion of the *crus cerebri*. Co-existing tactile hemianesthesia implies that the *tegmentum* is involved.

"5. Hemiplegia with crossed facial paralysis implies, with great certainty, that the lesion is situated in the pons.

"6. Posthemiplegic chorea (*vide infra*) seems to occur especially when there is focal disease in the neighborhood of the posterior part of the internal capsule.

"7. Hemianesthesia of the skin and of the organs of special sense, associated with hemianopsia, is due chiefly to lesions of the most posterior portion of the internal capsule.

"8. Hemianopsia may be due to a lesion of the occipital lobe *cuneus*. Probably, also, a lesion of the posterior extremity of the internal capsule may cause it, in which case it is usually associated with hemianesthesia. Finally, it may be produced by affections of the *pulvinar* of the optic thalamus of the lateral geniculate body, or of one of the optic tracts.

"9. Genuine motor aphasia indicates disease of the foot of the third left frontal convolution.

"10. Word-deafness (loss of understanding of speech) is due to disease of the first left temporal convolution; word blindness (loss of understanding of writing) is due to disease of the left lower parietal lobe (*angular gyrus*)—*supramarginal gyrus* also, according to Ferrier.

"11. Difficulty in articulation implies disease of the medulla, as does also dysphagia.

"12. Staggering gait and vertigo are the most constant symptoms of cerebellar disease, but they may also occur in diseases of the *corpora quadrigemina* and of the frontal lobe (*vide supra*). Forced positions and forced movements perhaps indicate lesions of the *crura cerebelli ad pontem*.

"13. Staggering gait and ocular paralysis are indicative of lesions of the *corpora quadrigemina*."

DISEASES OF THE CRANIAL NERVES.

OLFACTORY NERVE.

The olfactory nerve may be affected in various parts of its course and distribution; at its central portion, either in the uncinatè gyrus or its frontal center (Flechsigs), in the frontal lobe, in the nerve trunk, in the olfactory bulb itself, or in its distribution to the olfactory region of the nose.

Morbid Anatomy.—The lesions may be *tumors of the brain*, instances of which have been found in the hippocampal gyri, or disease in the hemispheres. There may be *congenital defect* of the olfactory center or atrophy of the nerve, which may explain the occasional anosmia in locomotor ataxia. There may be *inappreciable changes*, caused by injuries to the head or by concurrent disease, such as epilepsy, the aura of which is sometimes manifested by parosmia. The area of distribution of the olfactory nerve in the nose may be destroyed by *chronic nasal catarrh* or by *polypus*. *Hysterical neuroses* of the olfactory nerve are not infrequent. The sense of smell is sometimes impaired in cases of tumor situated in portions of the brain remote from the olfactory area. This possibly may be caused by increased intracranial pressure.

Symptoms.—Lesions in any of these localities may produce subjective sensations of smell, or *parosmia*, of which various foul odors are illustrations; hypersensitiveness of the normal sense, or hyperosmia, in certain highly developed degrees of which the patient, generally a highly sensitive woman, can distinguish one person from another by the sense of smell; or loss of the sense of smell, *anosmia*.

Diagnosis.—The nasal region should be carefully explored by the rhinoscope and the sense of smell should be tested. For this purpose the essential oils, such as anise-seed, cloves, or peppermint, in various degrees of dilution, are employed. Cologne water, musk, or asafetida may be used for the same purpose. Pungent substances should be avoided, as they stimulate the fifth nerve in the nasal mucous membrane, and thus the subject perceives what he does not smell. By such agents the fifth nerve is tested. No conclusion can be drawn as to anatomical differences on the two sides without a rhinoscopic examination.

Treatment is useless, unless the condition be due to curable or removable polypus.

OPTIC NERVE AND TRACT.

There may be derangement of the retina, of the optic nerve, of the chiasm, and of the optic tract.

I. AFFECTIONS OF THE RETINA.

These may be *organic* or *functional*.

(a) *Organic Diseases of the Retina.*

The organic affections include hemorrhage and inflammation, or both.

HEMORRHAGE into the retina (arterial sclerosis) occurs as a cause or result of Bright's disease, most commonly chronic interstitial nephritis, in gout profoundly affecting the system, in leukocythemia, anemia, syphilis, purpura, ulcerative endocarditis, and other forms of septicemia. The hemorrhages are in the layer of the nerve-fibers. At first bright red, and then becoming darker and eventually lighter in color, they ultimately assume a diffuse cloudiness, owing to serous infiltration. The hemorrhages vary in extent, and often follow the course of the vessels. In septicemia they are due to capillary septic embolism, and often have white spots in the center, owing to the massing of leukocytes. Other white spots are due to fibrinous exudate, fatty degeneration of the retinal elements, or localized sclerosis of the same. Similar hemorrhages sometimes occur in the pia mater in the same cases.

RETINITIS occurs under the same circumstances as hemorrhage, especially in chronic nephritis, syphilis, anemia, leukemia, and also malaria; and in diabetes mellitus, purpura, and chronic lead poisoning.

Albuminuric retinitis may occur in all forms of chronic nephritis, more frequently in the interstitial variety, of which disease it may be the earliest symptom recognized. It is characterized in general by the presence of white spots of various extent and distribution, as seen by the ophthalmoscope. They are caused by degenerative processes and hemorrhages. Gowers recognizes three forms:

1. A degenerative form, which is the most common, in which there are retinal changes, but scarcely any alteration of the optic disc.
2. An inflammatory form, in which there are much swelling of the retina and obscuration of the optic disc.
3. A hemorrhagic form, in which there are many hemorrhages, but little evidence of inflammation.

In some instances of the second the inflammatory changes in the optic nerve predominate over those of the retina, producing an *optoneuritic* form, in which the appearances are more closely allied to those of papillitis or choked disc, such as is caused by intracranial disease.

Syphilitic retinitis is a rare affection in acquired and congenital disease. In the latter it is called *retinitis pigmentosa*. *Syphilitic choroiditis* is less rare. Retinitis is not uncommon in *chronic anemia*, especially in the pernicious form. After excessive loss of blood the patient often becomes blind, either suddenly or in the course of one or two days. In such cases a neuroretinitis has been found quite sufficient to explain the blindness, which, in rare instances, may be permanent and complete. A rare variety of anemic retinitis is *malarial retinitis*, first described by Stephen MacKenzie. It may be associated with hemorrhage. In *leukemic retinitis* the retinal veins are large, and hemorrhage may also occur, with white and yellow areas. Tumor of the brain, especially of the cerebellum, has been found in some instances to cause a condition of the retina like that of albuminuric retinitis.

(b) *Functional Disturbance of the Retina, or Amaurosis.*

This may be *toxic*. Of this, the most striking and best known variety is *uremic amaurosis*. Its suddenness is its most striking feature, and it is very frequently the forerunner of uremic convulsions, although it may occur without them. It, too, may be the first symptom noted in Bright's disease.

The retina is free from any changes visible by the ophthalmoscope, and the condition is probably due to the action of the poison on the nerve centers. It generally disappears, not quite so suddenly as it comes on, but comparatively quickly, while the impaired vision of retinitis albuminurica is a more or less permanent condition. Similar are the amauroses from *lead poisoning* and from massive doses of *quinin*. *Hysterical amaurosis* is more frequently a dimness of vision,—amblyopia,—but true blindness may occur in one or both eyes. *Tobacco amblyopia* is usually gradual in its appearance, and affects more especially the center of the field of vision. There may be congestion of the optic disc, and if the use of tobacco is persisted in, there may be a permanent organic change, with atrophy of the discs. A scotoma for red and green is invariably present.

In *nyctalopia*, or night-blindness, objects are clearly seen by the day or by strong artificial light, but are invisible in the shade or at twilight. In *hemeralopia* the reverse state of affairs exists, objects being seen with discomfort in bright daylight or by strong artificial light, but being easily seen in deep shade or at twilight. *Retinal hyperesthesia* is sometimes met in hysterical women.

2. AFFECTIONS OF THE OPTIC NERVE.

Those which are of medical significance are *optic neuritis*, or choked disc, and *optic atrophy*.

(a) *Intracranial Trunk.*

The intracranial trunk of the nerve is rarely affected, by reason of its shortness. It may, however, be compressed by a *tumor* in adjacent parts, as of the pituitary body or of the bone; by *aneurysm of the ophthalmic artery* within the orbit or of the internal carotid within the skull. The trunk may also be the seat of inflammation, which may extend from carious bone or meningitis, or may be rheumatic.

(b) *Optic Neuritis, Papillitis, or Choked Disc.*

Definition.—Inflammation of the intra-ocular end of the optic nerve.

Anatomical.—It will be remembered that the optic nerve pierces the sclerotic and choroid coats about 1-10 inch (2.5 mm.) to the nasal side of the center of the retina, which is occupied by the yellow spot of Sömmering. In this spot the sense of vision is most nearly perfect, while the optic papilla or disc is the only part of the retina from which the power of vision is absent. A central depression, or “cup,” is due to the separation of the nerve-fibers, pale because of the absence of blood-vessels, while the periphery of the disc has a rosy tint from the presence of the minute blood-vessels that lie among the nerve-fibers. The “cup” varies in size, and may be absent, the vascular portion of the disc at times extending over it. The tint of the vascular portion of the disc also varies, and differences are of significance only when noted at successive examinations of the same case.

Morbid Anatomy.—It is by swelling and diminished transparency rather than by recognizable signs of congestion that the *first stage* of optic neuritis is characterized. Then there follows lessening of the sharpness of the edge of the disc, and finally its total obscuration, as seen in the right

half of Figure 125 as contrasted with the left half. It is to be remembered that the normal contrast is sometimes diminished within the limits of health, with this difference: that the pathological indistinctness is better seen with the direct method of examination, while the indistinctness sometimes normally present is more evident to the indirect. The abnormal change is earlier recognized on the nasal side, because there are more nerve-fibers there than at the temporal edge. In the *second stage* the swelling rapidly increases and the whole circumference of the disc disappears, though the cup is still represented by a slight depression. The swelling extends even beyond the normal disc, becoming two or three times as wide. The swollen disc assumes a red or grayish-red color to the indirect examination, but by the direct a fine striated appearance is noted, the striæ radiating from the center of the disc in the direction of the fibers. White spots may appear on its surface, due to degeneration of the nerve-fibers, and may be seen in the illustration. As the swelling increases the retinal vessels, at first

Fig. 125.—Commencing Optic Neuritis from a Case of Caries of the Sphenoid Bone with Secondary Meningitis—(after Gowers).

The left-hand figure shows the normal right optic disc with clear outline and deep central cup. The right-hand figure of the left papilla shows well-marked neuritis; the edge of the disc is concealed by a swelling which extends beyond the normal limits of the disc. The central cup is encroached upon, but not yet quite obliterated. Some of the vessels are partly concealed at their points of emergence, and the veins lose their central reflection.

unaffected, suffer from the compression, the veins becoming wider and more tortuous, the arteries being narrowed or remaining normal, while hemorrhages may occur. The retina may also be invaded, producing a neuroretinitis.

In very slight degrees of inflammation the swelling subsides and recovery takes place. In high degrees it remains for a long time, owing to the presence of inflammatory products, which gradually, however, undergo the usual contraction of cicatricial tissue, a condition of "consecutive atrophy" resulting, in which the disc is white and atrophied.

Etiology.—Most commonly optic neuritis is caused by intracranial disease; especially in nine-tenths of all cases tumor is said to be present. It gives no information as to the seat of the tumor. It is ascribed by some to a descending neuritis; by others, to intracranial pressure. In over ninety per cent. of cases the neuritis is bilateral, though often unequal in the two eyes. Unilateral neuritis is generally due to disease within the orbit or at

the optic foramen, but may be due to intracranial tumor. *Meningitis*, either tubercular or simple, is the next most frequent cause. It is said to be rather more common in meningitis of the base than of the convexity. Such optic neuritis is less severe than that caused by tumor. *Cerebral abscess* may cause it; so may *diffuse cerebritis*. In *thrombotic softening* and *hemorrhage* optic neuritis is rare, but in *embolic softening* it is more common.

Optic neuritis may result from *Bright's disease*, *chlorosis*, *anemia*, or *lead-poisoning*, and may occur after *acute fevers*, especially scarlet and typhoid. In the latter it may be associated with brain symptoms, especially headache. About six per cent. of all cases of *multiple sclerosis* are accompanied by optic neuritis, due to inflammatory or sclerotic patches in the nerve, usually slight and of short duration, often one-sided in consequence of unilateral involvement of the nerve by a sclerotic patch.

Symptoms.—Mild degrees of optic neuritis may be without symptoms, except such as are revealed by the ophthalmoscope. With higher degrees, acuity of vision, color vision, and the visual field all suffer and may be lost. Its severest effect on vision may not appear until contraction sets in, because it is at this period that the nerve elements suffer most in integrity. The defective sight is not, however, necessarily due to changes in the disc or retina; it may be due to intense inflammation in the nerve behind the eye or to intracranial disease.

Prognosis.—Even in severe cases there may be some improvement of vision with subsidence of the inflammation. On the other hand, vision may be permanently lost.

(c) *Optic Atrophy.*

There are three varieties of atrophy of the optic nerve:

(1) Primary; (2) secondary; (3) consecutive.

1. *Primary* or *simple atrophy* is that form which is not preceded by any recognizable inflammatory change in the papilla or surrounding structures. It occurs in degenerative diseases of the brain and spinal cord, more frequently in multiple or disseminated sclerosis and tabes dorsalis. It is present in about forty per cent. of all cases of multiple sclerosis, and, in various degrees, in at least fifteen per cent. of those of tabes. In dementia paralytica it is present in about five per cent. Primary atrophy is sometimes hereditary, occurring in the males of a family after puberty. Other causes to which the condition has been ascribed are cold, alcoholism, lead-poisoning, sexual excesses, diabetes, and the specific fevers.

2. *Secondary atrophy* is the result of damage to the optic nerve behind the eye or at the chiasm. It is characteristic of it that demonstrable signs of atrophy follow, instead of accompany, the deranged vision; of which, too, hemianopsia may be a form.

3. *Consecutive atrophy* is that form of atrophy which succeeds neuritis or papillary neuritis. It has the same causes and the same significance. Only secondary and consecutive atrophy are the result of uncomplicated intracranial diseases; for although primary atrophy accompanies disseminated sclerosis, tabes dorsalis, and general paralysis of the insane, it is not caused by the associated brain disease, but is the result of the same widespread tendency to degeneration.

The ophthalmoscopic appearances in primary atrophy differ somewhat

from those of the consecutive and secondary forms, the disc being gray-tinted,—whence the name *gray atrophy*,—with its edges well defined, while the arteries appear almost normal. In secondary and consecutive atrophy the disc has an opaque, white appearance, with irregular outline, and the arteries are small.

The **symptoms** of optic atrophy are the defects of vision already detailed when treating of optic neuritis.

As to **prognosis**, in primary atrophy the ultimate result is usually blindness, but in secondary and consecutive atrophy some vision remains, even in severe cases, while in mild cases recovery is not impossible.

3. LESIONS OF THE CHIASM AND TRACT.

Anatomical.—The decussation of the optic tracts at the chiasm is peculiar. As it reaches the chiasm each tract divides and sends a portion—the smaller—of its fibers to the temporal half of the corresponding retina, and the remaining portion to the nasal half of the opposite retina. Thus the right tract supplies the right or temporal half of the right retina and the right or nasal half of the left retina; the left tract supplies the left or temporal half of the left retina and the left or nasal half of the right retina. The decussating fibers occupy the middle of the chiasm, and the direct fibers the corresponding side. (See p. 993.)

Effect of Lesion of the Chiasm: Hemianopsia.—(a) If the central portion of the chiasm, composed of decussating fibers only, is involved (lesions *b* and *c*, Fig. 126), the result will be anesthesia of the inner half of each retina and blindness of the outer half of each field of vision, it being remembered, of course, that the half field which is blind is the reverse of the half of the retina which is anesthetic, since the picture formed on each half of the retina is projected from the opposite half of the field of vision. Such half blindness is known as *hemianopsia*, and the form just described, in which the outer or temporal half of each field is blind, is known as *bi-temporal hemianopsia*.

(b) If the whole chiasm is involved, as is not infrequently the case as the result of pressure by tumor, there will, of course, be total blindness.

(c) If the lesion is intermediate, involving the direct fibers on one side of the chiasm as well as the central fibers, there will then be blindness in one eye and temporal hemianopsia in the other.

(d) The rarest of all forms of hemianopsia is *bi-nasal hemianopsia*, due to a symmetrical lesion involving only the direct fibers passing to the temporal half of each retina, whence results blindness in the nasal field only. It is found sometimes in tumors involving the outer part of each tract, or of each optic nerve.

Effect of Unilateral Lesion of the Tract.—If there be a lesion involving the left tract at *d* (Fig. 126), the left or temporal half of the left retina and the nasal half of the right retina become anesthetic and useless, the right half of each field of vision is blotted out, and there results a right *lateral hemianopsia* which is called *homonymous hemianopsia*. The reverse is the case if the lesion is in the right tract. The number of cases involving the right side is about equal to the number involving the left. When the left half of one field and the right half of another are blind, or the reverse, the condition is known as *heteronymous hemianopsia*.

In the usual forms of bi-temporal hemianopsia the obscure fields are by

no means always exact demi-fields, which would be the case if the dividing line passed exactly through the fixing point, or macula lutea. It may diverge to the temporal side so as to leave a small area around this within the seeing half. These differences are due to peculiarities in the decussation rather than to the lesion. The half fields which remain, though com-

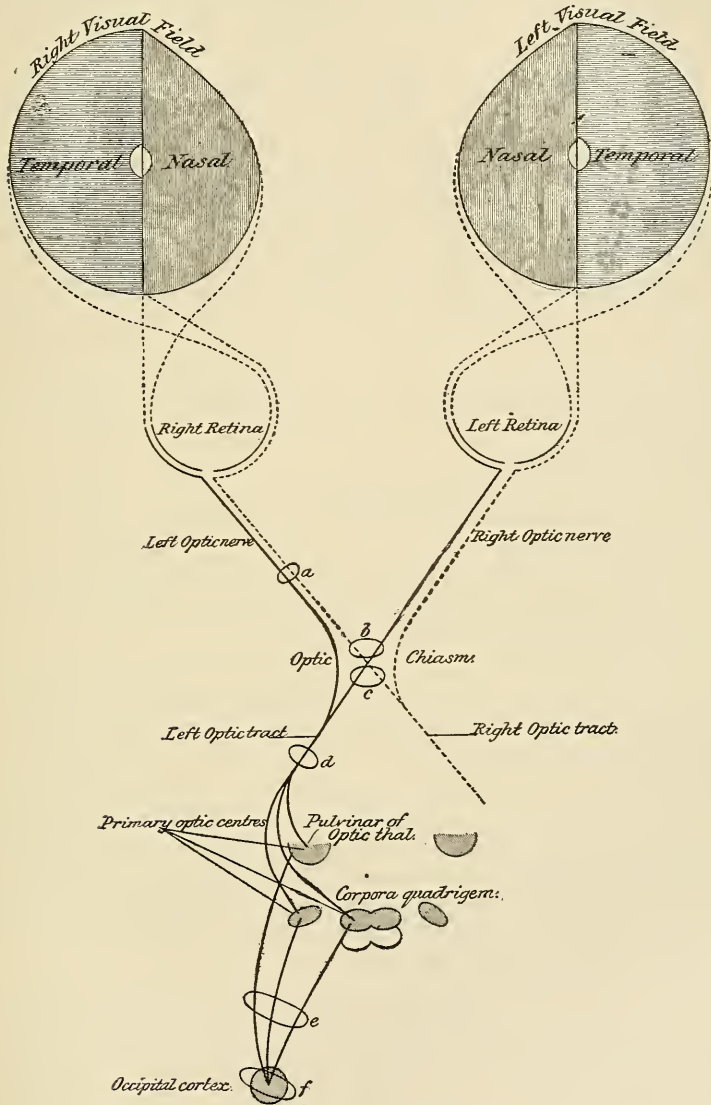

Fig. 126.—Diagram of Course of Optic Nerve-fibers from the Cortex to the Retina
—(after Sahl \grave{e} , Modified and Extended).

monly natural, are sometimes contracted. This is usually due to an inflammatory affection of the peripheral fibers of the optic nerves in front of the chiasm.

There are other differences in the dividing-line, such as obliquity, want of sharpness, etc., due to the same cause, but minute description of these belongs to special works on nervous diseases. Since vision remains intact

in the central region, equally in right and left-sided hemianopsia, it follows that there must be a passage of fibers from the macular region to the optic tract of each hemisphere, else this region would be blinded by disease of one or the other tract. There is usually the same loss of vision for color in the half field, but half vision for color may be lost in central disease without any change in the field for white. This is known as *hemiachromatopsia*.

4. LESION OF THE TRACT AND CENTERS.

The optic tract on each side crosses the crus cerebri backward and passes to the external geniculate body to the pulvinar of the optic thalamus, and to the anterior colliculus of the quadrigeminal body. From these so-called primary optic centers fibers pass backward through the posterior part of the internal capsule, forming the fibers of the optic radiation in the white substance of the occipital lobe, into the visual area of the cortex, of which the area about the calcarine fissure is the chief cortical center, though other parts of the occipital cortex possibly also receive and store up visual impressions.

When it is plain that vision may be influenced by lesions in any of the following situations:

1. In the tract itself.
2. In the external geniculate body.
3. In the pulvinar of the optic thalamus and in the anterior colliculus of the corpora quadrigemina.
4. In the fibers passing from the primary optic centers to the occipital lobe, as at *c* (Fig. 126), in the hinder part of the optic radiation.
5. In the area about the calcarine fissure.

The effect of lesion in any one of these situations is to produce anesthesia of that half of the retina corresponding to the affected side and a homonymous hemianopsia of the opposite half of the visual field.

Morbid States Affecting the Optic Nerve, Chiasm, Tract, and Centers.—Outside of the affections of the retina, which concern the ophthalmologist chiefly, and outside of optic neuritis or papillitis as a result of intracranial disease, already considered, the affections of the *optic nerve* which concern the physician are tumors springing from the pituitary body or the bone, aneurysm of the ophthalmic artery within the orbit or of the carotid within the skull, and interstitial inflammation from an adjacent focus, or rarely from rheumatism and injury.

The *optic chiasm* is encroached upon by tumors in the neighborhood, especially of the pituitary body; by tubercular or syphilitic growths in its substance, or by inflammation invading it from the adjacent dura mater or from carious bone; by internal hydrocephalus, the distended infundibulum of the third ventricle pressing on the middle of the chiasm; by interstitial inflammation of a possible gouty origin or associated with *tabes dorsalis*; and, finally, by interstitial hemorrhage.

The *optic tract* may be invaded or compressed by tumors springing from the inner part of the temporosphenoidal lobe, by softening after thrombosis of the internal carotid, or by disseminated sclerosis. Primary softening in the tract is rare, as is also hemorrhage.

The *cortical visual centers* may be invaded by hemorrhage, softening, tumors, pressure by depressed bone in fracture, and other traumatic causes.

Symptoms of Lesions of the Optic Nerve, Chiasm, Tract, and Cortex.—

1. *Visual Effects.*—(a) Lesions of the optic nerve cause defects of vision on the same side, with lessening of the reflex action of the pupil proportionate to interference with vision. The impairment of vision includes extent of field of vision as well as degree. There may be concentric limitation of the visual field because the peripheral layer of nerve-fibers near the optic foramen is damaged by processes external to it. In other cases there is irregular defect, and in others still the loss of sight is total and lasting.

To the ophthalmoscope there may be at first no change, but if the lesion is considerable, the atrophic condition soon makes its appearance “secondary” to changes in the nerves, as distinguished from “consecutive” atrophy, which succeeds papillitis. There may be slowly supervening atrophy without recognizable papillitis. Central loss of vision, due to axial neuritis, is less common, but occurs sometimes in tobacco amblyopia.

(b) In lesions of the chiasm the characteristic symptom is bitemporal hemianopsia, or loss of the outer half of each field of vision; this is because the lesions mainly affect the chiasm at its central portion, where the fibers, after decussating, pass to the nasal half of each retina. Usually, however, the process, be it tumor or inflammation, which causes temporal hemianopsia extends laterally, involving the non-decussating fibers of one side of the chiasm, causing total blindness of the corresponding eye; or, if extending to both sides, blindness of both eyes. These different stages may often be traced in a single case as the disease progresses. The term “oscillating bitemporal hemianopsia” is applied to a rapid and frequent variation of the dark fields, and is regarded as more or less clearly diagnostic of basal syphilis, such as gumma or syphilitic meningitis. More rarely we have the binasal hemianopsia already described. Slight variations in the extent of the dark fields have been referred to as the result of peculiarities in decussation rather than of lesion or seat of lesion.

(c) In lesions of the optic tract between the chiasm and the external geniculate body there is bilateral hemianopsia.

(d) Bilateral hemianopsia is also a result of lesion of the central fibers of the nerve between the primary visual centers and the cerebral cortex.

(e) Lesions of the cuneus cause bilateral hemianopsia. A lesion in each hemisphere, affecting the visual paths back of the chiasm, will cause a double hemianopsia, with total loss of vision in both eyes. Such a result has followed successive lesions in the two occipital lobes.

(f) Hemianopsia may be due to functional disease. Transient hemianopsia is sometimes a symptom of migraine, either as an isolated symptom apart from headache and gastric disturbances or associated with them. It may affect now one half of the field and now another.

Hemianopsia is also rarely a symptom of hysteria.

2. *Other Symptoms Associated with Hemianopsia.*—In about one-half the cases of hemianopsia there is transient or permanent hemiplegia, the result of the same lesion, the hemiplegia being on the side of the loss of vision, so that the patient cannot see the paralyzed side. Hemianesthesia may also be associated, and defects in speech are sometimes found when the paralysis is on the right side.

Hemiachromatopsia has been mentioned. (See p. 994.) In this con-

dition there is no change in the field for ordinary objects, but all colors appear gray as soon as the vertical line is passed. The symptom, according to Gowers, probably depends on disease of one part of the occipital lobe, and is proof of a separate center for color not yet precisely located, perhaps in some part of the occipital cortex in front of the apical region.

The limitation of the remaining functionally active half field and the isolated loss for colors are the only known differences in the features of hemianopsia due to variations in the seat of the lesion in the optic path behind the chiasm, the limitation of the active half field indicating a lesion in the optic radiation near the thalamus, the isolated loss for colors pointing to a lesion in the occipital lobe.

3. *Amblyopia*.—Amblyopia is another form of sight defect due to brain disease. The term is used to indicate a *partial loss or blurring of vision*. There is concentric limitation of the visual field, varying in different cases, and along with it the color fields are also reduced.

Similar eye defects, associated with hemianesthesia, occur sometimes in hysteria, with which it may be confounded. Since a simple functional loss of vision may rarely result as a reflex from irritation of the fifth nerve or from hysteria, so a functional amblyopia, affecting both eyes, may also result from such causes—indeed, is more common than the organic form. A carious tooth may act in this way. Amblyopia from errors of refraction must not be confounded with the amblyopia due to brain disease.

Diagnosis.—How shall we interpret these phenomena of vision concerned with the optic nerve and tract? Some conclusions are easy; others are difficult, by reason of the limitations of our knowledge. Accurate investigation of fields of vision, with a view to the study of hemianopsia and other defects in the visual fields variously caused, is made by means of the perimeter, for directions concerning the use of which instrument the student is referred to works on ophthalmology. Herman Sahli suggests an easy, rough method, quite sufficient for recognizing marked difference in the field of vision, performed as follows: The physician seats himself opposite the patient, whose right eye—supposing this to be the one to be tested—is opposite the physician's left, the other eye of each being closed. The two open eyes being thus fixedly opposed, the physician passes his finger to and fro across the field of vision exactly midway between the two eyes. In this way he can compare his own field of vision with that of the patient, noting at what moment the finger is seen approaching from the periphery of each. Care must be taken that the finger is kept exactly midway between the physician and patient, and in order to do this, the examiner must from time to time open his closed eye. Defective sight in one eye with diminished reflex action of pupil proportionate to the defect, the function of the remaining eye being intact, usually means disease of one optic nerve. In some rare cases of functional disease in which the sight of one eye only is involved, the perfect responsiveness of the pupil distinguishes it from organic disease of the nerve. Total loss of sight in both eyes may mean chronic atrophy, damage to the chiasm, or disease of both tracts or in both hemispheres. In these cases the symptoms are at first partial, and in this way the diagnosis is aided.

Central scotoma means damage to nerve-fibers in the center of the trunk of the optic nerve, either inflammatory or the result of hemorrhage. Peripheral limitation of vision means damage to fibers running in the periphery of

the nerve. Sectorial blindness in one eye means disease of the nerve, decided in degree but limited in extent.

Bitemporal hemianopsia means disease of the chiasm, while the combination of complete blindness of one eye with temporal hemianopsia in the other means disease of the chiasm which has extended to the outer fibers, and even to the optic tract or optic nerve, on the side on which blindness is complete.

Bilateral hemianopsia is due to disease back of the chiasm, and the determination of the spot involved in the tract between the chiasm and the occipital area which is the cortical center of vision, stimulates diagnostic acumen. The most that can be attempted is the settling of the question as to whether the disease is in the tract between the chiasm and the external geniculate body or in the fibers beyond bounded by the visual centers. To this end the *hemianopsic pupillary* reaction of Wernicke is sought. A perfect pupil reflex requires the integrity of the retina, of the fibers of the optic nerve and tract, of the center and fibers of the third nerve, and of the iris. When the light is thrown on the blind half of the retina the pupil contracts as much as if it is thrown on the seeing half, if the disease is in the hemispheres; but if the disease is in the tract, it does not contract because the path to the third nucleus below the corpora quadrigemina is interrupted. The employment of the test requires much care and experience. Seguin directs that the patient, being in a darkened room with a light behind his head in the usual position, be directed to look to the other side of the room, so as to eliminate accommodation movements. Then a faint light is thrown upon the eye from a plane or large concave mirror, held well out of focus, and the size of the pupil is noted. With the other hand a beam of light, focused by an ophthalmoscopic mirror, is then thrown directly into the optical center of the eye, then laterally in various positions and from above and below the equator of the eye, noting the reaction at all angles of incidence. According or not as a response is obtained in the pupil the inference is drawn.

Amblyopia with concentric reduction of the field, decided in one eye and slight in the other, may be due to atrophy of the nerve, to disease of the higher visual center in one hemisphere, or to hysteria. If atrophy, the ophthalmoscope recognizes the lesion and the responsiveness of the pupil is diminished. If disease of one hemisphere, the nerve is normal to the ophthalmoscope, the pupil contracts perfectly under the action of light, and the onset is sudden or accompanied with other signs of organic brain disease. Mind-blindness, described on page 975, may also be a result of lesion in this locality. In hysteria the symptoms are the same as in disease of the higher visual center, and the diagnosis depends on the presence or absence of signs of organic or functional disease. In hysterical blindness the loss of sight is rarely complete. In hysterical and neurotic defects of vision there may be a derangement of the natural relation in color fields. Thus, while normally the blue field is most conspicuous in the last-named conditions, it is often overshadowed by other colors.

LESIONS OF THE MOTOR NERVES OF THE EYEBALL.

Anatomical.—The third cranial nerve (oculomotor) supplies the levator palpebræ superioris, the superior and inferior recti, the rectus internus, the obliquus inferior, the sphincter of the iris, and the ciliary muscle. The fourth cranial nerve (the trochlear) supplies the superior oblique; the sixth cranial nerve (the abducens), the rectus externus. The functions of the muscles to which these nerves are distributed are sufficiently indicated by their names.

THIRD NERVE.—Lesions may involve the nerve at its nuclear origin or in its course. Lesion of the third nerve *at its origin* involves also usually the origin of the other motor nerves of the eye, producing general ophthalmoplegia, as a result of which the eyeball is motionless, and an object moved about in front of it can be followed only by moving the entire head. The nerve may be invaded *in its course* by traumatic causes, meningitis, gummata, aneurysm, or neuritis, frequently rheumatic, and may also be affected in diphtheria, tabes dorsalis, and diabetes mellitus. The effect may be spasm or paralysis.

The results of *spasm* of the muscles supplied by the third nerve are manifested in *nystagmus*. This consists in an involuntary, clonic, rhythmic, oscillatory movement of the eyeball, usually horizontal, but sometimes rotary, more rarely vertical. It is seen in congenital or acquired brain lesions, and is often a striking feature in albinism. In meningitis and hysteria there is also sometimes spasm of the muscles supplied by the third nerve, especially the internal rectus and the levator palpebræ, the antagonist of the orbicularis.*

Paralysis of those muscles supplied by the third nerve, which include all the eye muscles except the external rectus and the superior oblique, results in outward squint; ptosis, or drooping of the upper eyelid; the absence of contracting power in the pupil, which remains of medium size; loss of accommodation; the double vision, or diplopia. Such paralysis, involving all the branches of the nerve, may be recurrent, especially in women, often at the menstrual period, or at wider intervals.

It is sometimes associated with pain in the head and at other times with migraine. The individual attack lasts a few days, or as many weeks. Partial involvement of the third nerve last may include the levator palpebræ, the superior rectus, the ciliary muscle, and the iris, while the external muscles—that is, the internal and inferior recti and the inferior oblique—may escape.

Ptosis only, due to paralysis of the levator palpebræ, complete or partial, may occur under various conditions. It may be congenital and incurable, or due to cerebral lesion; or it may be hysterical, when it is apt to affect both eyes and is associated with other symptoms of hysteria. It may be caused by disease of the sympathetic nerve (pseudoptosis), and may be associated with symptoms of vasomotor palsy—viz., elevation of temperature on the affected side, redness or edema of the skin, and contraction of the pupil on the same side. Finally, it is seen in weak, delicate women as a transient event, especially in the morning. When the result of a definite

* Blepharospasm is a spasm of the orbicularis muscle, which is supplied by the facial nerve. It amounts usually only to twitching of the eyelids, but may be so severe as to close them completely, so that it is not in the power of the patient to open them.

lesion of the third nerve, at its nucleus or in its course, it may also be associated with a paralysis of the superior rectus alone, or of the internal and inferior recti in addition.

Condition of the Pupil.—The condition of the pupil should be studied with light of moderate intensity, and in doubtful states the pupil under examination should be compared with that of the eye of a healthy individual about the same age.

Miosis, or contraction of the pupil, is found physiologically during sleep, especially in elderly persons; pathologically, as an early symptom in tabes dorsalis, in progressive paralysis of the insane, and as an effect of eserine, pilocarpin, morphia, and in complete chloroform narcosis.

Mydriasis, or dilatation of the pupil, occurs in deep unconsciousness, during extreme pain, in dyspnea, in peripheral blindness, especially from optic atrophy, in oculomotor paralysis, rarely in tabes dorsalis and progressive paralysis of the insane. It is also an effect of atropine, duboisine, and cocaine, and of the early stage of chloroform narcosis.

The pupil may be unduly large from palsy of the sphincter (third pair) fibers or from spasm of the radiating (sympathetic) fibers; or the pupil may be abnormally small from the opposite conditions.

Other limited paralyzes due to third nerve disease are cycloplegia and iridoplegia. *Cycloplegia* is paralysis of the ciliary muscle, producing loss of the power of accommodation. In this state of affairs distant vision is good, but near objects cannot be seen distinctly. It may occur in one or both eyes, being in the latter event more usually due to disease of the nuclear origin of the third nerve. It is one of the earliest manifestations of diphtheritic paralysis, and is a symptom also of tabes dorsalis. It may be corrected by the use of eye-glasses.

Iridoplegia is paralysis of the iris, and its three forms are thus classified by Gowers, one associated and two reflex:

1. *Accommodative iridoplegia* is a form in which the pupil does not diminish in size during accommodation. It is tested by having the patient look at a distant object and then at a near one in the same line of vision, so as to avoid any change in the amount of light entering the eye. It is usually associated with paralysis of accommodation, but the ciliary muscle may be efficient and yet the associated action of the iris be lost, or the reverse. This loss is less common than that of reflex action. It is the result of the same cause as cycloplegia.

2. *Reflex Iridoplegia, or Argyll Robertson Pupil.*—The path for the optic reflex is along the optic nerve and tract to the nuclei of the third nerve; thence to the ciliary ganglion, and through the ciliary nerves to the eye. In testing for this condition each eye should be tried separately, the other being covered, but not closed. The patient is asked to look toward a dark part of the room, when a bright light is thrown suddenly in front of the eye at a distance of three or four feet, so as to avoid the effect of accommodation. If the patient looks at a nearer light, he will accommodate for it, and the pupil may contract when there is no action to light. Such absence of light reflex without loss of the accommodation contraction was first pointed out by Argyll Robertson.

3. *Skin Iridoplegia.*—Loss of skin reflex. If the skin of the neck is pinched or pricked, or stimulated by an electric shock, the pupil dilates reflexly. Since active dilatation of the pupil is through the sympathetic nerve, the motor path for this action must be along the cervical sympathetic,

and along the fibers connecting this with the cord, at the lowest part of the cervical region.

These reactions are lost when the path is interrupted or the center is damaged. Thus, the light reflex is lost or impaired in disease of the optic nerve including the retina, or in disease of the third nerve. Disease of one optic tract does not lessen the action unless the light falls on the blind half of the retina, because, as already stated, the fibers from the central and most sensitive region of each retina pass through both optic tracts, whence disease of one does not abolish the reflex. The skin reflex is lost in disease of the cervical sympathetic and sometimes of the cervical spinal cord, especially when there is associated loss of sensibility. Thus, tumor of the cord sometimes produces this symptom.

When the eye reflexes are lost without disease of the sympathetic or cervical cord, it is generally due to degenerate disease of the centers. *Tabes dorsalis*, in which it is a common and an early symptom, is a conspicuous instance. Less frequent is general paralysis of the insane, and other degen-

Fig. 127.—Situation of the Cranial Nerves—(after Edinger).

Cranial nerve nuclei, oblongata, and pons represented as transparent. Motor nuclei, black; sensitive nuclei, red.

erative processes less definite. It may occur also without other nerve symptoms. In most of the cases in which it has come under Gowers' observation thus isolated, the patient had suffered from constitutional syphilis for years. The two palsies, that of the skin reflex and that of the light reflex, are commonly associated, but not always. The pupils are often small, reduced to two millimeters, or even one millimeter, in diameter.

Inequality of pupils, or *anisocoria*, is also a symptom of progressive paresis and *tabes dorsalis*, but occurs also in healthy persons.

FOURTH NERVE.—The fourth cranial nerve (trochlear), as it passes around the outer surface of the crus into the orbit, is liable to be compressed by tumors, by aneurysm, or by the exudation of basal meningitis. Its nucleus below the aqueduct of Sylvius may be involved in tumors, or may undergo degeneration with other ocular nuclei. As the superior oblique muscle, supplied by it, acts in such a way as to direct the eyeball downward and rotate it slightly, paralysis causes retardation of downward and inward

movement, often so slight as not to be noticeable. The head is inclined somewhat forward and toward the sound side, and there is double vision when the patient looks down, as in descending stairs. Paralysis of this nerve is seldom met with alone, except in nuclear disease.

SIXTH NERVE.—The sixth nerve (abducens), emerging at the junction of the pons and medulla oblongata, passing forward and entering the orbit, is liable to be affected by meningitis at the base, or by tumors, especially gummata, or by cold. The external rectus being alone supplied by it, the effect of its paralysis is to produce *internal squint*, and the eye cannot be turned outward. There is diplopia when looking toward the paralyzed side. It is a frequent ocular palsy, because the nerve has so long and exposed a course.

If the nucleus of the sixth nerve is affected, a very interesting condition results, which was first studied by Beevor. In consequence of paralysis of the external rectus the eye of that side is turned inward, while at the same time the internal rectus of the eye of the opposite side has lost the power to turn its eye inward. Consequently, both eyes are turned to the side opposite and away from that of the injury. Thus, if the nucleus of the right sixth nerve is involved, both the right and the left eye are turned toward the left. Such opposite deviation away from the side of lesion is known as “conjugate deviation.” It is due to the fact that the nucleus of the third nerve, supplying the internal rectus, is connected by fibers with the nucleus of the sixth; whence in lesion of the nucleus of the sixth nerve there is paralysis of the internal rectus, supplied by the third nerve, in associated movements, though the nucleus of the third nerve is not involved, the power of convergence is not affected.

In consequence of the proximity of the nucleus of the sixth nerve to that of the seventh or facial, disease of the former is apt to involve the latter. Whence, say if there is lesion of the left nerve, there follows conjugate deviation of both eyes to the right, with a complete paralysis of the left half of the face.

Diabetes insipidus is sometimes associated with paralysis of the sixth nerve. Such a case I saw at the Philadelphia Hospital with J. Hendrie Lloyd. The paralysis of the sixth nerve was subsequently substituted by paralysis of the third, the polyuria remaining. A case of this character may be caused by syphilitic meningitis. Basal meningitis, involving the vascular supply to the floor of the fourth ventricle, was suspected. Other cases of polyuria associated with paralysis of the sixth nerve are reported, notably Maguire's.

Phenomena in General of Paralysis of Motor Nerves of the Eye.—These include, first, limitation of movement and strabismus, referred to. In addition to these certain derangements of vision, known as *secondary deviation*, *erroneous projection*, *double vision*, occur.

Secondary deviations are thus demonstrated: After covering the sound eye, let the paretic eye fix itself upon a point which it cannot reach at all, or can reach only after extreme exertion. Then remove the covering hand from the sound eye, and it will be found that the latter has been moved much too far in the same direction, the abnormal attempt at innervation of the affected eye passing over to the associated muscle of the healthy eye and causing in it too great a contraction.

Erroneous projection furnishes the idea that an object at which we are

looking is further on one side than it really is, or that the movement of the eye in following it, when moving, is greater than it is. Under these circumstances, in an attempt to touch the object with the fingers the latter may go beyond it. This grows out of the fact that when the eyes are at rest in the mid position, an object at which we are looking appears directly opposite the face. Turning the eye to one side, the object appears to the side of its former position; and if the object moves, we estimate the extent of its motion by the amount of movement of the eyeball following it. Now, when one muscle is weak, the increased innervation required to contract it gives the impression of a degree of movement greater than actually takes place. This is erroneous projection. Now, as the equilibrium of the body is largely maintained by a knowledge of the relation of external objects to it, obtained by the action of the eye muscles, the erroneous projection due to paralysis disturbs the harmony of visual impressions and may produce dizziness, known as ocular vertigo.

Double vision results from the fact that if one eye is paralyzed the axes of the two eyes do not coincide, nor do the images in the two retinae. The image produced in the sound eye is called the true image; that in the affected eye, the false image. In simple or homonymous diplopia the false image is on the same side as the paralyzed eye; in crossed diplopia it is on the other side. It is one of the most annoying symptoms of paralysis of the eye muscles.

OPHTHALMOPLEGIA.—Ophthalmoplegia, or nuclear palsy, is a term applied to a chronic progressive paralysis of the ocular muscles, due to disease of the ocular nuclei. It is called *internal* when the internal muscles only are involved—*i. e.*, the iris and ciliary muscles; *external*, when the external muscles are affected more or less completely. When both internal and external muscles are involved, it is known as *total ophthalmoplegia*.

Historical.—The term was first used by Brunner, in 1850. The nature of the cases was pointed out by v. Graefe in 1856, and in 1868 compared by him with bulbar palsy. Forster localized the lesion in 1878 for external palsy, including all the muscles except the iris and ciliary muscles. Internal ophthalmoplegia was described by Hutchinson in the same year, and the external form, with postmortem proof of its nature, in 1879.

Symptoms.—These vary according to the position and character of the lesion, which may be degenerative, hemorrhagic, or the result of pressure by tumors or the product of basilar meningitis. They are bilateral, except in the instance of the sixth nerve, with resulting conjugate paralysis. Gowers describes three modes of onset—chronic, sudden, and acute.

The *chronic* form is the most common, due to nuclear degeneration, or more rarely to tumor and embolic obstruction, and still more rarely to hemorrhage. In this form there is a great variety of combination and degree. Thus, there may be internal ophthalmoplegia only, or external, or both. In the internal form there may be loss of the iris-reflex only or of the ciliary muscle action only. In the external variety the levator and superior recti are commonly first involved, the other muscles gradually. There may be loss of the upward and downward movement of the eye, ptosis, and conjugate lateral palsy. There may be double vision, generally of short duration. In the total form the eye is fixed and immovable. Each variety may be associated with tabes dorsalis, general paralysis of the insane, progressive muscular atrophy, and bulbar palsy, often with syphilis. It is more common in

males, and occurs occasionally in the young. There is a form occurring in children, known as infantile oculo-facial palsy, which may be congenital or acquired; rarely, it occurs as a sequel of diphtheria, late and permanent.

The disease may be very slow in developing, and may require years. Sometimes one eye is more affected than the other. If the internal muscles are unaffected, the disease is quite certain to be nuclear disease, because these muscles can scarcely escape bilateral disease of the nerve trunks. Indeed, v. Graefe thought this absence of involvement of the internal muscles characteristic. Palsy of the external ocular muscles is likely to be accompanied by facial palsy.

In *sudden nuclear palsy*, the second in frequency, the onset may take but a few minutes or an hour or two. The causes in such cases are commonly obstruction to the basilar arterial branches, rarely embolic obstruction, and still more rarely hemorrhage. The obstruction is usually bilateral. The lesions are irregular, and the symptoms are correspondingly irregular and unsymmetrical; the tendency is to recover. In these respects it differs from the chronic form also in that hemiplegia is a frequent accompaniment, generally on the side opposite the greater eye palsy. When hemorrhage is a cause, the resulting ocular palsy lasts usually but a few hours, provided the hemorrhage acts on the ocular centers only by pressure, while the other phenomena of pressure by effused blood, which is apt to spread, make their appearance.

Acute nuclear palsy is rare. It develops in a few days or weeks, and is possibly of inflammatory or toxic origin, whence called by Wernicke *poliomyelitis superior*; but toxic cases may occur without inflammation. This form, according to Gowers, may be due to peripheral neuritis and not to nuclear disease. Alcohol may be a toxic cause. The eye muscles are invaded irregularly, and it is common for the internal muscles to escape. In fatal cases the causal influence extends to the centers of other nerves and possibly to the cortex. In cases that survive there is improvement, various in degree.

Treatment of Ocular Palsies.—The cause should be sought and, if found, treated. Although syphilis is thought to be one cause of this disease and of tabes dorsalis, with which it is so frequently associated, disappointment follows the syphilitic treatment in the majority of cases. Yet mercury perhaps accomplishes more than any other single remedy. Arsenic, strychnin, and iron are sometimes used, strychnin hypodermically.

In acute cases, when there is pain, hot fomentations, leeches, and counterirritation may be used. In chronic forms electricity has been extensively used, galvanism being preferred. Benedikt recommended placing the anode, or positive pole, on the forehead, and the cathode, or negative pole, on the margin of the orbit near the affected muscle. If the faradic current is used, the orbital pole is held still; if the voltaic, it is kept moving over the skin, or the current is broken by the commutator. To overcome the ptosis, electric stimulus is applied to the third nerve, as the muscle is not accessible.

The diplopia is removed by a prism not strong enough to fuse the two images completely, but of sufficient force to approximate them, so that the fusion may be completed by muscular action. Such action may be practiced for an hour each day. The dizziness due to erroneous projection can be removed only by throwing the eye out of use by an opaque glass. Operative treatment is not recommended.

Periodical Oculomotor Paralysis.—Up to June, 1890, according to A.

Nieden,* 21 cases of periodical oculomotor paralysis had been published. The organic lesion at the bottom of these paralyses is not yet settled upon. Möbius,† who was one of those who has contributed largely to the subject, claimed a nuclear degeneration as the cause, while Mauthner ‡ another contributor, considers that the majority of cases have a basal cause, by which it is presumed he means a basal meningitis or other cause compressing the trunk of the nerve at the base of the cranium.

In the paper referred to, Nieden reports a case of periodical combined facial and abducens paralysis occurring in a woman thirty-six years of age, who had seven attacks involving the sixth and seventh nerves, separately or jointly, at intervals of from a few days to several months. Between these attacks she was free from symptoms. At other times there was derangement of other cranial nerves, especially of the auditory on the same side, manifested by tinnitus, which considerably interfered with the sense of hearing for the time. Again, in the fourth attack there was a paralysis of the left half of the tongue, which made speech stammering and unintelligible. All the attacks were accompanied by severe headache, which is more or less characteristic of oculomotor paralysis.

Morbid Anatomy.—From these conditions Nieden infers an involvement of the muscular region of the sixth and seventh cranial nerves affecting first the nucleus of the latter on the left side, and after a short interval the former of the same side and a part also of the nucleus of the hypoglossal. He thinks that there may have been an exudation in the region of the floor of the fourth ventricle deep enough to involve the nuclei of these nerves as well as the trunks of some of them.

Treatment.—Because of syphilitic origin, in many of these cases mercurial treatment proved promptly efficient, while at times the symptoms subsided spontaneously.

LESIONS OF THE TRIFACIAL OR FIFTH NERVE (TRIGEMINUS).

Anatomical.—This important mixed nerve of the face supplies by its motor trunk the muscles of mastication; by its sensory portion, the skin of the face, the mucous membrane of the mouth and nasal cavity, the conjunctiva, and the cornua; also, according to some physiologists, the anterior part of the tongue with gustatory fibers. The gustatory fibers are supposed to reach the lingual fibers of the fifth nerve by the chorda tympani nerve. Recent studies of Harvey Cushing make this doubtful.

Lesions.—1. There may be lesions of the pons, especially hemorrhage, or areas of sclerosis invading the trigeminal nucleus.

2. Injury or disease at the base of the skull, especially acute and chronic meningitis and caries of the bone, tumors, syphilis, new formations compressing the trunk or the Gasserian ganglion. Fracture of the base rarely affects this nerve.

3. Tumors or aneurysms pressing on the first division (ophthalmic) of

‡ Mauthner, "Die ursächlichen Momente der Augenmuskellähmungen," "Vorträge," S. 415, Wiesbaden, 1885, Bergmann.

the nerve through the cavernous sinus, on the second division (superior maxillary) and on the third division (inferior maxillary) by invasion of the sphenomaxillary fossa.

4. There may be inflammation of the nerve, which is rare.

The sensory division may also be affected in hysteria. The gustatory fibers of the trigeminus may be influenced by peripheral lesions of the facial, whence the chorda tympani is derived.

Symptoms.—*Paralysis of the Sensory Portion.*—The distribution of the anesthesia varies according as the whole trigeminus or only a part is involved. In total anesthesia there is loss of sensation in half the corresponding side of the head, including the conjunctiva and cornea, mucosa of the lips, tongue, hard palate, and nose of the same side. Hence on the tongue or mucous membrane there are often ulcers which come from unconscious lacerations by the teeth. There is, according to the views of many, loss of the senses of taste and smell. The loss of the sense of smell is probably due to drying of the mucous membrane, as it is not probable that the fifth nerve contains olfactory fibers. The so-called trophic phenomena are also observed, and among them the much-discussed *neuroparalytic ophthalmia*, an ulcerative keratitis, beginning, also, always in the lower segment of the cornea, and passing over into purulent inflammation of the whole eyeball. It seems, on the whole, more likely that the inflammation is primarily due to the action of irritants which in health are excluded by the proper closure of the eyelids, though the inflammatory process itself may be trophically influenced. The salivary, lacrymal, and buccal secretions may be diminished and the teeth may become loose. Herpes is a trophic result which may develop in the course of the nerve, is painful, and may last a long time. So, too, the anesthesia may be preceded by tingling. The skin of the face is sometimes swollen.

Paralysis of the motor portion, which supplies especially the muscles of mastication, the masseters, temporals, and pterygoids, is not common. It is most frequent in diseases of the base of the skull, compressing this branch. Difficulty in chewing is the result. If on one side, the patient can chew only on the other; if on both sides, he cannot chew at all. The lower jaw hangs down, and cannot be moved from side to side because of the paralysis of the pterygoids. If on one side, the external pterygoid cannot push the jaw toward the sound side, and when depressed, the jaw is pushed by the muscle of the sound side toward the paralyzed side. Cases have occurred associated with cortical lesion; from one such Hirt inferred that the motor center for the trigeminus is in the neighborhood of the lower third of the ascending frontal convolution.

Spasm of muscles of mastication is found in connection with muscular cramp, the muscular contraction of tetanus (trismus), sometimes in tetany and meningitis, and reflexly through painful affections of the jaw or teeth, or from irritation near the motor nucleus. It is also sometimes hysterical. Clonic spasm occurs in muscles supplied by the fifth nerve, constituting "chattering teeth." It occurs generally in connection with general conditions, such as chorea, but it may happen as a local symptom in women late in life.

Diagnosis.—This is not difficult. Sensibility is tested in the ordinary way. The preliminary pain must not be mistaken for *neuralgia*. Gustatory sense is tested in the anterior end of the tongue by applying weak acid or salt solutions and comparing the effect on the two halves. The motor power

is tested by biting on a piece of wood or cork or by moving the jaws against resistance.

Treatment.—This must depend upon the cause, which should be carefully sought. Syphilitic new formations are the lesions most commonly amenable to treatment. In the absence of such causes the treatment must be symptomatic. Stimulating liniments and faradization through the electric brush are often useful. Galvanism may also be used, brushing the part with the cathode. The anesthetic part should be carefully protected against irritants.

In the absence of tangible cause, systemic treatment is not indicated, except to build up the general health of the patient.

LESIONS OF THE FACIAL NERVE, OR SEVENTH PAIR.

The seventh pair (portio dura of the seventh, old classification) is the motor nerve of the face, and is subject to paralysis of motion and to spasm.

PARALYSIS OF THE FACIAL NERVE.

SYNONYMS.—*Mimetic Facial Paralysis; Bell's Palsy; Monoplegia facialis.*

Monoplegia facialis may be caused by lesions in the cortical center of the nerve, in the brain between the cortex and the nucleus, in the nucleus itself, and in the nerve trunk.

Supranuclear Paralysis.—The cortical center resides in the foot of the central convolution, probably the anterior central, from which pass out fibers along with the pyramidal fibers through the internal capsule to the facial nucleus in the tegmentum of the pons on the opposite side. Accordingly, the nerve is commonly involved in hemiplegias—in fact, facial paralysis forms a part of most hemiplegias. Such a paralysis, due to lesion above the facial nucleus, is known as *supranuclear*.

In such a palsy the voluntary muscles of the lower half of the face are paralyzed, while the secretory and gustatory functions of the facial are not affected; nor are the orbicularis and forehead muscles, except in some cases in the beginning of the hemiplegia, these being innervated by the upper branch of the facial. These features, together with the normal electrical excitability of both nerve and muscle, the intact reflexes and taste sense, all point to a *central* facial paralysis as distinguished from a peripheral. The limitation of the paralysis to the lower half of the face is due to the fact that the lower portion only of the face receives more exclusively crossed innervation, while the upper part, like the ocular muscles and the motor trigeminus, is innervated more from both hemispheres, so that a lesion in one be overbalanced by the other. This will be understood by an examination of the schematic drawing (Fig. 128), from which it is plain that a one-sided brain lesion at *a* paralyzes only the inferior and not the upper facial. Recent investigations show that the upper and lower branches of the facial nerve have not separate nuclei. That they are *functionally* distinct is further shown by the fact that in bulbar paralysis, also a disease of the nerve nuclei of the medulla oblongata, only the inferior facial is involved. That the upper face muscles are totally uninvolved in central facial paralysis is not quite true, for careful examination will show

that the function is not quite so perfect as in health; the patient cannot close the eye of the paralyzed side by itself, as in the normal state; whence it follows that the upper half of the face is innervated from both hemispheres, as is also shown in Figure 128. The crossed influence is, however, the larger.

Cortical facial paralysis, *monoplegia facialis*, has been found associated with lesions in the center for face muscles in the lower Rolandic region, but isolated facial paralysis due to involvement of the nerve-fibers in their path from the cortex to the nucleus is extremely rare. Cortical or capsular facial paralysis, as already explained, is on the same side as that of the arm and leg.

Nuclear Paralysis.—Paralysis may also be caused by lesions of the nucleus, but is not common. There may be tumors, chronic softening, and

Fig. 128.—Schema for Central Innervation of the Facial Nerve—(after Sahli).

The nucleus of the upper branch is innervated from both hemispheres, though mostly from the opposite side, while the nucleus of the lower branch is innervated almost totally from the opposite side.

hemorrhage, while rarely anterior poliomyelitis may involve the facial nucleus or it may be attacked by the diphtheritic poison. The symptoms are essentially the same as those of paralysis of the trunk of the nerve, or peripheral facial palsy.

Infranuclear Paralysis, or, Peripheral Facial Paralysis.—This includes all cases due to involvement of the nerve trunk. The distinctive features of this, as compared with cortical paralysis, have already been stated. It still remains, however, to determine the precise segment of the nerve involved, to be again referred to when treating of diagnosis.

Etiology.—*Cortical paralyses* are usually due to compression or de-

struction of the cortical center, as by traumatism, hemorrhage, tumor, meningitis, or embolism. *Nuclear paralysis* may be caused by tumors, chronic softening, hemorrhage, or the diphtheritic toxin, while rarely anterior poliomyelitis may involve the facial nucleus.

The most frequent cause of *peripheral paralysis* is exposure to cold, as to a cold wind or draft from an open window. Such cases include so-called rheumatic paralysis, and may be due to neuritis. Disease of the middle ear and caries of the petrous portion of the temporal bone are relatively frequent causes, which have evident explanation in the course of the facial through the Fallopian canal adjacent to the tympanic cavity, whence it may be invaded. At the base of the brain, tumors, syphilitic new formations and inflammatory processes also involve the facial. Rarely swelling of the parotid gland is a cause of pressure. Finally, the facial is frequently implicated in disease of the brain and medulla oblongata.

Symptoms.—The symptoms vary with the exact seat at which the nerve is invaded. Paralysis of the facial muscles of expression produces the most striking change of physiognomy. The homely description, understood by everyone, is that the face is drawn to one side; and so it is—to the sound side, except in old cases after contracture has occurred. Examination discloses that on the opposite and paralyzed side there is a remarkable smoothness of face, the wrinkles have disappeared from the forehead, the labionasal fold is gone, and this half of the face is quite expressionless. The corner of the mouth is lowered, while saliva frequently flows from it; the eye is wider open than natural, and can be only partly closed, even during sleep,—*lagophthalmos*,—and the eye waters. These symptoms are rendered still more striking on effort at smiling, talking, or whistling, at turning up the nose, wrinkling the forehead, inflating the cheeks, or closing the eyes. On attempting the latter the upper lid drops as though heavy, the eye is turned upward, the pupil covered, but quite a space remains “uncovered.” The so-called “corneal” and “optical” reflexes, by which, through closure of the lid, the eye protects itself from the entrance of foreign bodies seen approaching, are lost, and a tendency to conjunctivitis results.

In complete facial paralysis winking is impossible. Whistling is also impossible, and speech may be interfered with, owing to the difficulty in forming labial sounds. The proper muscles of manifestation are not paralyzed, but, owing to paralysis of the buccinator muscle, food collects between the teeth and cheek on the paralyzed side, and an attempt to sniff reveals paralysis of the nasal muscles. The upper teeth cannot be uncovered, and an attempt to drink is only partly successful, because the lips cannot be kept close to the glass. The tongue is sometimes described as protruding toward the paralyzed side, but this appears to have been an error. The organ is really central, when examined in its relation to the incisors, and the erroneous impression arises from the fact that the lips are drawn to the sound side. Many authorities speak of a paralysis of the soft palate on the affected side, since facial fibers pass through the superficial petrosal nerve to the sphenopalatine ganglion. It is described as drooping, while effort at phonation raises the soft palate obliquely to the sound side. Both Gowers and Hughlings Jackson, however, deny this symptom in most cases, and are sustained by the discovery of Horsley, and Beevor, that the soft palate is innervated by the spinal accessory nerve. The innervation of the soft palate is not definitely known.

Derangement of taste also occurs in the anterior two-thirds of the tongue on the paralyzed side in cases where the facial is involved in that part of its course in which it contains the chorda tympani nerve—that is, in the Fallopian canal between the genu and the union of the chorda tympani with the facial. When the nerve is affected outside of the skull, the sense of taste is intact. Tactile sense in the tongue is also sometimes lessened; salivary secretion is diminished, producing dryness of the mouth. Hearing may be more acute, especially for low notes, because of paralysis of the stapedius muscle, antagonized by the tensor tympani, which is innervated from the

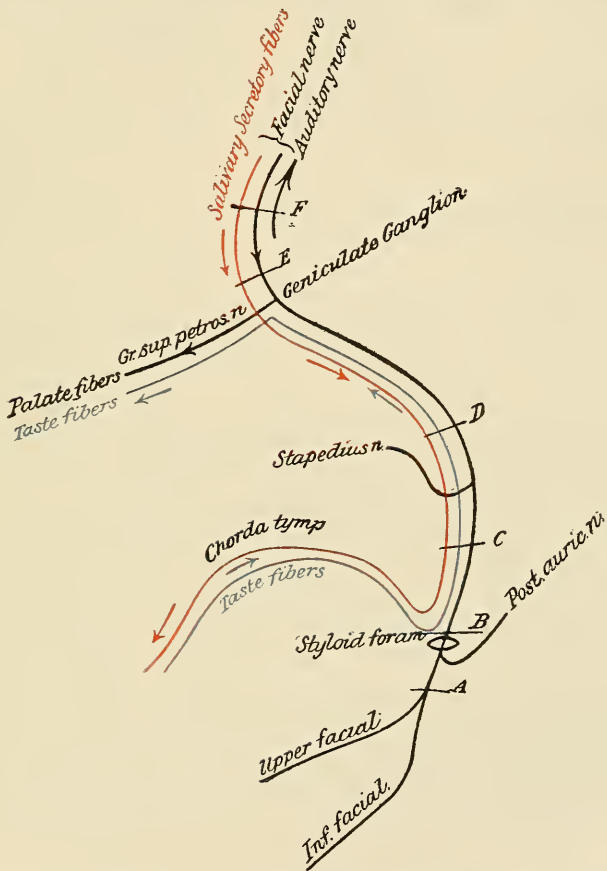

Fig. 129.—Simplified Drawing of the Peripheral Distribution of the Facial Nerve—(after Sahli).

trigemini. Hence results a greater sensitiveness of the membrana tympani. Other disturbances of hearing are also present, but they are generally due to associated aural trouble. Herpes is also an occasional symptom, and is ascribed to the presence of trigeminal filaments among those of the facial.

Facial paralysis usually sets in suddenly, rarely gradually. Sometimes there are prodromata, consisting in abnormal sensations of taste, pain in the ear and face, and ringing in the former, all from inflammation of the nerve. With this exception, pain is not common.

Diagnosis.—The recognition of the presence of paralysis of the facial is for the most part easy. More difficult, and proportionately important, is it to ascertain in what part of its course the function of the nerve is cut off. This is rendered easy by the appended schematic drawing of the distribution of the facial nerve, after Sahli. (See Fig. 129.)

The phenomena vary in accordance with the following:

(a) Lesion at *A*, trunk of the facial, affecting only the mimetic branches. Paralysis of all the facial muscles; taste, secretion of saliva, hearing, and palate normal.

(b) Lesion at *B*, within the styloid foramen. Paralysis of facial muscles, and occipital muscles innervated by the posterior auricular nerve.* Taste, secretion of saliva, hearing, and soft palate normal.

(c) Lesion at *C*. Paralysis of the facial muscles, derangement of taste, diminished secretion of saliva; hearing and soft palate normal.

(d) Lesion at *D*. Paralysis of the facial muscles, derangement of taste, diminished secretion of saliva, abnormal acuteness of hearing, and paresis of soft palate.

(e) Lesion at *E*, above geniculate ganglion. Paralysis of the facial muscles, diminished secretion of saliva, abnormal acuteness of hearing, paresis of soft palate, but no disturbance of taste.

(f) Lesions at *F*, in Fallopiian canal, often associated with a lesion of the auditory nerve in consequence of its proximity to it. Paralysis of facial, diminished secretion of saliva; hearing may be influenced by common lesions to auditory; palate normal, taste normal.

The student is referred to what has previously been said as to the modification rendered necessary by the observations of Gowers and others on the non-involvement of the soft palate in facial palsy.

We are aided also in recognizing precise forms by the causes, if known, like the presence of ear disease, or a history of exposure to cold or of traumatism. Coexisting symptoms of brain or bulbar disease must also be considered. Reaction of degeneration cannot occur in true cerebral facial palsy, only in peripheral palsy or in such bulbar paralysis as affects the facial below the nucleus itself. In cortical facial paralysis the frontal distribution of the facial nerve and the ocular muscles are not seriously affected except in the early stages; in the peripheral paralysis they are.

The existence of bilateral facial paralysis—*diplegia facialis*—points almost invariably to a central lesion, and more especially to a bulbar affection, since it must be a rare event to have a simultaneous involvement of both nerves in their peripheral distribution, though its possibility cannot be denied.

Prognosis and Course.—The prognosis varies with the etiology and with the degree of severity. Some cases get well rapidly; others partly recover; many are permanent. The following division of forms with their probabilities, according to Erb, will be helpful:

1. *The Mild Form of Facial Paralysis.*—To this many rheumatic cases belong. The affection is usually one of facial muscles only. Electrical excitability in the paralyzed muscles remains normal, and there are no severe and deep-seated changes in nerves or muscles. Recovery is rapid, usually taking place in two or three weeks.

2. *Middle Form.* There is partial reaction of degeneration, the ex-

* Since the occipital muscle is in most men not under control of the will, its paralysis can be ascertained only by the electrical test (reaction of degeneration).

citability of nerve being diminished but not lost; in the muscles, however, in two or three weeks, there is decided increase of galvanic excitability to direct excitement, the anodal closure contraction being greater than the cathodal while contractions are slow. Recovery may still be quite rapid, usually in from four to six weeks.

3. *Severe Form.*—Complete reaction of degeneration in nerve and muscles—*i. e.*, loss of faradic and galvanic excitability of nerve, loss of faradic excitability of muscle, and quantitative and qualitative changes in galvanic excitability of muscle. In this form there is always degeneration of nerve and muscle, so that, if recovery takes place at all, it is only after two or six months, or longer.

In these cases there often intervene symptoms of motor irritation, consisting:

1. In a marked tonic contraction of the paralyzed muscles, sometimes very striking.

2. Single spasmodic contraction of muscles.

3. Special associated movements. Thus, if the patient closes his eyes or winks, there always follows a marked distortion of the corner of the mouth, which cannot be restrained.

4. An increased reflex irritability, as the result of which, on pricking or blowing on the skin, vigorous muscular contractions follow.

These symptoms last for a long time—for years in incurable or imperfectly cured cases.

Further points bearing on prognosis have reference to the nature of the primary disease. Paralysis caused by tumors of the base of the brain and caries of the petrous bone is almost always incurable. If the paralysis is due to middle-ear disease, the prognosis depends on the curability of the ear disease. The electrical examination affords helpful data. If at the end of one or two weeks electrical excitability still remains normal, a rapidly favorable termination may be predicted. If, on the other hand, the reaction of degeneration is present, a much longer course and delayed recovery, if any, may be expected. Relapses may occur.

Treatment.—The treatment, is, of course, that of the lesion which lies at the bottom of the paralysis. If it is a syphilitic, inflammatory product, the iodids should be administered in the usual ascending doses. Middle-ear disease should receive the promptest and closest attention, as some of the most unfortunate cases are thus caused. Any possible cause of pressure should be sought and removed.

When cold is the cause, and the case comes early under observation, warmth, either dry or moist, should be applied to the distribution of the nerve in the face, while mild counterirritation at the *pes anserinus* is useful. Decided blistering is of questionable utility, but it is harmless and may do good.

For the paralysis remaining after the removal of the cause electricity is indicated, and more especially the constant current. A weak current should be used for from three to five minutes at a time, interrupting from four to six times a minute, placing first the anode and then the cathode in the auriculo-mastoid fossa, the other pole in front of the ear. Galvanism and faradization may be applied to the muscles themselves, including the orbicularis, the direct effect of the electricity on which is shown by an increased power to close the eye immediately after the application of the current. Massage of the muscles may be used.

Sulphate of strychnin is a drug which has some reputation in facial paralysis, although it is difficult to trace the results of its use. Its administration by subcutaneous injection, daily or on alternate days, is recommended. The salicylates may be used with advantage in some cases.

FACIAL SPASM.

SYNONYMS.—*Mimetic Facial Spasm; Convulsive Tic.*

Facial spasm is manifested in a variety of ways. Mimetic facial spasm, or convulsive tic, consists in a clonic contraction of the muscles supplied by the facial nerve, a few or all, usually unilateral, sometimes bilateral. A similar condition, especially frequent in children, as the result of imitation or of habit of grimacing, is known as *habit spasm*.

Etiology.—No cause can be found for most cases. Possible causes are exposure to cold, lesions at the base of the skull, or irritation of the facial center in the cerebral cortex. Other cases may be explained by reflex causes, such as irritation by carious teeth, intestinal worms, or disease of the sexual organs. Others have been ascribed to violent mental excitement. Predisposition to the disease is heightened by a hereditary neuropathic habit.

Symptoms.—These consist in short contractions in the muscles affected. Sometimes the contractions are of longer duration. The face is the seat of constantly changing grimaces during waking hours. Sometimes, however, there are intervals of complete rest. The contractions are commonly without exciting cause. Sometimes they invade adjacent muscles, as those of mastication, the tongue, or the muscles of the neck. Voluntary motion is unimpaired, and there is no pain or anesthesia.

Blepharospasm.—A variety of the partial form is *blepharospasm*, a tonic or clonic spasm of the orbicularis muscle. In the clonic form it is apt to be associated with spasm of the lateral facial muscles, and there is constant twitching of the side of the face, with partial closure of the eye. In another clonic variety there is constant contraction of the eyelids and consequent winking.

The tonic form is usually reflex in origin, bilateral, and may last for days or weeks, with occasional interruptions. The reflex cause is commonly some affection of the eye, producing photophobia, or it may reside in some other point in the distribution of the trigeminus. The clonic form may also sometimes be traced to a reflex cause.

Very interesting in connection with blepharospasm is the discovery by v. Graefe of certain so-called "pressure points." These are points at which pressure causes the spasm to cease, so that the eyelids "fly up as if by a spring." These are commonly found at points of exit of the trigeminus, but have also been found on the vertebral column and elsewhere.

For other forms of spasm of the facial nerve see *Choreiform Affections*, page 1097.

Prognosis.—This in all forms is, as a rule, unfavorable. There are intervals of suspension, sometimes of considerable length, but the spasm recurs, and the disease generally remains incurable.

Treatment.—The treatment is correspondingly unsatisfactory, but a number of things may be done. Causes of reflex irritation should be sought and removed, such as carious teeth and ophthalmia. Paquelin's cautery may be applied to the trunk of the nerve, or to pressure points, if

they exist. Nerve section of the supra-orbital nerve has been practiced in blepharospasm. Nerve stretching has been followed by relief, at least as long as the paralysis continues, which is commonly a welcome substitute for the twitching. The constant current may be used, seeking also for pressure points, to which the anode is to be applied. If there are none, this pole should be applied to the trunk of the nerve and to the different branches of the pes anserinus. In cases of reflex origin Berger reports that satisfactory results were obtained by applying the anode to the occiput just under the protuberance, while the cathode was held in the hand—an attempt at galvanization of the medulla oblongata. The single sitting should last from five to ten minutes. Weir Mitchell recommends the freezing of the cheek every day or every other day with the rhigolene spray; at least transient relief follows.

As to medicines, those usual in nervous affections should be tried—bromid of potassium, strychnin by hypodermic injection, arsenic, iron, oxid of zine, atropin, curare.

The treatment of convulsive tic is that of hysteria.

LESIONS OF THE AUDITORY OR EIGHTH NERVE.

The eighth pair (portio mollis of the seventh in the older classification of Willis) may be affected anywhere in its course from its cortical center in the upper part of the first temporo-sphenoidal convolution, thence in the internal capsule across to its nucleus at the junction of the pons with the medulla oblongata, or at the base of the brain after it passes out of the pons into the internal auditory meatus to its distribution in the cochlea and vestibule. The proximity of this nerve to the facial at the base of the brain and in the internal auditory meatus is to be remembered. As indicated by its name, it is softer and more vulnerable than the facial, so that equally acting causes may affect it and leave the facial intact.

The auditory nerve should be regarded as two nerves—the cochlear and the vestibular; the former having to do with hearing and the latter with co-ordination.

Symptoms.—Directly due to disease of the auditory nerve are limited to some derangement of hearing, and it is their association with others which widens their significance in the study of nervous diseases. The derangements of hearing resulting from such lesion are six:

1. Loss of hearing, or deafness.
2. Increased sensitiveness, auditory hyperesthesia, or hyperacusis.
3. Symptoms of irritation, causing subjective aural sensations—tinnitus aurium and allied symptoms.
4. Disturbances of equilibrium or sensation of such, due to irritation of the fibers in the semicircular canals—Ménière's disease.
5. Certain rare instances of involuntary movements, due to disease of the nerve within the ear, as oscillatory motions of the head.
6. Purely functional derangements of hearing, occurring especially in connection with hysteria and with anemia following large hemorrhage.

I. LOSS OF FUNCTION; NERVOUS DEAFNESS.

Etiology.—Deafness may be congenital when it is due to labyrinthine defect. According to Gowers, 80 per cent. of deaf mutes are congenitally

deaf. The remaining 20 per cent. become so from disease in early life. Of congenital cases it is said that the intermarriage of relations having similar defects is responsible for some, while such intermarriage, even where there is no such defect, is held responsible for a smaller number. Partial as well as total deafness may be congenital.

Of the cases of acquired nervous deafness, disease of the labyrinth, either primary or secondary to that of the middle ear, causes most. The labyrinth is subject to inflammation, acute or chronic, to syphilitic disease, to degeneration, and to hemorrhage. It may be invaded by meningitis, cerebrospinal or tuberculous. Its membrane may undergo degeneration, due to gout or simply to old age. The product of all these may be fibrous or calcareous new formation. The deafness caused by certain drugs, as quinin, has been ascribed to congestion of the internal ear, and that by loud noise, as the explosion of artillery, to hemorrhage.

Lesions of the nerve trunks are less common causes. They may be of the same character as those of the labyrinth, except primary inflammation, although even this is said to be a cause. Primary degeneration may occur in tabes dorsalis. The nerve may be compressed by thickening of the cranial bones, calcareous nodules, tumors, or extravasated blood.

The nuclei within the pons may be damaged by hemorrhagic extravasations and tumors. Above the nuclei there may be a lesion encroaching on the superficial layer of the tegmentum, a lesion in the internal capsule, or in the cortical center.

Symptoms.—Since, as already stated, derangement of hearing constitutes the only essential symptom of nervous deafness, any enlargement of the subject can be made only by considering the modifications and conditions of this symptom, and by reviewing such methods of determining the precise seat of the lesion as exist.

The ability to hear through the bone while the air conduction is impaired implies that the function of the labyrinth is intact, and that deafness is due to obstruction of the meatus or to disease of the middle ear and not to nerve deafness. This is further confirmed if the bone conduction is intensified by closing the meatus, since in this way the vibrations, which ordinarily pass out by the meatus, are retained. On the other hand, if there is diminished bone conduction, it does not necessarily follow that the labyrinth is diseased, because there may be ankylosis of the stapes, which will diminish bone conduction, although no amount of disease of the middle ear will extinguish it if the labyrinth be intact. Further, in health air conduction is heard after bone conduction ceases. This is the basis of Rinne's test, in which the vibrating tuning-fork is first placed upon the mastoid process and allowed to remain until the sound dies away to the patient, when the fork is suddenly transferred to the external auditory meatus of the same ear. If the air-conducting apparatus is normal, the vibration of the fork should again be heard. Again, there may be a moderate impairment of hearing and maintenance of the relative delicacy of the air conduction. Absence of bone conduction is, however, the characteristic symptom of nervous deafness. So, to a less degree, is deafness to short and high-pitched sounds, whence the high-pitched, short sounds of the ticking of a watch is a delicate test of the ability to hear through the bone. Simple senile labyrinthine degeneration may be responsible for inability to hear the ticking through bone in persons sixty years old or more.

Can we distinguish between labyrinthine disease and disease of the

nerve before its terminal distribution? Given the absence of bone conduction, if the facial nerve is paralyzed, and there is no disease of the middle ear or of the bone, we may conclude that the nerves (facial and auditory) are affected at the base of the brain or in the internal meatus. If there is disease of the middle ear along with deafness and paralysis of the facial, it is probable that the facial nerve and labyrinth are affected by extension of the disease from the tympanum, but this is not certain. An involvement of the trunk of the nerve at the base is also probable if some other nerve near it, as the sixth, is involved. The fact that the auditory nerve is more sensitive to pressure than the facial has already been mentioned, whence an agency, such as an inflammatory product, pressing on both nerves may affect the auditory and leave the facial intact.

No distinctive symptoms have been found associated with lesion of the auditory nuclei in the medulla oblongata. Such lesion is very rare, but has been found associated with deafness on the same side, while it has also been found when the hearing has been unaffected. Sudden deafness, associated with other symptoms of a lesion of the pons or medulla oblongata, should excite suspicion of nuclear lesion, especially if paresis of limbs on the opposite side be one of those symptoms.

The auditory fibers between the cortex and the auditory nucleus in the pons, in their passage through the tegmentum, may also be affected and may produce deafness. Such a lesion is a tumor of the corpora quadrigemina.

Lesions of the cortical center are very rare, though they have been sufficiently frequent to confirm the results of experiment on the monkey, which go to show that the first temporo-sphenoidal gyrus represents the center for hearing, since the destruction of this gyrus on the left side in man has been attended by word-deafness. It is possible that the first temporal gyrus in each hemisphere in man must be damaged in order to produce cortical deafness for sound. Hemorrhages, softening, and pressure by fractures or tumors may be causative lesions in this situation.

Treatment.—This is for the most part unsatisfactory, at least from the physician's standpoint. Careful otoscopic examination should be made with a view to discovering the existence of disease of the external and middle ear, and the aural surgeon should invariably be consulted in derangements of hearing of more than brief duration, with a view to obtaining certainty of diagnosis between nerve deafness and disease of the middle or external ear. Suspected syphilitic tumors should be treated by iodids. A blister in front of or behind the ear may be useful, especially in acute cases; but deep blistering should be avoided in front lest it cause facial neuritis. Electricity has been employed with partly satisfactory results.

2. AUDITORY HYPERESTHESIA.

True hyperesthesia, or hyperacusis, is a condition in which ordinary sounds are heard with more than normal acuteness, and in which sounds inaudible become audible. In dysesthesia, or dysacusis, ordinary sounds, although not intensified, produce discomfort. There is generally present some pre-existing symptom, as a headache, during which sounds usually without effect intensify the headache. Both these conditions occur in functional as well as in organic brain disease. Of the former, hysteria is an instance; of the latter, meningitis.

Treatment.—The treatment, outside of the removal of the cause, is by nerve sedatives, as the bromids, preparations of valerian, and asafetida.

3. IRRITATION OF THE AUDITORY NERVE—TINNITUS AURIUM.

The term tinnitus includes almost every conceivable form of auditory subjective sensation, of which the most common is ringing, roaring, or hissing. The tinnitus may include humming, ticking, the sound of rushing steam, the roaring of machinery and the like, the sound of a bell, and even articulate speech, music, or the sound of voices. It may be persistent or intermittent, with rhythmical intermissions—these commonly corresponding with the beating of the pulse. The sounds may be so slight as to be forgotten when the attention is directed to something else, or they may be heard through everything, causing the sorest distress and misery. In fact, their victims have even been impelled to self-destruction. The clicking symptom, sometimes audible to those standing near, is often very annoying, and may be due to clonic spasm of the muscles connected with the Eustachian tube or levator palati. The so-called premonitory "aura" of epileptic seizures may be a variety of tinnitus.

Etiology.—Beyond what is conveyed by the word "irritation," it is exceedingly difficult to discover the cause of tinnitus. Changes in the labyrinth appear to be the most common, and Gowers tells us that "evidence of nervous deafness, mostly due to changes in the internal ear, is distinct in four-fifths of the cases which come under the physician's notice. Disease of the middle and external ear, including inflammation and wax accumulation, is also a fruitful cause, while in a few cases the process may be wholly in the auditory centers, in the nucleus of the nerve, or in the cortical area. Blood movement, not usually audible, may become so. Internal aneurysm is a possible cause. Tinnitus is a very frequent symptom in gouty cases, in my experience, especially when associated with the nervous temperament. So it is in anemia and neurasthenia. An epileptic aura is often a tinnitus. A systolic brain murmur is sometimes heard over the ear in children, and even in adults.

Treatment.—This is generally most unsatisfactory. The ear should be explored and its surgical diseases treated.

The gouty diathesis must be treated by the administration of the salicylates, colchicum, and purgatives, and by regulation of the diet; anemia and neurasthenia by iron, arsenic, nutritious food, and rest. Large doses of salicylic acid and quinin, it is known, produce ringing in the ears—a fact to be remembered always.

The bromids are sometimes beneficial, and a few drops of tincture of belladonna are sometimes added. Nitro-glycerin has been highly commended. Beginning with doses of 1-100 grain (0.00066 gm.), they should be rapidly increased until the physiological effect is produced. My experience with nitro-glycerin is that the physiological effect is often not attained in adults even by doses of 1-100 grain (0.00066 gm.).

Counterirritation is undoubtedly useful at times. It should be applied behind the ear, and actual vesication is the most efficient form. The temporary effect is sometimes striking, while permanent results may be produced by repeated blistering.

4. DISTURBANCE OF EQUILIBRIUM ASSOCIATED WITH DEFECT OF HEARING—LABYRINTHINE VERTIGO. MÉNIÈRE'S DISEASE.

Definition.—The term Ménière's disease is applied to a vertigo, usually sudden, associated with deafness and noises in the ear.

Pathology and Etiology.—In 1861 Ménière described some cases in which vertigo was produced by a sudden lesion of the labyrinth. Since then the term Ménière's disease has come to be applied to all cases of sudden vertigo associated with labyrinthine disease. Gowers says that "in nine cases out of ten in which there is definite giddiness, not epileptic in nature or obviously due to organic brain disease, it is due to a morbid state of the labyrinth or auditory nerve endings." Thus the vertigo becomes the result of the irritation of the nerve.

In addition to clinical sources for the confirmation of this view there is the fact that experimentally induced lesions in the semicircular canals of animals result in vertiginous movements. In point of fact, aural vertigo results from almost any one of the morbid processes possible to the labyrinth and the nerve endings it contains, but not from disease of the middle ear. The precise nature of the morbid change can only be conjectured. It is twice as frequent in men as in women, and four-fifths of all cases occur between the ages of thirty and sixty. Cold, gout, and syphilis have been followed by it, probably through inflammation, and possibly resulting hemorrhage. The slower forms may be due to degenerative processes, like those of tabes or such as are due to age. Vasomotor neuroses of the vessels of the labyrinth have been held responsible.

Symptoms.—The vertigo is usually sudden and paroxysmal, though there may be slight continuous dizziness between paroxysms, which occur at intervals of from a few days to as many weeks. Occasionally they occur daily. They may be spontaneous or an exciting cause of trifling character may bring them on, such as turning, coughing, or sneezing. Gastric disturbances may excite them—a fact to be remembered in the differential diagnosis from gastric vertigo. There may be brief unconsciousness. The attacks generally pass off in a few minutes, leaving the patient pale, faint, and nauseated, often in a cold, clammy sweat. Vertigo may or may not be accompanied by a tendency to fall forward, backward, or to one side, and the victim may have to grasp something to save himself from falling. External objects may appear to circle about him. The seeming movements of person and external objects are usually in the same direction.

The auditory symptoms—deafness and tinnitus—may be in one or both ears, and more marked in one side than in the other. In the latter case the sense of movement may be toward or from the ear most affected; but when the subjective and objective movements coincide in direction, they are more often toward the affected side.

The deafness is nervous and always partial. The tinnitus is usually roaring or throbbing. There may be ocular symptoms; these are secondary, and include nystagmus and diplopia. Pressure on the drum or on the meatus may bring on the nystagmus, and sometimes an apparent jerky movement of objects. Diplopia, nystagmus, and jerky movements may occur together.

Diagnosis.—The essential symptoms of Ménière's disease are dizziness, tinnitus, and deafness. Gastric disturbance is not peculiar to it. The deaf-

ness must be proved to be nervous and not the result of defective air conduction. True *gastric vertigo* is not associated with deafness, while other symptoms of dyspepsia are present with it.

While the aura of *epilepsy* is sometimes accompanied by giddiness, there is no impairment of hearing. Moreover, in Ménière's disease slight vertigo is more or less constant, the tinnitus is persistent, and loss of consciousness, if present, is very brief. It is the *petit mal*, with its brief unconsciousness, with which the confusion may occur.

The vertigo of *cardiac valvular disease*, especially aortic insufficiency, of *arteriocalillary fibrosis*, and of *chronic interstitial nephritis* is unaccompanied by any of the other distinctive signs of Ménière's disease. *Gelicr's vertigo*, characterized by attacks of paretic weakness of the extremities, ptosis, and profound depression, but without loss of consciousness, occurring especially among laborers in the canton of Geneva, should be mentioned as a source of possible error.

Prognosis.—This depends upon the durability of the lesion causing the malady. In cases resulting from remedial causes—such as gout and even syphilis—recovery is possible, while palliation is not infrequently attained. Other cases are obstinate and incurable. Relief, however, comes to the dizziness when the deafness becomes total.

Treatment.—When traceable to gout and syphilis, the remedies appropriate to these diseases should be prescribed. The salicylates and iodids are most frequently useful, but the lithium salts and colchicum are to be remembered. The salicylates should be given in moderate doses rather than large ones, which produce the ringing in the ears. In the absence of knowledge of a definite cause the bromids are the remedies to be most relied upon. From twenty to thirty grains (1.3 to 2 gm.) should be given at a dose, and Gowers recommends the addition of a few minims of the tincture of belladonna. Nitro-glycerin has been recommended. The general health should be looked after.

Counterirritation by blistering behind the ear is sometimes promptly followed by favorable results.

LESIONS OF THE NINTH OR GLOSSOPHARYNGEAL NERVE.

Anatomical.—This triply mixed nerve supplies sensibility to the soft palate, the tonsils, the upper part of the pharynx, the Eustachian tube, and the tympanic cavity; motor impulses to the stylopharyngeus and to the middle constrictor of the pharynx; and the sense of taste to the posterior third of the tongue and to the palate.

The study of the precise pathology of this nerve is rendered difficult by its numerous communications with other nerves, notably with the fifth, the facial, and the pneumogastric, and by the fact that it is rarely involved alone. Experimental inquiry with it is also difficult.

The nerve may be invaded by meningitis, tumors, or degenerations.

Symptoms.—Symptoms of such lesion would be *difficult deglutition* and *perversion of the sense of taste*—*parageusia*—or *complete gustatory anesthesia*.

Modifications of the sense of taste are tested by means of sapid substances in solution, applied to the anterior and posterior parts of the tongue

by a glass rod or a brush, suitable substances being used for each taste. Thus, for bitter a solution of quinin may be used; for sweet, a solution of sugar; dilute acetic acid or vinegar for acid, and common salt for the saline taste.

Ageusia may result not only from lesions of the glossopharyngeal nerve, but also from those of the gustatory or lingual branch of the fifth, and of the fifth itself within the cranial cavity; from affections of the chorda tympani in disease of the middle ear, of the facial between the entrance of the chorda tympani and the geniculate ganglion, and in lesions of the peripheral organs of the nerves of taste. Disturbance of taste may possibly result from cerebral lesions, but the cortical area for taste is not known.

Perversion of the sense of taste is known as "parageusia." It is a rare phenomenon, found in patients with facial palsy, in the hysterical, and in the insane, in whom, also, subjective sensations of taste may be present. The latter also occurs as an aura in epilepsy. Hyperesthesia of taste is even more rare, and is purely a hysterical symptom.

LESIONS OF THE PNEUMOGASTRIC OR VAGUS NERVE— THE TENTH PAIR.

Anatomical.—This nerve has by far the widest distribution of any of the cranial set, supplying the pharynx, larynx, lungs, heart, esophagus, and stomach, and in part also the intestines and spleen. The symptoms of its involvement are, therefore, numerous and varied.

It is a *mixed nerve* of motion and sensation, some of its most important motor functions being derived from the spinal accessory nerve. It is the chief sensory nerve for the respiratory center in the medulla oblongata, but contains, also, accelerating and inhibitory fibers for this center. The former office preponderates, so that section of the nerve renders respirations less frequent, though deeper, while stimulation of the divided central end accelerates them, and acceleration may proceed to tetanic arrest. The inhibitory fibers are contained chiefly in the superior laryngeal nerve, stimulation of which arrests breathing with the muscles in a state of relaxation.

It is also the inhibitory nerve of the heart, slight stimulation increasing the length of diastole, while stronger stimulation arrests its action. On dividing the nerve cardiac contractions become more frequent. It is also inhibitory for the vasomotor center, and its stimulation produces relaxation of the arteries throughout the body. It is the motor and sensory nerve for the esophagus, sensory nerve for the stomach, and partly the motor nerve for the stomach and intestines.

LESIONS INVOLVING THE NUCLEUS AND TRUNK OF THE PNEUMOGASTRIC AND BRANCHES.

The *nucleus* in the medulla oblongata may be involved in softening, hemorrhage, or slow degeneration, but adjacent nuclei are also affected at the same time, whence resulting effects are associated and are especially seen in bulbar palsy.

The *trunk* of the nerve near its origin may be compressed by thickened meninges, tumors, or aneurysm of the vertebral artery. In its course it has been implicated in incised wounds, and tied in ligation of the carotid.

Neuritis and neuromata are possible. The results of such lesion are commonly paralytic, rarely irritative. The former, if total, are diminished breathing-rate, "suffocation," frequent pulse-rate, and death. According to Traumann and others unilateral division of the vagus in experiments on animals caused few pulmonary symptoms. One vagus seems to be sufficient for the function of both lungs. The results of partial paralysis are better considered in connection with lesions of the separate branches of the pneumogastric, some of which are also invaded separately.

LESIONS OF THE PHARYNGEAL BRANCHES.—These branches of the pneumogastric, together with branches of the glossopharyngeal, form the pharyngeal plexus, from which the muscles and mucous membrane of the pharynx are innervated.

Etiology.—Nuclear disease is a most common cause of paralysis of the pharynx. It shares with disease involving adjacent nuclei, constituting bulbar palsy, already considered; but it may also be caused by meningitis or bone disease at the base of the skull, or it may form part of the lesion of diphtheritic paralysis.

Symptoms.—The results are mainly paralytic, occasionally irritative, producing spasm. The symptoms of *paralysis* are difficulty in swallowing, food lodging in instead of descending into the esophagus. A most frequent consequence is the entrance of food into the larynx, causing spasm and even choking. Pulpy food is better swallowed than liquids, the latter passing easily into the posterior nares when there is paralysis of the soft palate, and even when the paralysis is limited to the superior constrictor of the pharynx owing to contraction of the middle constrictor. When the nerves on one side only are involved, the difficulty is much diminished. Should there be a doubt in diagnosis between paralysis of the pharynx and obstruction or morbid growth, the passage of a bougie will clear it up.

Spasm of the pharynx is always functional in origin, chiefly hysterical. The so-called "globus hystericus," or sensation as of a ball in the throat which has to be swallowed but immediately rises again, is one of its manifestations; so is eminently the spasm in hydrophobia. Extreme degrees are those in which persons cannot swallow their food in the presence of others.

LESIONS OF THE LARYNGEAL BRANCHES.—The laryngeal branches are two, the superior and inferior, or recurrent laryngeal. The former supplies the mucous membrane above the vocal cords, the cricothyroid, and the depressors of the epiglottis. The inferior or recurrent laryngeal on the left side winds around the arch of the aorta; on the right, around the subclavian. The nerves then pass up to the larynx between the trachea and the esophagus, supplying all the laryngeal muscles except the cricothyroid and epiglottic, and the mucous membrane below the cords; also that of the trachea. It has been supposed that the motor fibers in these nerves come from the spinal accessory nerve, but this is now doubted. The sensory filaments of the laryngeal branches pass to the medulla oblongata in the roots of the pneumogastric.

In order to appreciate the phenomena of paralysis of the larynx it should be remembered that the glottis is opened or closed only by the movement of the posterior extremity of the cords, the anterior remaining fixed, and that this movement is effected chiefly by the arytenoid cartilages attached to the cricoid cartilage by an articulation which permits free move-

ment. Each arytenoid is shaped like an irregular pyramid prolonged at the base into two processes—an anterior or vocal, from which the cord passes to the thyroid cartilage, and an external or muscular, to which the muscles are attached. When the latter, which is at right angles to the vocal process, is moved back, this process moves outward from its fellow, the cord is abducted, and the glottis opened. If the muscular process is moved forward, the vocal process is moved inward toward its fellow, the cord adducted, and the glottis closed. These movements are further aided by movements of the arytenoids away from or toward each other.

Symptoms.—These are phonic and respiratory, together with altered position of the cords, as recognized by the laryngeal mirror. The voice may be changed or lost, the entrance of air in breathing impeded, while the closure of the glottis, necessary to coughing, is usually imperfect. The voice and respiratory functions of the larynx are regulated by the same muscles and nerves, but by centers that differ in anatomical connection, if not in position.

In breathing the cords are abducted or separated during inspiration, the extent being proportionate to the force of inspiration. During expiration they are a little nearer than in inspiration. In phonation they are made tense and brought together, the degree of adduction and tension varying with the note produced. After death the vocal cords assume a position of slight abduction from the middle line, a little nearer than during ordinary breathing, known as the cadaveric position. The position is one of partial relaxation, complete relaxation being never fully attained during life.

The symptoms of deranged function of the laryngeal nerves admit of classification into those of *paralysis* and *spasm*.

1. *Total Paralysis of Both Cords or of One.*—In what is known as *complete paralysis* of the laryngeal muscles—which does not, however, usually include the cricothyroid—the vocal cords assume the cadaveric position previously mentioned, from which they cannot be moved. Hence vocal sounds cannot be produced. In deep inspiration the current of air may bring them a little closer, and there may slight stridor, and instead of the natural explosive cough, there is only a sudden rush of air through the glottis. If *one cord is paralyzed*, it alone is motionless in the cadaveric position. Phonation may still be possible, because the unaffected cord may be overadducted beyond the middle line, but the voice is low-pitched and often hoarse. During inspiration the abduction of the healthy cord prevents stridor, while an explosive cough is impossible because the glottis is not closed with sufficient firmness to produce it, unless the paralysis is very slight.

The *causes* of complete paralysis are central disease and disease of the trunk of the vagus or of the recurrent laryngeal.

2. *Bilateral Abductor Paralysis.*—In abductor paralysis involving the posterior crico-arytenoids the cords are near together—in the position of phonation—and cannot be abducted even as far as the cadaveric position. They can, however, be brought together in phonation and in coughing, at the cessation of which they recede a little, but the normal wide abduction of inspiration does not take place. This slight recession is due to the elasticity of the attachment of the cords. The adductors, unopposed, undergo secondary contracture, so that if the paralysis is of long duration, the chink of the glottis becomes permanently narrower. The tensors are still active, as well as the adductors, hence the voice is little affected. The chief diffi-

culty is in breathing, since the normal recession of the cords essential to inspiration does not take place, while they are even brought closer together by the pressure of the entering air. Hence inspiration is accomplished with stridor, and the obstruction to the entrance of air brings into play the extraordinary muscles of respiration, the effect of which is to prolong the inspiratory act. Expiration is unimpeded, the current of outward air tending to open the cords. The absence of voice involvement and of cough may cause the obstruction to be referred to the trachea, but the absence of expiratory stridor excludes this, while the movement of the larynx up and down during breathing is greater than in tracheal stenosis. The added urgent dyspnea, the loud inspiratory stridor, livid features, and cold extremities finish an unmistakable picture; so that a laryngoscopic examination is therefore not necessary to complete the diagnosis. In bilateral palsy there is even great danger, as a slight catarrhal swelling may close the larynx and tracheotomy may be necessary to save life.

The *causes* of abductor paralysis are central disease and local influence such as laryngeal catarrh and degeneration of the posterior cricothyroids, possibly of toxic origin. Disease of the recurrent laryngeal has produced such paralysis, although this nerve supplies fibers to the adductors as well as abductors. On the other hand, the abductors have been found degenerated when the other muscles were found normal. Paralysis of both cords is generally due to disease of both nerves, and may be produced by pressure on both vagi and both recurrent laryngeal nerves. Central causes are tabes dorsalis and bulbar palsy. Abductor paralysis is also a rare symptom in hysteria, when it is bilateral, with characteristic symptoms, and has caused death.

3. *Unilateral Abductor Paralysis*.—In this the affected cord is near the middle line, and it does not move in inspiration. There are hoarseness and roughness of voice and sometimes dyspnea, but the mobility of the other cord permits the function of the larynx to be carried on with tolerable comfort. If the adductors become involved, as is sometimes the case, phonation is still more impaired.

The most frequent cause is *aneurysm*, and *the left cord* is most frequently involved,—though other tumors may cause it,—and on the right side the nerve may be involved in a thickened pleura.

4. *Adductor Paralysis (Phonic Paralysis; Hysterical Paralysis)*.—In adductor paralysis due to involvement of the lateral crico-arytenoid and the arytenoid muscles the cords are apart and cannot be approximated. In true adductor paralysis there is still the power of separating the cords on deep inspiration, but no power to bring the cords nearer than in the cadaveric position.

The *causes* of adductor paralysis are rarely organic diseases of the nerves or centers. It is the condition causing the oft-quoted *hysterical aphonia*, and may be brought on by overuse of the voice and catarrhal laryngitis. The patient with hysterical aphonia can sometimes sing, though she can talk only in a whisper. It is most common as a partial paralysis. While the cords cannot be approximated for phonation, they can be in coughing. Hence it was called by Türk "phonic paralysis." Another partial adductor paralysis is due to the loss of power in the arytenoid muscle, resulting in defective closure of the posterior part of the glottis and hoarseness or loss of voice.

5. *Tensor Paralysis*.—Little is known of this except that palsy of the

internal fibers of the thyro-arytenoideus causes the edge of the cord to be concave.

Diagnosis.—The laryngoscope is necessary to a proper diagnosis of laryngeal palsies, but symptoms are also useful. The inability to produce explosive cough is of great value in pointing to palsy of organic origin, if there is no local lesion to prevent it.

(a) Absence of cough with entire loss of voice points to bilateral palsy of organic origin.

(b) No cough, voice low-pitched and hoarse, paralysis of one cord.

(c) Loud inspiratory stridor without loss of voice, total abductor paralysis.

(d) Little change of voice or cough, unilateral abductor paralysis.

(e) Perfect cough, no voice, no stridor, unimportant adductor palsy.

The following table from Gowers contains in separate columns the symptoms, laryngoscopic picture, and lesions :

SYMPTOMS.	SIGNS.	LESION.
(a) No voice; no cough; stridor only on deep inspiration.	Both cords moderately abducted and motionless.	Total bilateral palsy.
(b) Voice low-pitched and hoarse; no cough; stridor absent or slight on breathing.	One cord moderately abducted and motionless, the other moving freely and even beyond the middle line in phonation.	Total unilateral palsy.
(c) Voice little changed; cough normal; inspiration difficult and long, with loud stridor.	Both cords near together, and during inspiration not separated, but even drawn nearer together.	Total abductor palsy.
(d) Symptoms inconclusive; little affection of the voice or cough.	One cord near the middle line, not moving during inspiration; the other normal.	Unilateral abductor palsy.
(e) No voice; perfect cough; no stridor or dyspnea.	Cord normal in position and moving normally in respiration, but not brought together on an attempt at phonation.	Adductor palsy.

Spasm of the Larynx.—In spasm of the larynx the adductors are alone concerned. The closers of the glottis are stronger than the openers, while reflex mechanism is connected chiefly with those muscles because of the importance in guarding against the entrance of foreign bodies into the larynx. Spasm is quite common in children, especially in the rickety, and is not rare in adults under the name of laryngismus stridulus. It is generally reflex, although the reflex cause is not always discoverable. The patient commonly wakes up at night in an attack of intense dyspnea; but it may occur at any time. The symptoms are like those of ordinary croup.

The paroxysm differs from that of abductor paralysis in that the stridor accompanies expiration as well as inspiration. The attacks occur in the so-called laryngeal crises of tabes dorsalis, in tetany, in the paroxysms of hydrophobia, sometimes in alternation with attacks of migraine, and in hysteria.

Spasm is also sometimes excited by attempts to speak, when aphonia results. The condition is the reverse of phonic paralysis, in which the cords cannot be brought together in speaking, while in spastic aphonia they come together too forcibly.

Disturbances of the sensory innervation of the larynx are chiefly confined to the irritation which causes cough and spasm.

LESIONS OF CARDIAC BRANCHES.—The cardiac plexus is made up of fibers derived in part from the pneumogastric and in part from the sympathetic. The vagus fibers are motor, sensory, and probably trophic.

The *motor fibers* include those which inhibit, control, and regulate the cardiac action. Their *irritation* inhibits the heart's action and causes slowness of the pulse, or bradycardia. In *complete paralysis* of the vagi the inhibitory action is abolished and the accelerator influence is unhampered, producing rapid pulse, or tachycardia. Yet it sometimes happens that complete paralysis of the vagus is followed by no cardiac symptoms.

The causes of these effects are, unfortunately, not always discoverable. Pressure of a tumor, accidental ligation of one vagus, irritation of its nuclei, anginal attacks, in one instance associated with a small tumor of the vagus, have all been followed by bradycardia. Toxic blood states are also held responsible for it. Some persons are able to control the action of their own hearts, notably a Colonel Townsend, who could control the action of his heart at will. The heart may sometimes be slowed by pressure against the pneumogastric in the neck.

The opposite condition, tachycardia, has been produced by diphtheritic neuritis, tumors of the vagus, or accidental removal of the vagus.

Sensory phenomena in connection with parts supplied by the cardiac branches of the pneumogastric are unusual, but any uncomfortable sensations arising from palpitation or irregularity are conveyed by branches of the pneumogastric.

Trophic influence in the pneumogastric is inferred from the fact that the heart has been found in a state of fatty degeneration after injury to the nerve.

LESIONS OF GASTRIC AND ESOPHAGEAL BRANCHES.—Among phenomena ascribed to effect on these branches are spasm of the esophagus and difficulty in swallowing. The vagus is also the sensory nerve of the stomach, and pain in this organ is felt through this nerve. The severe gastric crises which occur in tabes dorsalis are due to central irritation of the vagus nuclei. The senses of hunger and thirst are also believed to be conveyed through it, and have been lost in disease involving the root, but appetite is not always lost after section of the nerve, while in some cases of disease of the nerve there has been excessive appetite. On the other hand, loss of appetite is due to so many causes that it cannot be ascribed to pneumogastric lesion without careful investigation.

The pneumogastric is also the motor nerve of the stomach, though motion of the organ is not entirely arrested after its section. Vomiting is probably produced through its agency, and is excited by central and reflex irritation. Meningitis, which so frequently excites vomiting, does so through it; the pressure of a tumor on the nerve has had a similar effect, also direct pressure on an exposed nerve.

LESIONS OF PULMONARY BRANCHES.—While the vagus sends branches to the lungs, little is known of their office. They are supposed to go to the bronchial muscles, and it is held that asthma is a neurosis of these fibers. Irritation of the afferent pulmonary fibers certainly produces spasm. Stimulation of the respiratory center also causes energetic respiratory movements, while rapid congestion and even hemorrhage have been noticed after section,

though these effects may possibly be of reflex origin excited through the sympathetic, since the vasomotor fibers in the vessels of the lungs are derived from the sympathetic. After section of the vagus animals die of broncho-pneumonia. This has not been considered the result of trophic influence, but because of the entrance of foreign particles into the bronchi in consequence of paralysis of the larynx and esophagus; this was shown by Traube as far back as 1871, and confirmed by Frey by numerous experiments in 1877. Such broncho-pneumonia has also been ascribed to paralysis of the bronchial musculature and of the vaso-constrictor fibers which causes neuroparalytic hyperemia of the pulmonary tissue. Spiller's case, recently reported,* has some bearing on the subject. This patient suffered an injury of the left glossopharyngeus and vagus by a fracture of the base of the skull. He died 46 days after the accident and at necropsy numerous areas of bronchopneumonia were found. It seemed improbable that the pulmonary condition was caused by the entrance of foreign bodies into the lungs in this case, because the patient was unable to swallow. Saliva, however, doubtless passed into the trachea and carried with it muco-organisms. The patient was tested with a glass of water and his choking was so alarming that the attempt was not repeated. He was nourished by rectal enemas and the stomach tube was passed only on the day before his death. The choking was probably the result of impaired function of the epiglottis. Spiller thinks it reasonable to attribute the pulmonary condition to the paralysis of the vagus nerve, although the pulmonary lesions were not recognized until the necropsy was made.

The phenomena of hiccough may be the result of disease of this nerve, as they are also the result of disease of the respiratory center.

Prognosis in Pneumogastric Lesions.—This varies greatly. In central and nuclear disease it is unfavorable; it is unfavorable also when it is the result of pressure from intrathoracic tumors, especially aneurysm. In hysterical and purely local affections the prognosis is more favorable.

Treatment.—This is, of course, that of the causal lesion, if it can be discovered. Syphilis is the more curable of the central causes. Other causes of central disease are not removable.

Of diseases of the trunk, neuritis of the vagus is as amenable to treatment as the polyneuritis of which it is a part. The laryngeal symptoms due to involvement of the recurrent laryngeal are as remediable as the causes which produce them. If they are caused by aneurysm of the aorta or cancer, treatment is useless; if caused by syphilitic and scrofulous growths, the prognosis is more hopeful.

In the paralyzes of more purely local origin, especially the hysterical, phonic, and diphtheritic forms, electricity offers the most promising results. The method of its employment will be found detailed under diseases of the larynx. Either form of electricity may be used. Strychnin is a useful remedy, used locally as mentioned. The method preferred is by hypodermic injection, the nitrate being employed in doses of from 1-60 to 1-30 grain (0.0011 to 0.0022 gm.) daily.

In addition to strychnin, other tonics should be used to restore the general health of the patient. Laryngeal gymnastics have been recommended and used with some success. They consist in pressing firmly with the thumb and forefinger on each side of the upper and hinder part of the

* "Univ. of Fenn. Med. Bull," March, 1903.

thyroid cartilage, the patient being requested to make a simple sound during the compression.

The treatment of laryngeal spasm demands also the removal of the cause if possible, in addition to which sedatives, local and general, especially the bromids and cocain, may be used. Chloral, chloroform, and nitrite of amyl by inhalation may be necessary to break up the spasm.

LESIONS OF THE ELEVENTH PAIR OR SPINAL ACCESSORY NERVE.

Anatomical.—This nerve, purely motor in its function, has two portions—an internal, which passes to the pneumogastric and innervates the laryngeal muscles, and an external or spinal portion. The former has been considered. It should be regarded as probably a part of the vagus, and the eleventh nerve is called by some the vago-accessory nerve. The latter, *i. e.*, the spinal portion, is essentially a set of motor fibers from the cervical spinal cord, which ascends into the cranial cavity and passes out again with one of the cranial nerves to be distributed to the sternocleidomastoid and trapezius muscles, whose innervation they share with the spinal nerves. The purpose of the trapezius is chiefly to raise the shoulder; that of the sternocleidomastoid is to assist in turning the head to the opposite side, the chin being at the same time raised. This is accomplished by drawing the occiput toward the side of the muscle acting.

Lesions.—The nuclear origin of the nerve may be involved and contribute to the phenomena of bulbar palsy, or it may share in progressive central degeneration, causing wasting in the muscles supplied, which may be a part of a more general muscular atrophy. The trunks of the nerve or both nerves may be compressed in the foramen magnum by meningitis or tumor. Outside the skull there may be wounds, tumors, caries of the vertebræ, and resulting abscesses, and sometimes abscesses springing from the cervical glands. Rarely the spinal accessory may be invaded by rheumatic neuritis.

The resulting conditions are *paralysis* and *spasm*. Those of the internal or accessory portion have been described under lesions of the pneumogastric. It remains to consider only those of the external branch.

Symptoms of Paralysis of the External Branch of the Spinal Accessory Nerve.—The seats of the paralysis are the sternomastoid and trapezius muscles. When one sternomastoid is involved, the head may still be moved to the opposite side, and there is no wry-neck, or torticollis, though in some cases the head is held obliquely. The trapezius is not so much involved because it is well supplied with cervical and thoracic nerves, but the portion which passes from the acromion to the occipital bone is motionless. The middle portion of the muscle is also weakened, the shoulder droops downward and forward, and the inferior angle of the scapula is rotated inward by the action of the rhomboids and the levator anguli scapulæ. Elevation of the arm is also partial, because the trapezius does not fix the scapula at a point whence the deltoid can work. The paralysis is well seen when the patient takes a deep breath or tries to shrug his shoulders. Wasting almost always accompanies the loss of power, and there is usually reaction of degeneration.

In bilateral paralysis the power of holding the head in the upright position is impaired. If both sternocleidomastoids are affected, the head tends to fall backward; if both trapezii, it falls forward so that the chin rests on the sternum. The latter is the characteristic position of the head in progressive spinal muscular atrophy, and in children who have chronic meningitis about the foramen magnum, pressing on both nerve-trunks, and in cervical meningitis the result of caries. A peculiar drooping of the head is sometimes seen during the first year of life in children, which Gowers says may be due to injury to the spinal accessory nerves in difficult labor. In recent cases the nerves may give characteristic reaction of degeneration. In central disease the reaction varies, as it does in progressive spinal muscular atrophy.

Treatment.—This must have for its object, first, the removal of the cause, or the morbid process which produces it. After this the weak muscles are to be treated by massage and electricity. Faradization is, perhaps, most efficient for this purpose, and either form of current will answer.

Symptoms of Accessory Spasm (Torticollis; Wry-neck).—Though the muscles supplied by the spinal accessory are not the sole ones responsible for these conditions, they are the ones chiefly concerned. The terms are applied to unnatural positions of the head resulting from contraction of these muscles. There are two principal varieties:

1. Fixed wry-neck, or congenital torticollis.
2. Spasmodic wry-neck.

These two may be regarded as *true* torticollis, and are to be distinguished from two somewhat similar states which may be called *false* torticollis. The first of these is the ordinary "stiff-neck," which is really a rheumatic condition due to exposure to cold, and characterized by pain and tenderness, for the relief of which the position is assumed, and should not be called wry-neck. The second is a twist-neck, not due to muscles, but to some other cause, most frequently disease of the cervical vertebræ. This deviation puts the sternocleidomastoid muscle on the stretch, and thus may give rise to the impression that it is responsible.

1. CONGENITAL TORTICOLLIS, OR FIXED WRY-NECK.—This depends on the shortening of some muscle, commonly the sternocleidomastoid, which is also often atrophied, hard, and firm. It is met most frequently in children, and is thought to be due, in some cases at least, to injury of the muscle produced by traction during birth. In others it is ascribed to developmental shortening of the muscle, due to the inclined position of the child's head in the pelvis. It is not always noticed immediately after birth because of the natural shortness of the child's neck. A similar condition may result from injury to the muscle during life, producing inflammation and cicatricial contraction. It affects the right side almost exclusively. It is more or less constantly associated with facial asymmetry, first noticed by George Wilks and further studied by Golding Bird, who suggested that the two conditions are parts of one affection which has a central origin. In fixed wry-neck the head is turned toward the side opposite to that of the contracted muscle, which stands out conspicuously, and cannot be turned toward the latter. While the sternocleidomastoid is the muscle almost invariably responsible in these cases, the trapezius is occasionally the seat of similar atrophy.

Treatment.—The treatment is by section of the contracted muscle. Some appliance may be necessary for a time to keep the head in proper

position, especially when secondary changes in the articulation have taken place. In simple rheumatic wry-neck I have used an appliance consisting of webbing or "saddle girth" about three inches wide, stretched from side to side of the bed and raised a few inches above the mattress,—the distance to be regulated by circumstances,—on which the patient lay at night, instead of on a pillow on the side to which the head is drawn. This expedient may be used after operation. The facial asymmetry is apt to remain after the wry-neck is cured, and may even become more conspicuous.

2. SPASMODIC WRY-NECK.—This is a condition analogous to the facial spasm, occurring as a symptom of disease of the facial nerve. There are two forms, the tonic and the clonic, which may alternate in the same case or, as is most usual, occur separately and remain so.

Etiology.—It is for the most part an affection of adults, and, according to Gowers, is more common in females—that is, in twenty-two out of thirty-two cases. While this must be true of England, the opposite seems to be the case in this country, since of eight or ten cases observed by Osler in Philadelphia and Montreal, all were men. It is more common in middle life, two-thirds of all cases occurring between the ages of thirty and fifty. In women under thirty it is apt to be of a hysterical origin; rarely it is ascribable to the same cause in boys. It is prone to occur in neurotic families. Very rarely it occurs in the first year of infantile life, ceasing after a few months. Cold has been assigned as a cause; also traumatism.

In the *tonic* form, when the sternocleidomastoid is responsible, the head is continually turned to the opposite side, the chin is raised, and the occiput is drawn down toward the affected side—the *caput obstipum spasticum*. When the trapezius is involved, the head is still more depressed toward the same side. In combined and bilateral spasm of these muscles the head is drawn backward, producing the *retrocollic spasm*. In prolonged cases the muscles involved are prominent and rigid, and there may be spinal curvature with the convexity toward the sound side.

In the *clonic* form there are paroxysmal twitchings of the head, which may be very severe and correspondingly distressing. When there is predominating unilateral spasm of the sternocleidomastoid, the head is turned to the opposite side and the chin is raised with every contraction of the muscle. In unilateral spasm of the trapezius the head is drawn more backward with each contraction and toward the shoulder of the affected side. In bilateral and combined spasm there is clonic retrocollic spasm, with shaking and nodding movements—the so-called "salaam convulsions" sometimes seen in children. They may be produced also by contractions of the other muscles of the neck. Tonic and clonic spasm of the splenius may occur either alone or in combination with that of the trapezius and sternocleidomastoid. In splenius spasm the head is also drawn backward and toward the affected side, and there will be noticed muscular swelling to the outside of the cervical portion of the trapezius. The splenius is, according to Gowers, associated with the sternomastoid about half as often as the trapezius. The retrocollic spasm is commonly associated with a wrinkling of the forehead in both the tonic and clonic form.

In the clonic form the contractions may come on suddenly or be preceded by stiffness and irregular pain. The movements occur every few minutes, and the head cannot be kept still, although the movements cease during sleep. They are increased by emotion, excitement, or fatigue.

Sometimes there is pain, but at other times there is merely a sense of fatigue. The muscles in time may become hypertrophied, but never waste.

Pathology.—This is very obscure. Reasoning, rather than demonstration, leads to the conclusion that the muscular contractions probably depend on the overaction of nerve-cells, and not on irritation of nerve-fibers; the movement usually involves the deep rotators on one side of the neck and the sternocleidomastoid muscle on the opposite side. It is therefore a movement of associated muscles, and this suggests a cortical origin, at least in many cases.

Diagnosis.—The distinction lies between true and false torticollis, in which there is deviation of the head from some other cause than muscular contraction, and it is only the form of true torticollis due to shortening of one sternocleidomastoid which is likely to be confounded with the false. In the spurious form the sternomastoid is tense on the side toward which the face is turned, and in the true form the tension is on the side opposite. In retrocollic spasm the invariable association of contraction of the frontalis muscles, producing the peculiar wrinkling of the forehead, distinguishes it from simple tremor. The hysterical form occurs in women under thirty, and this fact is presumptive evidence of its presence, while hysterical spasm is also apt to spread from the neck to the trunk; in the true form of torticollis it is limited to the neck.

Prognosis.—The prognosis is always grave, and the more severe and extensive the spasm, the more unfavorable. Relief is more possible in the first half of life than in the second. Cases do, however, occasionally get well, and temporary relief is more frequent.

Treatment.—If the cause can be found which is responsible, it ought to be removed. If discovered in an acute stage, absolute rest in bed and fomentations or dry heat are indicated. Electricity has, perhaps, more reputation than any other remedy. The faradic brush may be applied over the skin of the affected muscles and to the swelling. Gradually increasing faradic currents may be used. If the galvanic current is used, a weak one is preferred, and the anode, or positive pole, is placed below the occiput or highest accessible part of the nerve, and the negative on each contracting muscle, for ten minutes at a time.

Sedatives and narcotics have also some reputation. Among these the bromids and cannabis indica are included in large doses. Five-minim (0.3 c. c.) doses of the fluid extract of cannabis indica may be given, rapidly increased. The drug is proverbially unreliable. The hypodermic use of morphin is of undoubted value in relaxing the spasm, but the dangers of its protracted use almost preclude it. It would be unfair to the drug, however, to omit the statement of Gowers that, "continued for several months in doses increased gradually to half a grain or a grain a day, it has entirely removed the spasm." Naturally such persons are weaned from the drug with difficulty. The hypodermic use of atropin in the affected muscles has also been recommended.

Mechanical supports for fixing the head are recommended, but are not well borne. Surgical measures have been employed—such as section, exsection, stretching of the nerve, and section of the muscle—with, at best, but temporary results. Mention should be made, however, of the deep-seated operation of W. W. Keen and Noble Smith, which consists in dividing the spinal accessory nerve and the posterior branches of two or three cervical nerves which also supply the splenius and complexus. This reduces the

spasms that reside in these muscles to a slight degree, while the otherwise paralyzing effect of the division of branches of the spinal nerves is comparatively unimportant.

LESIONS OF THE TWELFTH PAIR OR HYPOGLOSSAL NERVE.

Anatomical.—This is the motor nerve of the tongue, and supplies also the depressors of the hyoid bone and the hyoglossus and geniohyoid of the elevators. It arises from the medulla oblongata beside the olivary body. Its cortical center is probably the lower part of the ascending frontal gyrus or the posterior part of the third frontal convolution. It is subject to paralysis and spasm.

Etiology.—1. *Cortical disease* is frequently responsible for paralysis of the tongue on the opposite side, as is seen in the numerous cases of hemiplegia associated with this condition. The same accident occurs when the fibers between the cortex and the nucleus in the medulla oblongata are invaded, and probably this is the most frequent cause of paralysis of the tongue. Apoplexies and other causes of compression, softening, thrombosis, and embolism, are agencies operating to this end.

2. *Nuclear disease* is another cause. It is usually degeneration, rarely sudden softening: the former as a part of bulbar palsy and tabes dorsalis, and the latter from vascular obstruction. The effect is almost always bilateral, the nuclei being so close together that it is scarcely possible to involve one only, although such isolated result has occurred in sudden cases and, rarely, in slow ones, as in tabes dorsalis and general paralysis.

3. *Infranuclear disease* may operate at various sites—

(a) Within the medulla oblongata the root fibers may be invaded by a tumor or by softening.

(b) Outside the medulla oblongata the fibers may be damaged by the products of meningitis, simple or syphilitic, and by new formations. The nerve may be compressed in its foramen by outgrowth of bone. Outside the skull the nerve is compressed by tumors, by inflammatory products, or injured by disease communicated from caries of the upper cervical vertebrae and by penetrating wounds. Hence the spinal accessory and vagus nerves are often implicated coincidentally and there is paralysis of the palate, occasionally of the vocal cords, with or without wasting of the trapezius and sternomastoid. The hypoglossal may be the seat of neuritis.

Symptoms.—1. *Of Hypoglossal Paralysis.*—These are motor only. When there is supranuclear disease in addition to the palsy of the tongue, there is hemiplegia, but no wasting of the tongue, which is protruded toward the affected side, nor change in electrical reaction. In nuclear disease the lesion is apt to be bilateral palsy. The tongue lies motionless in the floor of the mouth, and speech and deglutition are seriously impaired. Mastication is interfered with mainly because the tongue cannot regulate the position of the food, the proper muscles of mastication being intact. There are atrophy and reaction of degeneration. The mucous membrane is thrown into folds. The condition is likely to be a part of a bulbar palsy. In infranuclear disease only one nerve is affected, there is wasting with reaction of degeneration and fibrillary twitching. Speech is not much impaired, nor is swallowing.

2. *Of Spasm.*—Spasm of the tongue as an isolated event is very rare.

It may be unilateral or bilateral. It commonly occurs as a part of some other convulsive affection, as epilepsy or chorea, or spasm of the facial muscles. It may also occur in hysteria. In the biting of the tongue in epilepsy the organ is thrust between the teeth by spasmodic contraction of the genio-glossus and caught by the jaws through a spasm of the masseters. Spasm of the tongue occurs in some forms of stuttering, the spasm often preceding the explosive utterance of words. In other cases there are various protrusions and deviations of the tongue, produced in some instances by irritation of the fifth nerve, variously induced, as by a carious tooth. The spasm may be clonic, the tongue being thrust in and out many times in a minute, at others more slowly. It may be associated with facial spasm. It may occur during sleep.

Diagnosis.—This is generally easy. If there are hemiplegia and palsy, but no wasting of the muscles of the tongue, no reaction of degeneration, the lesion is supranuclear. If there is paralysis of the tongue on the one side and of the limbs on the opposite, there is probably a unilateral lesion in the medulla oblongata, involving the nucleus or the fibers arising from it. When the disease is on the surface of the medulla oblongata, the paralysis is commonly unilateral, and is associated with paralysis of the corresponding half of the palate and vocal cord, because of the involvement of the spinal accessory nerve. Spiller believes it is because of involvement of the vagus.

Prognosis.—The prognosis is usually unfavorable because the lesion is incurable.

Treatment.—The treatment embraces that of the disease producing it. The symptom of lingual paralysis may be treated with electricity—with an electrode in the shape of a tongue depressor.

The treatment of spasm has been by sedatives, including bromids, by iodid, and by electricity.

DISEASES OF THE SPINAL NERVES AND BRANCHES.

CERVICAL PLEXUS.

AFFECTIONS OF THE PHRENIC NERVE.—Paralysis of this nerve may be the result of a lesion in the anterior horn of the gray matter of the cord, at the level of the third and fourth cervical nerves; of a lesion to these nerve-roots in disease of the membranes of the cord or of the vertebræ; or by compression by aneurysms or other tumors. Exposure to cold, producing neuritis, may cause it, and it may be a part of a diphtheritic palsy.

Symptoms.—The result is *paralysis of the diaphragm*, which is complete if both nerves are involved, as is the case in disease of the cord or its membranes; partial when a tumor or other cause affects one nerve. Respiration is still carried on by the intercostals, and when the victim is quiet, there is little or no embarrassment, but examination shows the abdomen to be retracted in inspiration and protruded in expiration. In other cases, in consequence of increased movement of the thorax, the upper abdominal walls are drawn outward with inspiration—a movement not to be mistaken for movement of the diaphragm. On exertion, however, there is *dyspnea*, which is also observed if the paralysis is sudden. The effect of paralysis

of a single phrenic, involving one-half of the diaphragm, is scarcely noticeable.

A further effect is to aggravate any lung affection, as bronchitis or pneumonia. There is difficulty in coughing effectually, and, therefore, of emptying the lungs of mucus, accumulation of which may result in impairment of resonance at the base of the lungs in bronchitis, and in the physical signs of edema.

Diagnosis.—Nervous breathing resembles the breathing of paralysis of the diaphragm in that this muscle is used very little, while the upper thorax is freely used. If, however, the attention of persons thus breathing is distracted, or they are watched when not conscious of observation, the diaphragmatic breathing will at once become apparent.

The diaphragm does not move when it is inflamed or in diaphragmatic pleurisy, but it is because of the extreme pain which its motion causes under these circumstances.

The diaphragmatic palsy from diphtheritic neuritis is only a part of the symptoms due to such neuritis. In diaphragmatic paralysis due to spinal disease there is usually atrophy of other muscles, together with other symptoms of that disease.

Prognosis.—This depends upon that of the disease of which it is a part, except in diphtheritic neuritis, in which it is the direct result of the disease, and where the prognosis is unfavorable.

Treatment.—The treatment is that of the disease of which it is the result. If there is neuritis, effort should be made to galvanize the nerve by pressing one pole outside the clavicular portion of the sternomastoid, and the other pole over the epigastrium or the corresponding half of the diaphragm. Counterirritation may also be applied in the triangle of the neck outside the clavicular portion of the sternomastoid.

BRACHIAL PLEXUS.

OF THE COMBINED PLEXUS.—This may be affected above the clavicle by causes producing pressure on the nerve-trunks—the five lower cervical and first thoracic—after they leave the spine and before they unite to form the plexus. Such causes are tumors and other morbid processes in the neck. More frequently, causes operate below the clavicle, of which the most frequent is prolonged luxation of the humerus, especially under the coracoid process. One or more branches may be thus involved, producing a corresponding degree of paralysis, to which is added wasting of muscles, with reaction of degeneration and trophic changes in the skin. Fracture of the humerus is another cause. Blows or falls on the shoulder and injuries in the neck may produce the same results, as may also compression during birth. The muscles involved may be the deltoid, supraspinatus, infraspinatus, biceps, and brachialis anticus.

Neuritis of the brachial plexus also occurs rarely as a primary inflammation. The result ultimately may be complete loss of power in the arm. A still rarer disease is neuroma of the plexus.

LESIONS OF INDIVIDUAL NERVES.—*Of the Long Thoracic or Posterior Thoracic (Serratus Palsy).* This nerve is particularly subject to pressure through its long course and position, especially in the posterior triangle of

the neck. Such pressure may be direct, as by carrying heavy burdens on the shoulder, or as the result of severe muscular effort in carrying or wielding a hammer, or long exertion with the arm raised, as in whitewashing a ceiling. The result may be a neuritis. Neuritis may also be caused by cold. The same nerve may be involved in progressive spinal muscular atrophy or poliomyelitis anterior. From natural causes it is more common in men.

The result is a dislocation of the scapula of the corresponding side, which presents a winged appearance in consequence of projection of its angle and posterior border, rendered especially distinct when the arm is moved forward, since the scapula is no longer held to the thorax by the serratus. In severe cases faradic irritability is lost, though voltaic excitability may remain. Severe neuralgic pain may precede the paralysis.

The course of serratus palsy is slow, and the paralysis is sometimes permanent.

Treatment.—The treatment consists in maintaining the nutrition of the muscles by electrical stimulation. Counterirritation may be applied over the scalenus muscle, because it is in it that the nerve is most frequently injured. The arm should be kept at rest, and to this end should be carried in a sling, embracing the elbow in such a way as to raise the shoulder.

NERVES OF THE ARM.—1. *Of the Circumflex Nerve.*—This rises from the posterior cord of the plexus and supplies the deltoid and teres minor, and the skin over the deltoid. It may be injured by dislocations, blows, bruises, pressure by a crutch, or position long maintained, as during illness. Neuritis may result from these causes and from cold, or by extension of inflammation from the joint.

There is loss of power in the deltoid and the arm cannot be raised, also a loss of sensation in the skin over the lower part of the muscle. The muscle wastes and the shoulder becomes flattened. The joint may relax and a space arise between the head of the humerus and the acromion. On the other hand, adhesions may form, partly trophic, since the articulation is supplied by the same nerve. Movement may be further impaired by thickening of the ligaments.

Paralysis of the deltoid is to be distinguished from ankylosis, in which the scapula moves with the arm, which it does not do in palsy.

2. *Suprascapular Nerve.*—This nerve rises from the trunk formed by the union of the sixth, fifth, and a branch of the fourth cervical, but its own fibers are derived from the fifth and partly from the fourth cervical. It is occasionally injured alone or with the circumflex in dislocation of the humerus, and by falls on the shoulder, or by carrying heavy weights. The result is palsy of the supraspinatus and infraspinatus muscles. The first is of little significance, but the latter causes a defect of rotation outward of the humerus, interfering with many movements, of which one is carrying the hand along in writing. The scapula is rotated so that the lower angle is rotated upward and inward.

3. *Musculospiral Paralysis.*—The musculospiral nerve arises from the posterior cord of the brachial plexus, and apparently derives its motor fibers from the nerve-roots forming the plexus except the first thoracic. With the branches it supplies the triceps, all the muscles of the back of the forearm, the extensors of the wrist and fingers, both the supinators, as well as the skin on the radial side of the back of the hand, back of the thumb, index-finger, and half of the middle finger. As the musculospiral nerve is

called the radial by the Germans, its paralysis is described in German literature as radial palsy.

It is more frequently paralyzed than any single nerve, because of its position—winding around the head of the humerus after it leaves the plexus. It is often bruised by crutches, producing the so-called “crutch palsy,” by blows and fractures, and especially by pressure when sleeping with the arm over the back of a chair or with the arm under the body. Even a sudden and violent contraction of the triceps, as in pulling on a tight boot, or forcible extension of the forearm as in throwing a ball, may bruise it. More rarely it is the subject of a neuritis from cold.

In a lesion of the nerve high up all the muscles previously named are involved; when near the middle of the humerus, the triceps generally escapes. The supinator longus and exterior carpi radialis longior usually are involved, but escape if the lesion is below the origin of the branches supplying them, and sometimes in partial injury of the nerve higher up. A

Fig. 130.—Wrist-drop in Musculospiral Paralysis—(Leube).

characteristic symptom of extensor palsy is the “wrist-drop,” while the inability to supinate is also striking. Sensation is rarely lost, though there may be tingling without loss of sensibility.

Paralysis of the musculospiral is to be distinguished from the wrist-drop of lead palsy, which is, however, bilateral, while the supinators are unaffected and the onset is gradual. However, in lead palsy the supinator longus may be affected, and in wrist-drop from pressure this muscle may escape. Bilateral wrist-drop is common in other forms of neuritis, especially the alcoholic, but the gradual mode of onset, the involvement of the legs, and the sensory symptoms are their characteristics.

The prognosis is usually favorable, the pressure palsy disappearing in a short time, while recovery is the rule even when delayed.

Erb's rules as to prognosis apply as follows: If both faradic and galvanic irritability are maintained, recovery may be expected in from fourteen to twenty days; if these are lessened for the nerve and increased for the muscle, while $An\ C > Ca\ C$, with contraction sluggish, recovery may take

place in from four to six weeks, sometimes in from eight to ten weeks. When there is evidence of degeneration of the nerve, the prognosis is more unfavorable, so that recovery may be delayed for from two to fifteen months.

4. *Ulnar Nerve*.—This comes through the inner cord of the plexus from the last cervical and first thoracic. It is the first of all the brachial nerves to be affected by disease ascending from the thoracic to the cervical part of the cord. It supplies the ulnar flexor of the wrist, the ulnar half of the deep flexor of the fingers, the muscles of the little finger, the interossei, two of the lumbricales, the adductor, and the inner head of the short flexor of the thumb. Its sensory portion supplies the ulnar side of the hand, back and front,—more on the back,—two fingers and a half, with one finger and a half on the front, although the distribution is not invariable.

The course of the nerve, superficial behind the elbow and at the wrist, makes it vulnerable. It may be injured in wounds of the forearm and about the elbow, in dislocations and fractures about the shoulder and elbow, and

Fig. 131.—Position of Wrist, Hand, and Fingers in Ulnar Paralysis—(Leube).

continued flexion of the elbow. Neuritis is a possible cause. The most common cause is probably a blow upon the arm.

The hand moves toward the radial side because of paralysis of the ulnar flexor, and adduction of the thumb is impossible, the first phalanges cannot be extended, and in long-standing cases the "claw-hand" may be produced, consisting in overextension of the first phalanges and flexion of the others. There may be wasting of the muscles supplied by the nerve. There is loss of sensation in the sensory distribution.

A similar condition of the ulnar nerve may be produced by lesion of the lower cervical portion of the cord.

5. *Median Nerve*.—Its motor fibers arise from all the cervical roots that enter the brachial plexus. They supply the pronators, the radial flexor of the wrist, flexors of the fingers,—except the ulnar half of the deep flexor,—the muscles that abduct and flex the thumb, and two radial lumbricales. The sensory fibers supply the radial side of the palm and the front of the thumb, the first two fingers, half of the third finger, and the dorsal surface of the same fingers.

Isolated palsy of this nerve is not frequent, but it may be caused by

wounds or fractures of the forearm, rarely from injuries of the upper arm. There may be neuritis from compression.

The wrist can only be flexed toward the ulnar side, and the thumb is in a state of persistent extension and cannot be opposed to the tips of the fingers. Pronation is impossible beyond the midposition to which the supinator can bring the forearm; an attempt is made to supplement this by rotating the humerus inward and separating the elbow from the side. The second phalanges cannot be flexed on the first, nor the distal phalanges of the first and second fingers, while in the third and fourth fingers this action can be performed by the ulnar half of the deep flexor. There is conspicuous wasting of the thumb muscles, which gives a characteristic appearance.

There may be complete or partial loss of sensibility. If there is anesthesia, it is more marked on the palmar surface.

Treatment of Lesions of Nerves of the Arm.—The first principle of treatment is the removal of the cause, whatever it may be, as determined from the etiology. If neuritis is present, it must be treated. Rest by supports or splints may be necessary, on the one hand, and electrical stimulation and massage on the other.

LUMBAR AND SACRAL PLEXUSES.

THE LUMBAR PLEXUS.—This is sometimes damaged by growths in the abdomen, especially of the lymph glands, by inflammatory process, by psoas abscess, and by diseases of the bones and vertebræ affecting the nerve-roots. The obturator nerve may be injured during parturition; the anterior crural nerve by the same cause, by wounds of the groin or thigh, by dislocation of the hip, and sometimes by growths about the spine.

Symptoms.—In paralysis of the *obturator*, adduction of the thigh and crossing of the legs are impossible, while outward rotation is also deranged.

In paralysis of the *anterior crural* extension of the knee is impossible; there is wasting of muscles, with anesthesia of the anterolateral part of the thigh and of the inner side of the leg and big toe. There may be pain in the area of distribution.

Paralysis of the *superior gluteal nerve*, which is rare in the isolated form, causes loss of the power of abduction and circumduction of the thigh from paralysis of the gluteus medius and minimus.

THE SACRAL PLEXUS.—This suffers from compression by growths in the pelvis, pelvic inflammations, and compression during labor. In addition to spontaneous neuritis, there may also be a neuritis ascending to it from the sciatic nerve. The sciatic may be affected by wounds, dislocation of the hip, disease of the bone, and morbid growths. It is also occasionally the seat of neuroma.

The result of lesions of the *sciatic* varies with its seat. If near the sciatic notch, there is paralysis of the flexors of the leg and all the muscles below the knee, while injury below the middle of the thigh involves only the latter muscles, the flexors of the legs escaping. There is anesthesia of the outer half of the leg, of the sole and greater portion of the dorsum of the foot, but the leg may escape, perhaps through the intermediation of other nerves. Frequently there is wasting of the muscles, with other trophic symptoms. In lesion of one sciatic the leg is fixed in extension by

the action of the quadriceps extensor, and the patient can walk, even when all the muscles below the knee are paralyzed, the foot being raised by over-flexion of the hip.

The *small sciatic* is implicated only when the pelvic plexus is impinged upon, and it rarely suffers alone. The effect is palsy of the *gluteus maximus*, with difficulty in rising from the sitting posture, and a strip of anesthesia along the back of the middle third of the thigh and upper half of the calf.

Injury to the *external popliteal* or *peroneal* nerve results in paralysis of the *tibialis anticus*, long extensor of the toes, *peronei*, and extensor *brevis digitorum*. There results inability to flex the ankles or extend the first phalanx of the toes, or to raise the foot from the ground in walking—there is foot-drop. *Talipes equinus* ultimately results, and may be attended with persistent flexion of the first or proximate phalanges from contraction of the unopposed *interossei*. In walking the whole leg must be lifted, and there is the steppage-gait of neuritis. In old cases there may also be wasting of the anterior tibial and peroneal muscles. There is also anesthesia in the outer half of the front of the leg and on the dorsum of the foot.

Lesion of the *internal popliteal* produces paralysis of the *popliteus*, calf muscles, *tibialis posticus*, long flexors of the toes, and muscles of the sole. The symptoms are loss of plantar flexion, inability to extend the ankle-joint, and, if the disease is high enough to involve the branch to the *popliteus*, loss of power to rotate the flexed leg internally; the foot cannot be adducted, nor can the patient rise on tiptoe. *Talipes calcaneus* results, and the toes may assume a claw-like position from secondary contraction, due to over-extension of the proximal and flexion of the second and third phalanges. There is also loss of sensation on the outer lower part of the back of the leg and on the sole of the foot.

Treatment.—The treatment of lesions of the nerves of the legs is similar to that of lesions of nerves of the arms. Secondary contractures are to be guarded against, being favored by position. Fatigue and exposure to cold should be avoided, as they favor fresh attacks of neuritis.

DISEASES OF THE MEMBRANES OF THE BRAIN.

Although, anatomically considered, the brain is enveloped by three membranes,—the tough dura mater, the delicate arachnoid, and the highly vascular pia mater,—the diseases of the membranes are practically confined to the dura on the one hand, and the arachnoid and pia conjointly on the other, the last two being always affected together. The dura is, however, separable into two layers—a thin internal layer with its endothelial covering, and a looser external layer which serves as a periosteum to the bones; these two layers may be affected separately.

The term pachymeningitis is applied to inflammation of the dura mater, and leptomeningitis to that of the pia and arachnoid; the latter is commonly meant when the word meningitis is used alone.

PACHYMENINGITIS.

SYNONYM.—*Inflammation of the Dura Mater.*

EXTERNAL PACHYMENINGITIS.

Etiology.—External pachymeningitis is *always acute* and is commonly circumscribed. It usually results from injuries to the head, especially *fractures*; from *caries* of the petrous portion of the temporal bone itself, the result of middle-ear disease; or from *syphilitic disease* of the bone with pus formation. Sometimes no cause is discoverable. Rarely pus infiltrates between the two layers of the dura mater. More frequently there is pus between the dura and the bone. This may occur in syphilis, which, too, may cause thickening of the bone.

Symptoms.—These are indefinite and are often obscured by those of its causal disease. They are pain, delirium; sometimes, but not always, fever; sometimes convulsions, and signs of pressure. Such pressure may or may not be sufficient to cause paralysis of the opposite side.

Treatment.—The treatment is that of the causing disease, with surgical interference to remove pressure and give vent to pus.

INTERNAL PACHYMENINGITIS.

This is *usually chronic*. Three forms are commonly noticed—purulent, pseudomembranous, and hemorrhagic.

PURULENT and PSEUDOMEMBRANOUS INTERNAL PACHYMENINGITIS are not recognized before death. The former may follow an *injury primarily*, but commonly it is an *extension from* inflammation of the *pia*. Pus between the dura and arachnoid is rare. Pseudomembranous internal pachymeningitis may occur as a secondary process in *infectious diseases*.

INTERNAL HEMORRHAGIC PACHYMENINGITIS.—Hemorrhagic pachymeningitis, or *hematoma* of the dura mater, is a rare, but well-recognized condition; it is much more common in infirmaries and hospitals connected with almshouses and asylums. It occasionally occurs in children.

Etiology.—It is probably most frequently a result of chronic alcoholism, though it has been found in chronic insanity without association with alcoholism, especially in general paralysis of the insane; also in acute fevers, when it is associated with profound anemia. Syphilis is a possible cause; in like manner, tuberculosis. It occurs chiefly in males over fifty, but also in those between thirty and forty. In mild degree it is sometimes found in chronic cardiac, renal, or pulmonary diseases, when it is commonly first recognized at necropsy.

Pathology and Morbid Anatomy.—The original dictum of Virchow continues for the most part to be held—viz., that it begins as a hyperemia in the area of the *middle meningeal artery*, extending thence forward, backward, and downward. The arteries become tortuous, dilated, and surrounded by thickened adventitia, while the capillaries, being overfilled, produce a rose-colored flush on the under surface of the membrane. To this succeeds a delicate weblike tissue containing wide, thin-walled capillaries three or four times the natural width, between which is a delicate reticulum of spindle cells extending over the greater part of one or both hemispheres. This becomes afterward paler and firmer. Upon this succeeds another delicate vascular layer, succeeded by another and even another. From three to seven layers are thus superposed until a product of from 1-8 to 1-5 inch (3 to 5 mm.) in thickness results. The delicately walled capillaries, however, easily give way, causing hemorrhages which vary in extent from mere points to large collections of blood—the smaller being interstitial and the larger between the youngest vascular layer and the next older. The proportion of blood and organized membrane varies greatly, now one predominating and now another. At times there seems to be blood only. The hemorrhage is believed by some to be the initial event.

Both products are subject to degenerative changes, the effused blood being disintegrated and partially absorbed, while the blood-vessels become obliterated and substituted by lines of pigment deposit along their course. There may also be serous infiltration, cystic degeneration, and even diffuse suppuration.

Symptoms.—The symptoms are indefinite. There may be *apoplectic form seizures* coincident with fresh hemorrhages, *drowsiness*, or *coma*. *Muscular weakness* was very marked in a case under my own observation. *Headache* in the region involved, *vomiting*, *nystagmus*, *convulsions*, generally unilateral, and even hemiplegia may be present, and, toward the close, *optic neuritis*; extensive disease may, on the other hand, exist without any symptoms whatever.

Diagnosis.—In the absence of distinctive symptoms the possibility of the presence of hematoma should be remembered when there are other signs of general paralysis or chronic alcoholism. If to such symptoms great muscular weakness is added, further suspicion is justified.

Treatment.—With a prognosis absolutely unfavorable as to recovery, it remains only to treat symptoms as they arise. Indications of hemorrhage should be treated by rest in bed, elevation of the head, and an ice-cap.

LEPTOMENINGITIS.

SYNONYM.—*Inflammation of the Pia Mater.*

Of leptomeningitis there may be an acute and a chronic variety. In addition, other adjective terms are used to indicate its seat and the nature of its cause; such as basilar meningitis, meningitis of the convexity, tuberculous meningitis, etc. Epidemic meningitis has received separate consideration.

ACUTE LEPTOMENINGITIS.

Definition.—An acute inflammation of the pia and arachnoid membranes, attended by exudation between the two membranes.

Etiology.—All ages are subject to meningitis, that of the convexity being possibly more frequent in adults because they are more subject to traumatic agencies which cause it, while the basilar form is more common in children. It is rather more frequent in males, and there is a hereditary tendency to one form—tuberculous meningitis.

Of the direct causes—

1. An eruption of *miliary tubercles* is the most frequent. This cause may operate at all ages, but is most active in children. In adults it generally starts from a recognized tuberculosis elsewhere; in children the process is almost always part of a general tuberculosis. Tuberculous meningitis takes place generally at the base of the brain, constituting the chief form of *basilar meningitis*.

2. *Adjacent disease*, which may be outside of the dura mater, such as caries, especially in the petrous portion of the temporal bone. Even disease outside the skull, like erysipelas or suppurative disease of the scalp, may be a primary focus. In these cases it is usually unilateral, and may be accompanied by thrombosis of the sinuses and abscess; or the disease may result in abscess within the brain.

3. The bacterium or toxin of the acute *infectious diseases*—pneumonia, ulcerative endocarditis, measles, scarlet fever, smallpox, typhoid fever, acute rheumatism, and septicemia. Care must, however, be taken not to confound the simple intense delirium in some of these affections with meningitis, remembering, too, that the latter complication is, under any circumstances, a rare one. The toxin of pneumonia is the most common cause, and perhaps after this that of smallpox. The inflammation thus caused is chiefly of the *convexity*, except in septicemia, when it is general.

4. Chronic Bright's disease and other *cachectic conditions*. In these the inflammation is commonly basilar.

5. Sunstroke.

6. Mental excitement and brain work—doubtful cause.

7. Rarely in acute inflammation, syphilis, whose product is also basal.

8. Finally, unknown causes may produce meningitis of the convexity or of the base. Possibly, as Gowers suggests, organisms otherwise powerless may become sufficient causes during ill health. Thus may be caused some undoubted though rare cases of non-tuberculous basilar meningitis of children—*leptomeningitis infantum*.

In tuberculous meningitis, which is chiefly basilar, the eruption of tubercles precedes the inflammation. There may even be tuberculosis of the

pia without inflammation. In tubercular meningitis the inflammation is never actually purulent, though the lymph has often the appearance of pus. The tubercles are most abundant about the optic chiasm, over the pons, and in the fissure of Sylvius, but the cortex is often affected. According to Dr. Spiller's experience the brain cortex has contained more tubercles than were found at the base.

Morbid Anatomy.—The early results of leptomeningitis are the same in all varieties. They consist, first, in a hyperemia of the capillaries producing a diffuse pinkish tinge. The next visible changes are a turbidity and an opacity of the arachnoid which extend to the pia, where opacity is especially distinct along the blood-vessels, consisting, in fact, in an infiltration of the lymph spaces and lymphatic sheaths with leukocytes. As the cellular accumulation increases the exudate beneath the arachnoid assumes a yellowish-white, creamy appearance. The subarachnoid fluid increases, constituting *hydrocephalus externus*. In suppurative cases it becomes pus, which forms a greenish-yellow layer at the convexity or base, or both.

Ventricular effusion is present in the majority of instances,—about four out of five,—constituting *hydrocephalus internus*, generally associated with closure of the opening of the fourth ventricle. The effusion is usually limited to a few ounces, but it may be large in quantity, distending the ventricles and compressing the cortex. The walls of the ventricles and the choroid plexuses may be inflamed, and the ventricular effusion may be the result of such inflammation.

In all varieties of meningitis, and especially in the tuberculous, the superficial layer of the cortex is also involved, being at least hyperemic, and sometimes softened; it may also be the seat of punctiform hemorrhages, constituting *red softening*. This is especially prone to occur in tuberculous meningitis, because of the extension of the tuberculosis along the blood-vessels which dip into the cortex. In pulling off the pia these blood-vessels are dragged with it, leaving a ragged appearance of the cortex.

Leptomeningitis infantum presents an appearance similar to that of tuberculous meningitis. It involves chiefly the posterior part of the meninges and cerebellum, closing sometimes the foramen of Magendie, whence the term *occlusive meningitis*. It may also cause an acute, sometimes purulent, hydrocephalus.

Symptoms.—These are varied and not always distinctive of the different forms. First, it is important to remember that all except those which are peculiar to inflammation of the base may be present in any of the serious infectious fevers without meningitis, especially pneumonia, typhoid fever, and smallpox; but in some cases of typhoid fever the typhoid bacillus has been found in the cerebral membranes. When secondary to these affections, they are accompanied by the symptoms of the disease to which they succeed.

Meningitis is usually ushered in by *premonitory symptoms*, which, again, are not distinctive, being those usual to acute disease. Perhaps *irritability* is more constant than in other acute diseases. In case of children, *vomiting* with a slight cause, or without discoverable cause, is a symptom of more suspicious nature. It is especially frequent in basilar meningitis, of which it is more or less characteristic. It has this peculiarity, that it is not usually accompanied by nausea and retching. Generally there are *high fever*, *coated tongue*, and *constipation*, although fever is not invariable. The usual temperature is from 103° to 104° F. (39.5° to 40° C.), but it may reach from 105° to 106° F. (40.5° to 41.1° C.), and toward the close of fatal cases, 108°

F. (42.2° C.). It is especially apt to be mild or absent in the meningitis of Bright's disease or of debilitated children. The *pulse* is increased in frequency at first, but later may be slow and irregular.

Of the symptoms the direct result of the disease, *pain in the head* is the most constant. Commonly frontal, it may be general. Its constancy and severity are characteristic. Yet it is subject to such exacerbations as may cause the patient to cry out, constituting the *hydrocephalic* cry of children. The headache is invariable, followed sooner or later by *unconsciousness*. Delirium is an early symptom and soon follows the headache; at first wandering, it soon becomes active, and may alternate with drowsiness or stupor.

General *convulsions* are also another symptom, occurring in all forms and at all ages, but more frequently in the tuberculous meningitis of children. When the inflammation is at the base, *rigidity of the neck* with retraction of the head is very marked, especially when the inflammation extends down the membranes of the spinal cord. *Optic neuritis* is another symptom, usually late in occurrence,—at the end of the first week,—and possibly due to involvement of the sheath of the optic nerve within the skull. *Strabismus* is also common. There may be weakness of the eye muscles and slight *ptosis*. The *pupils* are usually *contracted* in the early disease from intolerance of light; later, they are *dilated*. *Inequality* of the pupil is even a more characteristic symptom, though transient and variable. It occurs in connection with inflammation of the convexity as well as of the base.

The *facial nerve* may be involved in basilar cases, producing slight paralysis, as may also be the *fifth nerve*, producing anesthesia and trophic changes in the cornea. On the other hand, *hyperæsthetic* skin is often present; also *hyperæsthesia* of the *special senses*, especially hearing and sight.

Symptoms in the limbs may present themselves, such as *muscular rigidity*, *unilateral convulsions*, and even *hemiplegia*, but the last is rare. When they occur, they are late symptoms.

Diagnosis.—The diagnosis is not always easy, because so many symptoms may be simulated by simple congestion due to the poison of the *infectious diseases*. The *basilar symptoms* are the most distinctive, and it is a real help to know that a possible cause is present, either predisposing or exciting; such, for example, as the tuberculous taint, or tuberculous disease, or middle-ear disease. Retraction of the head, so characteristic of this form, may result from *rheumatism* of the muscles of the back of the neck. Sir William Jenner pointed out a difference between the relation of headache and delirium in general disease and meningitis: In general disease the headache ceases when the delirium begins; in meningitis the headache continues and coexists with the disease. Convulsions, too, when present, occur at the beginning of a general disease, particularly in scarlet fever, while they occur late in meningitis. Optic neuritis and other eye symptoms are common in meningitis.

A rapidly growing *intracranial tumor* often gives rise to difficulty in the diagnosis between it and meningitis. In tumors which may be tuberculous or gliomatous, symptoms in the extremities, such as weakness, hemiplegia, and convulsions, are manifested only after the tumor once begins to interfere with function, which it may not do at first; the loss of power, moreover, comes on gradually, while in meningitis all these symptoms are rapidly developed. Higher degrees of optic neuritis, as observed by the ophthalmoscope, are found in connection with tumor rather than with meningitis. The duration of the disease will settle the question ultimately, as meningitis is of short

duration—from two or three days to as many weeks—while tumors last for months.

Meningitis, especially tuberculous, is sometimes mistaken for *hysteria*, but the almost invariable presence of fever in meningitis and its total absence in most cases of hysteria should prevent error. In children the symptoms even of tuberculous meningitis are sometimes closely simulated in bad *cachectic states*, in which there is no meningitis whatever. What is regarded as meningitis after *sunstroke* is a prolonged state of mental hebetude with symptoms usually aggravated on slight exposure to the sun.

Prognosis.—The prognosis in leptomeningitis is unfavorable, although not necessarily hopeless. In meningitis of the convexity recovery is possible; in undoubted tuberculous meningitis it is very rare, and yet it may occur. But I have so often known an erroneous diagnosis of tuberculous meningitis with corresponding prognosis followed by complete recovery in children, that I have grown very cautious in making a prognosis. Especially in general tuberculosis should we avoid too unfavorable a prognosis, because mistakes here are quite frequent. In meningitis from adjacent bone disease much depends on the accessibility of the bone lesion, but as this is generally difficult of access, the prognosis is correspondingly serious. This is especially the case in ear disease. In syphilitic meningitis if the diagnosis is made early, chances of recovery or improvement are better.

Treatment.—The *treatment of adjacent disease* which may cause the meningitis is of the first importance. Surgical interference should be promptly resorted to in middle-ear disease. In the absence of such disease the treatment is mainly symptomatic. The utmost *quiet* and the avoidance of all causes of excitement are paramount. It is the one disease, outside of ophthalmia, in which the darkening of the room may be justified. The *head should be raised*. *Leeching* is a most valuable measure toward cure, when possible, and temporary relief when cure is impossible. Leeches should be applied to the back of the ear and to the temple. *Ice* should be kept applied to the head. *Counterirritation* by blisters to the back of the neck is also very useful, and not so painful or annoying as its appearance suggests. It has even been applied to the whole scalp after shaving the head, but I have never felt justified in doing this, especially when the diagnosis of tuberculous disease is quite clear. The *bowels* should be kept free.

The *diet* should be liquid—milk and animal broths of a light kind are the best food. Such drugs as meet the symptoms should be given. *Phenacetin* to relieve pain in the head if the ice and abstraction of blood do not do it. The temperature is kept down by *sponging* and even by cool *bathing*. *Mercury* is still an acknowledged drug in meningitis not tuberculous; and as chances of error of diagnosis always exist, it may be employed in any case. It should be administered to the production of slight salivation, preferably by inunction because the effect is more rapidly produced. The mercurial ointment should be used.

CHRONIC LEPTOMENINGITIS.

Etiology and Morbid Anatomy.—This comparatively rare disease affects chiefly the convexity of the brain, and is the result of alcoholism, syphilis, or tuberculosis.

In milder degrees, seen in alcoholics, the pia arachnoid is opaque, as

seen over the sulci, the opacity and thickening being more marked along the borders of the blood-vessels. In syphilis there are often foci or thickened patches, thickest in the center and receding toward the edges. These may reach dimensions to justify the term gummy outgrowth or tumor. The blood-vessels are the seat of endarteritis. In the tuberculous forms in children the base of the brain is affected, as in acute tuberculous meningitis. Internal hydrocephalus may be a consequence when there is obstruction to the orifice of the fourth ventricle.

Symptoms.—These are those of the acute form in a milder and more prolonged manner—headache, vomiting, mental symptoms, sometimes convulsions, rigidity, retraction of the head, optic neuritis, more rarely strabismus, and nystagnus. They may last from a month to a year or more. Fever is more frequently absent in chronic meningitis, but careful observation will generally find some elevation of temperature.

Diagnosis.—It is, in fact, the chronic variety of leptomeningitis which is separated from *tumor* with the greatest difficulty. Loss of motor power is more characteristic of tumor. Optic neuritis is also a more decided symptom in tumor, and goes on increasing, while it seldom reaches an advanced stage in chronic meningitis. Other eye symptoms—strabismus, irregularity of pupil—are more distinctive of meningitis. Strabismus occurs in *hysteria*, but it is always convergent and there is total absence of fever, as shown by the absence of elevation of temperature.

Prognosis.—This is not so unfavorable as in the acute variety. The syphilitic form is quite amenable to treatment, the alcoholic less so; the tuberculous is almost always sooner or later fatal. Caution in prognosis is demanded by occasional error in diagnosis.

Treatment.—The cause must be carefully sought. If syphilitic, iodids and mercurials must be used, as for this disease. In alcoholism and tuberculosis the symptoms must be treated by measures already indicated.

AFFECTIONS OF THE BLOOD-VESSELS OF THE BRAIN.

HYPEREMIA.

SYNONYMS.—*Cerebral Hyperemia; Congestion of the Brain.*

Definition.—A condition of the brain in which the blood-vessels are surcharged with blood. The congestion is *active* as the result of increased flow of blood to the brain, as in alcoholic hyperemia; *passive* when there is obstruction to its outward movement, as in constriction of the vessels in the neck.

Etiology.—The causes of *active* hyperemia are prolonged mental activity, excitement, and overwork, pre-eminently alcohol and the causes of the acute fevers; the hypertrophy and overaction of the heart which attend aortic regurgitation may be causes. The causes of *passive* congestion are mainly mechanical, including mitral valvular heart disease, emphysema, straining, or other cause obstructing the return of blood from the brain,—such as tumors pressing on the vessels of the neck, or tight clothing.

Morbid Anatomy.—While, from the standpoint of morbid anatomy, our ideas may be very definite as to what should constitute active and passive hyperemia, it cannot be said that a definite set of symptoms is associated with either in the case of the brain. In the first place, the amount of blood in the brain varies greatly within the limits of health, and while it might be said that physiological hyperemia ends where abnormal mental phenomena present themselves, it is undoubtedly true also that an overfullness of the vessels of the brain may exist for some time without the symptomatic expression which finally appears. With the appearance of such symptoms we commonly date the clinical beginning of the pathological state known as chronic hyperemia.

The difficulties are increased by the fact that in acute active and passive hyperemia, at least, no postmortem evidences of it remain, the congestion having disappeared with death, although an unusual distinctness of the puncta vasculosa has long been regarded as postmortem evidence. The difficulty of recognizing such condition makes this sign an unreliable one. In chronic hyperemia there result, sometimes at least, a turbidity and even an opacity of the pia mater, with slight thickening, together with elongation and tortuosity of the vessels, which are regarded as characteristic.

Symptoms.—These are not very distinctive. The symptoms of active hyperemia, so far as recognizable, are a sense of fullness or pressure, headache, mental excitement, irritability, confusion of ideas, insomnia, vertigo, ringing in the ears, and, in extreme cases, hallucinations, delirium, and mania. These symptoms are increased when the head is held downward or there is straining. The phenomena of so-called “rush of blood to the head” are probably the result of active hyperemia. They include a suffusion of the skin of the face and head and a feeling of warmth in these situations, strong beating of the carotids, headache, tinnitus aurium, spots before the eyes, vertigo, and sometimes actual falling.

It is not easy to separate the phenomena of passive hyperemia from those of active congestion. They are, however, less pronounced and slower in their development.

Treatment.—The indications for treatment are, nevertheless, plain. The *head* is to be kept *raised*. *Purgation* is the first measure to be thought of. The saline and hydragogue cathartics are especially indicated, because of their depleting effect. The *ice-cap* should be used. In extreme cases even *blood-letting* may be necessary, the efficiency of which is sometimes seen in the relief afforded by bleeding of the nose. Leeches applied behind the ears often afford magical relief to the symptoms commonly ascribed to congestion of the brain. Wet cups may be placed upon the back of the neck for the same purpose. The diet should be spare and easily assimilable, in acute cases liquid only.

Of medicines, the *bromid of potassium* theoretically fulfills the indications, and in full doses of from fifteen to thirty grains (1 to 2 gm.) every three hours to adults is often useful, though it should not be allowed to substitute the other measures mentioned. *Phenacetin* and *phenalgin* are admirable remedies for the headache, a single dose of ten grains (0.66 gm.) being often sufficient. It may be repeated if necessary, or smaller doses may be given more frequently.

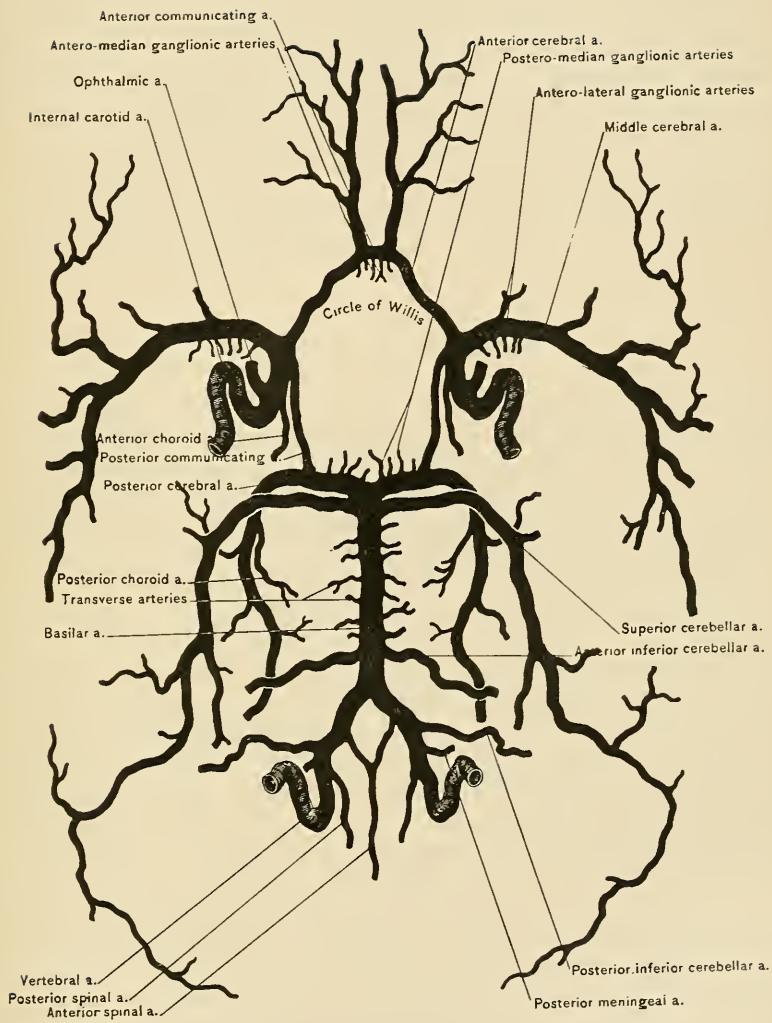

ANEMIA OF THE BRAIN.

Definition.—The more usual application of the term anemia of the brain is to conditions in which the quantity of blood in the organ is diminished, although depraved states of the vital fluid without loss of bulk may also produce the same symptoms.

Etiology.—The causes leading to this condition are for the most part those which withdraw blood from the brain, but they include also such as prevent its access. Among the former are hemorrhages, profuse and rapid; bowel fluxes, such as those of cholera in adults and cholera infantum in children; and the opening of vascular areas by the removal of pressure caused by large tumors or ascitic fluid. Thus is explained the fainting which sometimes succeeds the removal of a large abdominal dropsy. In the second set of causes are feeble action of the heart, ligation of the carotid artery, or other obstruction in vessels carrying blood to the brain. Such obstructions are thrombi and emboli. The brain substance adjacent to the dilated ventricles in hydrocephalus interna is anemic from compression. The fainting due to sudden emotion, such as fright, is ascribed to a withdrawal of blood from the brain.

Morbid Anatomy.—This is more distinctive than in hyperemia. The membranes are pale, the blood in their vessels, except the larger ones, is scanty, and over the convolutions the vessels are quite empty. The gray and the white matter are both pale on section, and the puncta vasculosa are less distinct and less numerous. The cerebrospinal fluid is increased.

Symptoms.—Some of these are definite and the direct result of loss of blood to the brain. Such are the dizziness, confusion of ideas, flashings of light, roaring in the ears, nausea, and ultimate loss of consciousness and even death which succeed hemorrhages or emotion. In other cases the skin is cold and clammy, and a cold perspiration starts to the surface. Other symptoms are less distinctive. They are ascribed to chronic anemia, but may result also from other causes. Such are mental apathy, disinclination to work, a sleepy feeling during the day, and insomnia at night. Nausea, headache, tinnitus, vertigo, hallucinations, and delirium are also conse-

CIRCLE OF WILLIS AND ARTERIES OF BRAIN.—(Deaver.)

quences more particularly of lowered composition of the blood, of anemia, in fact, the result of prolonged illness, like pulmonary consumption and Bright's disease. The convulsions characteristic of the latter disease have been ascribed to anemia and also to edema of the brain.

The hydrocephaloid symptoms, described by Marshall Hall as the direct result of prolonged diarrhea and of cholera infantum in children, are regarded as results of anemia. They include semistupor with eyes unclosed, later, dilated pupils, strabismus, convulsions, rigidity, and death.

Treatment.—The immediate consequences of the acute form of anemia are diminished or averted by placing the patient on the flat of the back with the head low; by diffusible stimulants, of which alcohol and ammonia are the types; also cardiac stimulants, and nourishing and easily assimilable foods. The chronic forms of brain anemia are treated by nutritious, easily assimilable foods, and tonics, especially iron and arsenic. In the hydrocephaloid condition in infants alcohol is the pre-eminent remedy, associated with warm baths and general restorative measures.

EDEMA OF THE BRAIN.

Definition.—The term includes two conditions, the most definite and easily recognizable of which is an abnormal accumulation of cerebrospinal fluid within the pia arachnoid. In the second condition there is added to the first an abnormal moistness of the substance of the brain.

Etiology.—The most common cause is mitral stenosis, although any cause obstructing the return of blood from the brain as well as recurring irritative hyperemias, such as are produced by alcoholism and the psychoses, are also causes. Bright's disease is a cause of edema of the brain, local or general.

Local edemas of the brain are also caused by obstruction of single sinuses of the dura mater, or compression by tubercular or other tumors of the veins of the velum interpositum, known as the *vena Galeni*.

Morbid Anatomy.—The membranes are turbid, their vessels are distended and serpentine in their course, and the subarachnoid space is filled with clear fluid. The substance of the brain is anemic, moist, and glistening. In extreme cases there is compression of the cortex, with resulting flattening of the convolutions and widening of the sulci. The fluid in the lateral ventricles may also be increased.

Symptoms.—These are ill defined. There may be *hallucinations* and even *mania*, very similar, in fact, to those of anemia. Traube and Rosenstein ascribed the *convulsions of Bright's disease* to edema of the brain, while certain *unilateral convulsions* and *paralysis* in connection with this disease have been assigned to the same cause. Even death has been ascribed to sudden serous effusions of this kind, constituting acute edema of the pia mater, or *apoplexia serosa*. In recent years much has been written on cerebral edema under the name of meningitis serosa.

Treatment.—The treatment is that of the conditions to which the symptoms are secondary. The effects of cardiac stenosis must be overcome by cardiac stimulants; Bright's disease must receive appropriate treatment. Thrombosis of the sinuses admits of no treatment, though its effects may diminish by gradual contraction and possible liquefaction and removal of the thrombus. The psychoses should receive treatment appropriate to them.

APOPLEXY.

Definition.—The term apoplexy is applied to a sudden loss of consciousness and motor power due to cerebral hemorrhage, or the sudden plugging of a blood-vessel. Laceration of the brain without hemorrhage produces a like effect. In point of fact, when the term apoplexy is used, cerebral hemorrhage is commonly intended.

Unconsciousness may also be produced by simple congestion, and it was formerly thought that a simple serous transudate could produce similar symptoms in a milder form and of shorter duration; whence the term "serous apoplexy." Concussion of the brain, however, causes similar symptoms.

I. CEREBRAL HEMORRHAGE.

Arterial Distribution.—In the first place hemorrhage is *meningeal* or *central*. Meningeal hemorrhage may be outside of the dura mater, between it and the bone, or between the dura and the arachnoid, or within the pia arachnoid. The extradural and subdural meningeal hemorrhages are both traumatic, one variety of which is produced during birth, but those in the pia arachnoid are due to the causes to be considered below. Central hemorrhages may also burst into the membranes as well as into the ventricles of the brain and in some instances the hemorrhage is almost entirely intra ventricular. Meningeal hemorrhage may occur in the infectious fevers, in leukemia, and in anemia.

It is a rare event to find a rupture in any of the large arteries of the circle of Willis, although white patches of atheroma are often seen upon them at autopsy. But the free anastomosis of this circle scarcely allows of increase of intravascular pressure sufficient to cause rupture. Further, it is the "central" rather than the "cortical" branches of this circle which rupture, and especially the central branches of the *middle cerebral*, which, entering the brain at the anterior perforated space, pass to the corpus striatum and internal capsule. One of these is the so-called artery of "cerebral hemorrhage," thus named by Charcot because of the frequency of its involvement. It passes to the internal capsule and lenticular nucleus, where the majority of the massive hemorrhages of the brain occur.

Etiology.—Disease of the artery involved is responsible for the vast majority of cerebral hemorrhages. Indeed, except in the case of traumatic hemorrhages either with or without fracture of the skull, it is very doubtful whether hemorrhage ever occurs without such disease. The simplest form is the fatty degeneration and "erosion" of the intima, characteristic of advanced age. *Endarteritis*, however produced, is perhaps the most frequent cause. Its ultimate result, as shown by Charcot and Bouchard as far back as 1868, is the *miliary aneurysm* which in almost every instance precedes the rupture. It is a spindle-shaped, rarely lateral, dilatation, from 1-25 to 1-5 inch (1 to 5 mm.) in diameter. The inflammatory process preceding it consists in a proliferation and degeneration of the intima cells, followed by atrophy, which extends also to the muscular layer and the scanty adventitia. These, yielding to the intravascular pressure at the weak points, dilate to form the little aneurysm, which is later ruptured by some further increment.

of pressure. Embolism is also a cause of endarteritis which may result in aneurysm.

The "fatty erosion" of the intima which is the next most frequent cause of vulnerability is favored by age, by chronic interstitial nephritis, and the overstrain of the vessels due to hypertrophy of the left ventricle, so often associated with that disease as well as with valvular heart disease.

While by far the larger majority of hemorrhages are preceded by miliary aneurysm or fatty erosion,—fully nine out of ten,—there still remain a number of instances in which careful search fails to find anything but *diffuse degeneration*; whence the miliary aneurysm and fatty erosion cannot be regarded as indispensable conditions. The *infectious fevers*, leukemia, and anemia are also causes of hemorrhage which is independent of miliary aneurysm.

Age is also a predisposing factor, most ruptures occurring after fifty, although apoplexy has occurred under ten; while the occupations and dissipations of men furnish an additional predisposing elements which accounts for its greater frequency in the male sex. Other predisposing causes are those usually responsible for endarteritis—viz., gout, alcohol, syphilis, Bright's disease, the apoplectic habit, as seen in the stout, short-necked, full-blooded individual; and, finally, heredity, which is, strictly speaking, a hereditary tendency to the favoring diseases.

The exciting causes are such as temporarily increase intravascular pressure, as violent exertion, straining, debauch in eating and drinking, and mental emotion.

Morbid Anatomy.—The *large central ganglia* in the *neighborhood of the lateral ventricles*—i. e., the optic thalami, the caudate and lenticular nuclei, and the adjacent white matter of the internal capsule and centrum ovale—are the favorite seats of miliary aneurysm and consequent hemorrhage. These aneurysms are found also, but much more rarely, in the smaller branches of the *cortical vessels*, in the *pons*, *cerebellum*, *crura cerebri*, or *medulla oblongata*. On section of the large ganglia these may be seen as small dark points, as large as a pin's head, and are often very distinct in arteries drawn out of the substance of the brain, especially the anterior perforated space. Coarser aneurysms are also found on the branches of the circle of Willis.

Given a massive hemorrhage, what is its effect on the brain substance, and what are the changes in the extravasated blood? The former varies somewhat with its situation. If extradural, the dura mater is torn away from the bone to a varying extent. If subdural or beneath the pia arachnoid, it separates these membranes from the brain substance, but in either event the convolutions are more or less flattened and the sulci more or less obliterated.

As already stated, central hemorrhage most frequently occurs in the neighborhood of the corpus striatum, through which, if large, the blood finds its way toward the outer section of the lenticular nucleus, pushing inward the optic thalamus and bursting into the lateral ventricle or into the white matter of the centrum ovale. The pressure exerted is often such as to flatten the convolutions, empty the parietal veins, and press the falx aside, sometimes even to produce a sense of fluctuation over the membranes. Hemorrhages may occur in the crura or pons or fourth ventricle, and also in the cerebellum, not infrequently from the superior cerebellar artery. Osler mentions two cases of death in women of twenty-five from cerebellar hem-

orrhage. Very rarely hemorrhages into the ventricle may start in the choroid plexus or the ventricular walls. Blood in large quantities may be poured out at the base of the brain, and it may flow down into the cord from a rupture of any of the arteries going to or from the circle of Willis.

If the patient survives, changes take place in the extravasated blood, which promptly coagulates into a dark-red mass. This almost immediately begins to contract, permitting often the return of a certain degree of function by removing pressure. As time elapses the dark-red mass passes into a chocolate-brown pulp, composed of liquefying blood-clot and disintegrated nervous matter. The microscope, at this stage, recognizes numerous hematoidin crystals and granular fat-cells which are probably fatty by imbibition of fat-granules. The adjacent nervous tissue is stained yellow by the imbibed hematoidin. The clot itself becomes encapsulated by fibrin and gradually absorbed, being often substituted by a semitransparent or completely transparent fluid, forming the apoplectic cyst. If smaller, the walls approach and unite, leaving only a linear pigmented scar. Especially is this the case with small clots on the surface of the convolutions, which may leave only a staining of the membranes. In other cases of abundant cortical effusion, especially in infants, there may be circumscribed wasting of the convolutions and a cyst of the meninges or brain. The position and extent of the permanent lesion determine the presence of secondary descending degeneration. If the motor cortex or motor tract is involved, there may be found, in persons dying some years after a stroke of apoplexy with hemiplegia, degeneration in the pyramidal fibers of the pons and medulla oblongata, in the direct pyramidal fibers of the cord of the same side, and in the crossed pyramidal fibers of the opposite side, and to some extent in the crossed pyramidal fibers of the same side.

Symptoms.—*Premonitory* signs are occasionally present. There may be a feeling of fullness in the head, headache, tinnitus, vertigo, or numbness, tingling, pains in the limbs on one side, loss of memory of words or choreiform movements,—prehemiplegic chorea,—possibly due to miliary aneurysm or otherwise diseased vessels.

With the bursting of a vessel of sufficient size there occurs the *apoplectic "stroke,"* or apoplectic shock. Its most striking feature is *sudden loss of consciousness.* If complete, the patient falls heavily to the ground, and there may be slight convulsive movement, but it soon ceases. More rarely a true convulsion ushers in the attack. The patient cannot be aroused, the face is suffused, cyanotic—sometimes, however, pale; the *breathing* is slow, noisy, stertorous, often attended with a puffing sound during expiration. corresponding with a blowing out of the relaxed cheek on the paralyzed side; it may also be of the Cheyne-Stokes type. In contrast with the foregoing, the development of unconsciousness is sometimes much more gradual, requiring several hours or a day, corresponding to which it is presumed that the hemorrhage is slow, constituting the "*ingravescent form.*"

The second major symptom of apoplexy is *motor paralysis*, of which hemiplegia is the most conspicuous form. In most cases the motor pyramidal tract, as it descends in the internal capsule, is either directly destroyed or indirectly affected. Hence most patients who survive the primary shock present a hemiplegia—paralysis of half the body opposite that of the hemorrhage, and most frequent on the right side. It is most noticeable in the arms and legs. These are thoroughly relaxed, falling limp when allowed to drop, as the limb of one thoroughly etherized. More rarely there is early

rigidity, especially on the paralyzed side. This symptom is possibly more frequently associated with hemorrhage into a lateral ventricle. *Reflex action* is early either totally suspended or only brought out in response to a deep pin thrust or severe pinching.

The signs of hemiplegia are not always easily elicited at first, because a certain degree of consciousness is necessary to stimulate attempt at motion, but it may be that the angle of the mouth hangs down lower on one side,—the paralyzed side,—while the puffing of the cheek alluded to may be present on the same side, or the limbs of one side may be appreciably more flaccid than those of the other, or a small amount of reflex response may be elicited on the sound side. The *pulse* is usually slow, full, strong, and tense. The *temperature* may be subnormal at first, rising to normal and even above, and in basal hemorrhage may be higher. In a rapidly fatal case it remains subnormal to the end. The *pupils* are *irregular*—*i. e.*, sometimes contracted, at others dilated, unequal. They respond to light either slowly or not at all. If the hemorrhage is where it can irritate the nucleus of the third nerve, the pupils are contracted. This may occur with hemorrhage into the pons or ventricles.

In *cortical lesions* quite often one of the early symptoms in hemiplegia is *conjugate deviation* from the paralyzed side and toward the side of lesion, from which we have the expression that “the patient looks at the lesion”; that is, in right hemiplegia the head and eyes look toward the left side. This symptom usually passes away, but sometimes continues for weeks, and, as Gowers suggests, is perhaps occasionally represented by nystagmus or movement in the direction concerned. Should, however, convulsion, or spasm, or early rigidity develop, the head and eyes are rotated toward the paralyzed side—*i. e.*, away from the side of lesion. This is true only of cortical lesions.

In lesions of the *pons*, on the other hand, where the conjugate deviation may also occur, the phenomena are reversed,—the patient looks away from the lesion, in the absence of spasm,—but if the convulsion or spasm or rigidity occur, the eyes and head look toward the lesion. These facts are a little confusing at first and may be expressed in the following.

In lesion of the cortex—

Without spasm, conjugate deviation is *toward* the side of lesion.

With spasm or convulsions or early rigidity, *from* the side of lesion.

In lesion of the pons—

Without spasm, etc., *from* lesion.

With spasm, etc., *toward* lesion.

This may be due to the fact that these movements in health are innervated from both sides, and when a lesion occurs on one side of the cerebrum, the innervation is given over to the other side until the injured one resumes its function, or until irritation in it causes it to assert or exceed its function. In pontile lesions the destruction occurs possibly below the decussation of the fibers innervating the parts affected in the conjugate deviation and the symptoms are reversed.

The *feces* and *urine* are passed involuntarily, and the latter is sometimes slightly albuminous.

As to further progress in a few cases there is no reaction from the previously described condition. The symptoms all deepen, the breathing becomes rapid and rattling, the skin cool, the pulse weak and rapid, and the

patient dies. In most cases, however, there is a certain abatement of the symptoms, even if the patient does not recover more fully. Consciousness returns partially or completely, the patient can be aroused by a loud voice, and one can recognize which side is paralyzed. There may, at this time, be a febrile movement, due to cerebral inflammation, during which the patient may die, or there may be another hemorrhage which carries him off.

On the other hand, improvement may continue to a further degree. The consciousness and intelligence may return completely, and the signs of paralysis may gradually grow less, *more rapidly in the legs than in the arms*. They, however, almost never disappear completely, the patient continuing lame and requiring the use of a cane for the rest of his life. In severe cases a remnant of paralysis of the face can almost always be recognized, while articulate speech may also continue defective.

Such marked improvement is, for the most part, reserved for the milder attacks, in which there is great variety as to degree. In such the loss of consciousness is of short duration, or it may not occur at all. Such attacks are not infrequently ushered in by nausea, vomiting, vertigo, or sudden headache. The paralytic symptoms may still be marked, and permit a study rather more satisfactory than the fulminating cases. In such study it will be found that all muscles are by no means equally paralyzed. Thus it will be seen that the lower division of the facial nerve, which supplies the muscles of the cheek, nose, and mouth, is plainly paralyzed; while the upper division, distributed to the muscles of the eyes and forehead, is almost, if not entirely, intact. The forehead may be wrinkled with equal ease on the two sides, but an attempt to draw up the nose or purse the mouth fails, while one labionasal fold may be obliterated and one angle of the mouth lower than the other. The natural wrinkles of the forehead are commonly less distinct on the paralyzed side than on the other. This event—the comparative freedom from paralysis in the upper part of the face—may be explained by the fact that while both sides of the face receive fibers from each cerebral hemisphere, this is especially true of the muscles of the upper part of the face, which are always exercised bilaterally.

The *tongue* may not be paralyzed, but when it is, if protruded, it goes toward the paralyzed side, being pushed out by the genioglossal muscle of the other side, the innervation being by the hypoglossal nerve. Occasionally paralysis of the tongue contributes to difficulty in articulation. The motor branch of the fifth nerve is sometimes involved on the hemiplegic side, and there is paralysis of the pterygoid, temporal, and masseter muscles.

Of the *trunk muscles*, the trapezius is almost solely involved, and that but slightly, permitting the shoulder to drop a little, and the paralyzed side of the chest may expand more than the normal side in ordinary breathing, while in voluntary deep breathing this is not the case. The reason of this possibly may be found in the exaggeration of the reflexes on the paralyzed side; ordinary breathing being a reflex action.

Sensation is but slightly impaired in most cases of hemiplegia due to cerebral hemorrhage, and such impairment usually grows rapidly less as time elapses. It is hemianesthesia when anesthesia exists, and it is on the side opposite that of the lesion. There may also be trifling paresthesia at first. Any marked disturbance of sensation means that the posterior extremity of the internal capsule is involved, or, according to some authors, it indicates that the optic thalamus is invaded. Distinct impairment of the deep sensi-

bility—the so-called muscular sense or sense of position—may indicate a lesion of the parietal lobe. There is sometimes temporary and even permanent *hemianopsia*, which implies some lesion of the fibers of the optic radiation posterior to the internal capsule or the posterior tubercle of the optic thalamus—the pulvinar.

The *tendon reflexes* are increased in nearly all cases on the paralyzed side, though at the very beginning of a severe shock they may be abolished, and if this abolition of the reflexes persists, it is regarded as a serious sign. In cases of any duration even the periosteal reflexes are increased, and to a less degree the reflexes of the sound side are increased, because each side of the body is innervated from both sides of the brain, although the number of fibers passing to the same side of the body is considerably less than those passing to the opposite side. There is even, at times, ankle clonus, and, more rarely, wrist clonus. These events are explained by supposing a suspension of the inhibitory reflex cortical centers, due to the cerebral lesion. The *skin reflexes*, on the other hand, are diminished on the paralyzed side, remaining normal on the sound side.

The *rapid improvement* mentioned as occurring in some cases is usually confined to a few weeks or days, after which improvement goes on more slowly, the lower extremities recovering more completely than the upper. The *gait* resulting from partial recovery is peculiar. Short steps are taken by the affected leg, and the toe is dragged more or less, while locomotion is sometimes accomplished by sweeping the leg around in a semicircle by the iliacus and psoas and the vastus externus, while it is held stiff, as in a splint, by the quadriceps extensor muscle. In the upper limb the hand muscles are the last to recover.

Later in the history of the case *contractures* may come on in the paralyzed muscles, shown especially in flexures of the fingers, contracture of the forearm in a position of pronation, and partial flexion, with the upper arm adducted. The lower extremity is usually in the position of extension. This contracture is explained by some, and notably by Strümpell, as a "passive contracture," the position assumed being the natural one in a state of rest. On the other hand, Charcot and his pupils hold that the contractures are due to secondary degeneration of the pyramidal tract, a view that is probably incorrect. There are also sometimes *associated movements* of the paralyzed muscles, to which Hitzig has called attention. In these, movements of the sound side excite associated movements in the corresponding muscles of the other side, and attempts to move the affected side result in motion of corresponding muscles of the sound side. Sometimes, also, involuntary movements of the lower extremity occur when the patient attempts to move the corresponding arm. A *posthemiplegic chorea*, first described by Weir Mitchell, should also be mentioned. It is seen not so much in the hemiplegia resulting from cerebral hemorrhage as from focal disease of the posterior end of the internal capsule and optic thalamus. A form of hypertonia has recently been described in which the muscles are in a state of exaggerated tonicity without much paralysis. In this condition the position of the spastic limbs varies from time to time. It is seen in some cases in which a cerebral lesion has occurred early in life.

Trophic symptoms may appear late in the disease, seen at first in elevation of temperature, increase of color on the paralyzed side of the face, swelling of the eyelids, and contraction of the pupil; also swelling of the hands. It is to be remembered, however, that slight swelling may result from

sluggish circulation of blood and lymph, contributed to by diminished muscular contraction and absence of use. In a more advanced stage the extremities become cooler and are often constantly moist. Among these vasomotor events Charcot has placed what he calls *acute malignant decubitus*—a disposition to rapid gangrene of the tissues over the sacrum. It may appear in a few days after the shock, beginning with a circumscribed redness and formation of vesicles, succeeded by deep-reaching necrosis. While this is probably, as Charcot regards it, a vasomotor phenomenon, it is also invited by the usual causes of gangrene in dorsal decubitus, such as irritation by urine, feces, and even inequalities in the bed-clothing. Charcot also considers an occasional arthritis, acute or chronic, a neuropathic event.

General nutrition is well maintained, the patient even gaining in flesh at times. More rarely there is rapid wasting.

The *mental condition* of patients who recover partially from the effects of hemorrhage is, for the most part, good, but it not infrequently happens that after a time mental weakness manifests itself in loss of memory and defective intellection, while imbecility sometimes ultimately supervenes.

Diagnosis.—The greatest difficulty lies in the differential diagnosis between cerebral hemorrhage, *embolism*, and *thrombosis*. I will, however, defer its consideration until cerebral embolism and thrombosis are treated.

In *fulminating cases* the coma is sometimes so profound that it is difficult or impossible to ascertain the presence of hemiplegia. The symptoms which aid in determining this have been mentioned on page 1050. To these may be added the increase of reflexes on the affected side, not present in an early stage of the paralysis, conjugate deviation of the head and eyes, and rigidity of limbs on one side. It is these cases that are sometimes confounded with *epilepsy*, *opium poisoning*, *acute alcoholism*, or *uremia*. In *epilepsy* there is the history of previous convulsions, and it is only when this has been overlooked that mistakes occur. In *opium poisoning* the coma is slow in its onset, the pupils are uniformly contracted, and the odor of laudanum is often on the breath. But here, too, the victim is often only discovered after coma has thoroughly developed. In *alcoholism* there is the odor of whisky, but many an innocent person has been treated as a drunkard on whose brain lay a clot pressing him to death. The young ambulance or police surgeon is wise who defers his opinion. Sometimes alcoholism and apoplexy are combined, when a conservative course will be no less astute. The coma of *uremia* in Bright's disease very strongly simulates that of apoplexy, especially in the rare cases of the latter in which there are convulsions. The presence of dropsy, or, in its absence, of the peculiar anemia of Bright's disease, and the finding of albuminuria and casts should suggest this disease, but albumin may be found in hemiplegia not of uremic origin. It is to be remembered, too, that uremic convulsion may terminate in hemorrhage, while Bright's disease is also associated with a state of the arteries which disposes them to rupture. Coma in a puerperal woman, associated with dropsy and albuminuria, means uremia.

Prognosis.—To have had a stroke of paralysis is justly regarded as having received a blow which marks the beginning of inevitable decline in health and usefulness, though cases are constantly occurring in which a "slight stroke" is followed by complete recovery. Some of these are probably errors of diagnosis, yet all are not. The cortical hemorrhages are those most frequently followed by recovery. After these come a large number of cases of first attack, from which the patient recovers quite a

considerable degree of health. Second attacks are prone to occur, which are more severe, and few survive a third attack.

The unfavorable cases are those in which the coma is profound and lasting. Such are hemorrhages into the ventricles and corona radiata, which are rapidly fatal. Meningeal hemorrhages are serious, but less so when traumatic than when due to diseases of the vessel. Cases attended by early and persistent fever and delirium are unfavorable, as are also cases complicating renal disease and alcoholism. Hemorrhages into the corpus striatum and internal capsule produce persistent hemiplegia, followed by contracture. When cases survive the primary stroke and improvement sets in, this is much more rapid in the first few weeks than later. In explanation of this it has been held that the symptoms thus rapidly removed are indirect focal symptoms, due to pressure of the clot on adjacent nervous tissue, while those more slow to yield are the result of destructive lesion.

Treatment.—The patient should be promptly placed in a horizontal position *with the head raised*. This is of the greatest importance, as it constantly happens that a patient in whom consciousness is returning immediately becomes comatose when the head is lowered. *He should then be bled*, unless the pulse be small and feeble. The bleeding should be accompanied by a *laxative*, which should be given alone if there be any reason why phlebotomy should not be practiced. In view of the unconscious state of the patient the best laxatives are croton oil and elaterium. Two drops of the former should be mixed in a little glycerin or oil and carried to the back part of the throat, or 1-4 grain (0.0165 gm.) of elaterium, dissolved in a small quantity of water, may be given in the same way. The rectum should be at once cleaned out by an enema of warm water. An ice-bag should be placed on the top of the head, hot water and mustard to the feet, while counterirritation may also be applied to the back of the neck, but it is doubtful whether any of these measures will accomplish much.

Compression of the carotid artery, formerly recommended and practiced on empirical grounds, has recently received the indorsement of Horsley and Spencer, these experimenters having found that bleeding from the lenticulo-striate artery ceases when the carotid is compressed. It is especially in the *ingravescent* form that it has been recommended. F. X. Dercum and W. W. Keen* report two cases of *ingravescent* hemorrhage treated by ligation of the common carotid, of which one recovered.

If, after bleeding and purgation, the pulse continues bounding, the *tincture of aconite* or *veratrum viride* may be given in doses of a minimum every half-hour until the pulse is influenced. *Iodid of potassium* can hardly be expected to promote absorption of the clot, but may be given if syphilis is suspected. It may, however, facilitate circulation by dilating the blood-vessels. 5-10

The foregoing treatment is for the period immediately succeeding hemorrhage. The remainder of treatment consists in measures to protect the patient against the effect of decubitus if this is prolonged, and in maintaining the nutrition of muscles and protecting against contractures. The former is accomplished by attending to the secretions, preventing the irritation of the body by putrid urine and feces or foreign substances like bread-crumbs, by bathing and drying the body thoroughly, by frequent changes of posture. The latter will also guard against pneumonia, which

* "Jour. of Nervous and Mental Disease," September, 1894.

is rather prone to *occur* on the paralyzed side. This last disease may also be caused by the inspiration of particles of food, liable to happen if there is paralysis of the muscles of deglutition. The second indication is met by massage, faradization, and gymnastics, but they should be deferred for two or three weeks. *Warm salt baths* three or four times a week are useful to the same end. Tonics in the form of iron in small doses, quinin, and strychnin may be given, but alcohol in more than very moderate amounts is contra-indicated.

Operative treatment has been suggested to relieve the pressure of a clot in cerebral hemorrhage, and when it is certain that the clot is meningeal, especially after fracture, satisfactory results show that it is justified. Careful attention should be paid to the facts mentioned under topical diagnosis with a view to determining the seat of hemorrhage and the place to trephine. Deep hemorrhage is, however, beyond reach.

II. EMBOLISM AND THROMBOSIS OF THE CEREBRAL VESSELS.

A.—Of Cerebral Arteries.

SYNONYMS.—*Cerebral Softening; Acute Softening.*

Definition.—By *embolism* is meant the plugging of an artery by a foreign body carried into the circulation from some point in the vascular system and taken by the blood current to a point beyond which it cannot pass. By *thrombosis* is meant plugging of an artery or vein by a clot formed *in situ*.

Etiology.—*Nature and Source of Embolism.*—The embolus is most frequently a vegetation from a diseased valve in the left ventricle. Less commonly it is a fragment of a clot in the same ventricle or in the auricular appendage or in an aneurysm, or it may be a calcareous particle from an atheromatous vessel or a piece of thrombus from the same. Even the territory of the pulmonary veins may contribute an embolus. Embolism is very much more frequent in chronic valvular disease than in primary acute endocarditis. It is prone to occur in recurring valvulitis, and especially in mycotic endocarditis. Pregnancy with or without heart disease, the infectious fevers, and blood dyscrasiæ may be predisposing causes.

The embolus commonly enters the brain by the carotid, especially the left,—which furnishes the most direct course,—thence through the internal carotid to the *left middle cerebral* in the fissure of Sylvius; more rarely by the *vertebral* and its *posterior cerebral* branch.

Thrombosis.—In thrombosis there is also plugging of a living vessel, but by a clot formed *in situ*, which is either primary at the point plugged or secondary about a previous embolus. Some favoring cause commonly exists. This is most frequently roughening due to endarteritis, with or without atheroma. Weak heart and blood dyscrasiæ are also predisposing causes. Ligation of the carotid artery is sometimes followed by thrombosis of cerebral vessels.

The vessels most frequently affected in thrombosis are the *middle cerebral* and the *basilar*, but the *vertebral*, the *posterior cerebral*, and the branches of the circle of Willis may be plugged, and the *basilar* at its bifurcation.

Relative Frequency of Thrombosis and Embolism.—Embolism has been thought to be more frequent in women, but of 79 cases collected by Newton

Pitt at Guy's Hospital, 44 were in men and 35 in women. Thrombosis is considered more common in men. Embolism is rare in children, being more frequent at from twenty to fifty; thrombosis in older persons, at from fifty to seventy.

Morbid Changes Due to Thrombosis and Embolism.—*Degeneration and softening of the brain* are the direct result of obstruction of its arteries, and occur sooner or later when the shutting off of the blood supply is sufficiently complete. The process generally begins within twenty-four hours, and the minimum time required to complete it is from one to two days. The local anatomical product of embolism is much less distinctive in the brain than in the lungs or spleen. Thus, there is almost never a distinct hemorrhagic infarct, though there is often a condition resembling it, the area cut off being infiltrated with blood. At other times the region is paler than in health and slightly softer. In either event the area becomes gradually infiltrated with serum and a more or less complete liquefaction results, presenting a reddish, yellow, or white color, whence, the terms *red softening*, *yellow softening*, or *white softening*. These variations are not the result of any essential difference in the nature of the process, as was formerly thought, but are rather accidental. In red softening the softened focus happens to contain an unusual amount of extravasated blood, due to punctiform hemorrhage or capillary apoplexy. This blood melts away and stains the softened mass. In yellow softening the proportion of fatty degenerated cells is larger, and it is found, therefore, chiefly in the cortex, where cells prevail. In white softening there are few or no cellular elements, hence the white softening is found in the white or fibrous nervous matter. It is most characteristically seen about tumors and abscesses. As the gray matter of the cortex is also the most vascular part of the brain, it is here also that we find red softening. Certain superficial yellow spots known as *plaques jaunes* are found at times on the surface of the cortex in old persons. They are sharply circumscribed, measure from 2 to 4 centimeters (.8 to 1.6 inches), are made up of a yellow, turbid material sometimes crossed by trabeculæ, and represent fatty degeneration of peripheral cortical arteries.

Minutely examined, the softened areas consist of fatty granules and oil drops, myelin drops, fragments of swollen nerve-fibers, fatty granular cells representing fatty neuroglia and nerve-cells, or leukocytes and neuroglia cells, and perhaps endothelial cells which have *imbibed* the oil drops, arising probably from disintegrated nervous matter. In the yellow softening these constitute the sum of altered materials. In red softening there are added in the early stages blood-discs, later pigment granules or hematoidin crystals, or there is general staining by dissolved hemoglobin. In the white softening the fragments of nerve-fibers together with myelin drops make up the chief bulk, as already stated. If collateral compensatory circulation is set up within two days, the destruction may not go so far, and the nervous elements may resume their function; or if this does not occur and the patient lives, the dead and disintegrated tissue may be gradually absorbed and eventually be replaced by a cyst, while a minute focus of softening may be replaced by indurated cicatricial tissue. If the embolus is derived from an infective focus, as ulcerative endocarditis, an abscess may result.

Symptoms.—Neither thrombosis nor embolism of the cerebral arteries is always followed by recognizable symptoms. All the large arteries of the base and the smaller arteries of the surface anastomose so freely

that the effects of obstruction are promptly equalized. Nay, more; it is not unusual to find at the necropsies of elderly persons yellow spots of fatty degeneration, the *plaques jaunes* referred to, scattered over the convolutions where nothing was suspected before death. Moreover, softening may take place in the "silent regions" without exciting suspicion. Very different is it with obstruction of the middle cerebral artery—the artery of the fissure of Sylvius.

The clinical aspect differs, however, according as this vessel is plugged at its origin or a little further on in its course. Allusion has already been made (p. 1049) to the two separate systems with which the brain is supplied—the "cortical arteries" (Duret), passing to the cortex, and the "central" arteries, passing to the central ganglia. The central arteries are the first given off by the cerebral branches of the circle of Willis, and are terminal arteries, unprovided with anastomoses. The cortical arteries spring from a network of branches of the cerebral arteries in the pia mater, in which tolerably free communication exists between the tertiary branches of the same trunk, and even between the branches of different trunks. These two systems of cortex and center are, however, altogether independent of each other, and no anastomosis takes place between them, the zone at which they meet within the cerebral substance being situated about an inch and a half below the cerebral convolutions. In the case of the middle cerebral artery, when it is obliterated beyond the point at which its "central" branches come off, the superficial parts of the brain are alone affected, and since its branches in the pia mater anastomose with those of the anterior and posterior cerebrals, there may be no softening at all, and but a temporary loss of function. At other times softening does occur, the exact situation and extent of which vary with the arteries plugged. The blood supply of the two central, the three frontal, and the three parietal convolutions being more or less cut off, there is motor paralysis of the opposite side of the body, and as the lesion is most frequent on the left side, there are right-sided hemiplegia and aphasia; the same phenomena, in fact, as follow hemorrhage, and which may be permanent or transient; or the lesion may be still more limited. The embolus may lodge in the artery, passing to the third frontal convolution, or in that of the ascending frontal or ascending parietal. It may lodge in the branch passing to the supramarginal or angular gyrus, or to the lowest branch, which is distributed to the upper convolution of the temporosphenoidal lobe. If, on the other hand, the seat of the lesion is at the point where the Sylvian artery arises from the internal carotid, the central ganglia are involved, and there is almost certain to be softening of the corpus striatum and optic thalamus, because the arteries have no anastomoses, while the cortex escapes entirely because its vessels are distinct.

Summary of the Effects of Plugging of the Cerebral Vessels:

Internal Carotid.—There may be no symptoms or there may be transient hemiplegia, or permanent hemiplegia and coma ending in death in a week or ten days. In the first alternative the circulation is maintained by the communicating vessels of the circle of Willis, which ordinarily dilate rapidly. If these vessels are small or absent, permanent hemiplegia and death must result, as a small part of the hemisphere only receives blood by the posterior cerebral. Thrombosis is very apt to extend from an initial focus in the internal carotid to its branches, and may extend to the ophthalmic artery.

Anterior Cerebral.—Because of the right-angled direction at which this vessel is given off from the internal carotid, it is rarely obstructed by embolus unless the parent trunk is plugged before this branch is given off, and then the mischief is trifling or *nil*, since branches of the middle cerebral may supply much of the same territory.

Middle Cerebral.—This is the most frequently plugged of all cerebral vessels.

The result is hemiplegia, permanent if the embolus lodges before the central arteries are given off, since softening of the internal capsule ensues; if beyond this point, the hemiplegia involving the arm and face is more apt to be transient. If on the left side, there is aphasia, and there may also be impairment of sensibility for a time. The symptoms vary somewhat, according as one or more of the cortical branches are obstructed by a plug at the point of division of the vessel in the island of Reil. Occlusion of the first branch may produce softening of the third frontal convolution and aphasia if on the left side; occlusion of the second and third branches, softening of the ascending frontal or ascending parietal convolution and hemiplegia, partial when the softening is incomplete; of the fourth branch, softening about the posterior limb of the fissure of Sylvius, and if on the left side, sensory aphasia—defective perception of words—with corresponding impairment of speech.

Posterior Cerebral.—Plugging of this branch distributed to the occipital and temporosphenoidal lobes is a rare cause of softening. So far as ascertainable the phenomena are mostly sensory, including hemianesthesia from softening of the tegmentum of the crus, or of the internal capsule, or hemianopsia from softening of the cuneus, though the same symptoms may result from interruption of the optic tract when the cortex is intact. Complete but temporary loss of sight has resulted from plugging of one posterior cerebral artery.

Basilar Artery.—Total occlusion of this vessel may produce bilateral paralysis from involvement of both motor paths in the pons, with other symptoms of apoplexy of this center—viz., bulbar palsies, irregularity of heart and breathing, spasm, and rarely convulsions; the temperature may rise rapidly to 109° F. (42.6° C.) or thereabouts after an initial fall.

Vertebral Artery.—The left is more frequently plugged, rarely alone, commonly along with the basilar. The nuclei of the medulla oblongata are affected, and we have symptoms of acute bulbar palsy.

Cerebellar Arteries.—Obstruction of the isolated cerebellar arteries is rare as compared with plugging of the parent trunk in the basilar. Even then the area of cerebral softening is limited, by reason of collateral anastomoses, and the symptoms are obscured by those due to damage to the pons and medulla oblongata. Inco-ordination of movement has been reported in one or two cases in which the region supplied by the posterior cerebellar was cut off.

Diagnosis.—It has already been said that the chief difficulty lies in the differential diagnosis between cerebral hemorrhage, on the one hand, and embolism and thrombosis on the other. Sometimes, indeed, at first it is impossible. Both are sudden. In *embolism* the patient is commonly younger, but not always so, and we look for valvular heart disease. According to Charles L. Dana, even in patients say between the ages of thirty and fifty, when there is no heart disease, the chances are six to one in favor of hemorrhage. *An apoplectic seizure after parturition is apt to be embolic.* In embolism, too, there is less disturbance of temperature, the paralysis is more apt to precede the coma and convulsions if the latter are present; the turgid face, hard pulse, loud breathing, and greater general disturbance of a serious stroke of apoplexy from hemorrhage are wanting.

In *thrombosis* the difficulty in diagnosis may be even greater. The symptoms of thrombosis are slower in their development, but in the "ingravescent" form of apoplexy, in which the hemorrhage is gradual, requiring sometimes a day or two, the development of symptoms is correspondingly slow. In thrombosis there are more frequently prodromata in the shape of slight seizures, quickly recovered from. Such events occurring in the aged, when there is evident atheroma of the blood-vessels and weak heart, point to thrombosis, in which, too, there is absence of stertorous breathing, of variations in temperature, and of pupillary disturbance. *Lesions in the pons and cerebellum* are more likely to be hemorrhages.

It is also important to be able to decide whether the obstruction is embolic or thrombotic. In the former the onset is sudden, without premonitory symptoms; in the latter it is gradual, and there are often premonitory symptoms. In the former there may be convulsive twitchings, but hemiplegia quickly follows, with or without temporary loss of consciousness. In the latter the patient has previously complained of headache, vertigo, or

tingling in the fingers; then paralysis may begin in one hand or foot and extend slowly, the hemiplegia often remaining partial. Speech may have been embarrassed for some days previous, and the memory defective. In thrombosis due to syphilis, especially, the hemiplegia may come on gradually without loss of consciousness. The same is true of the so-called senile softening, which is generally due to thrombosis after atheroma of the cerebral arteries. In a few cases the onset is more sudden, and may happen during sleep. The temperature usually has a slight initial fall, followed by rise, as in hemorrhage. In embolism aphasia is quite a characteristic symptom, as it seems to occur more frequently on the left side than on the right.

In both embolism and thrombosis the hemiplegia tends to improve rapidly unless the vessel obstructed be a large one or there be rupture of a collateral branch. It is true that acute softening may terminate fatally within twenty-four hours, but usually the patient survives the onset, and at the worst dies after several weeks, the phenomena of the chronic stage being almost identical with those of hemorrhage. Spastic symptoms are also likely to occur, and there is a tendency to the characteristic mobile spasm.

Prognosis.—A patient rarely dies of a first attack of cerebral embolism, unless a very large vessel is obstructed, such as the internal carotid or basilar, whose occlusion is fatal; next in seriousness after these is plugging of the middle cerebral and vertebral, while obstruction of the two vertebrals is always fatal. Every succeeding attack increases the danger. Embolism is less serious than thrombosis; and thrombosis due to syphilitic disease is more hopeful than senile softening. Sudden severity in thrombosis is serious, and deranged breathing is an unfavorable symptom. Convulsions may be a result of syphilitic thrombosis. When the embolism is due to valvular heart disease, it is apt to recur; when due to other causes, not. Thrombosis is prone to occur, especially when due to atheroma.

Treatment.—Neither thrombosis nor embolism demands blood-letting, as does hemorrhage. Indeed, it is strongly contra-indicated. *Rest in bed*, with head raised, is important. If syphilis is the cause of thrombosis, it should receive the usual treatment—the iodid of potassium in ascending doses until doses of a dram or more are reached. There is no treatment for atheroma. Attention should be paid to the heart, kidneys, and bowels. The heart is commonly feeble, and digitalis and strophanthus are needed to keep its action uniform and strong, by which one condition of thrombosis is removed. The urine is scanty and highly colored, but the treatment for the heart is also the treatment for the scanty secretion, which calls also for diluents. The bowels should be kept freely open to aid in promoting the circulation. The latter is aided by nitroglycerin, which may be given in doses of 1-100 grain (0.0066 gm.) every two hours. The iodid of potassium is useful also for this purpose. Its effects are more permanent than those of nitroglycerin. From five to fifteen grains (0.33 to 0.99 gm.) three times a day should be given.

Moderate stimulation is beneficial. The aromatic spirit of ammonia and alcohol are the most useful for this purpose. Mental excitement is to be especially avoided after a return to consciousness, and physical rest should be continued. Stimulants are then best discontinued, or continued in great moderation. Care should be taken to protect against the effects of decubitus.

Unfortunately there is no treatment which will restore softened brain matter, although a certain amount of function may be vicariously assumed. The same measures calculated to maintain nutrition and muscular integrity as are recommended in the treatment of hemorrhage should be taken.

B. Of the Cerebral Sinuses and Veins.

Description.—Thrombosis chiefly attacks the sinuses, and is *primary* or *secondary*. Primary thrombosis is the result of a state of the blood and circulation; secondary, a consequence of disease adjacent to the sinuses. The former is much the rarer, occurring half as often.

Primary thrombosis is met in the longitudinal sinus, more rarely in the lateral, sometimes in the cavernous. It is found associated with general malnutrition and prostration, more frequently in children during the first six months of life as the result of exhausting maladies, especially diarrhea. It is met also in older children. Brayton Ball and others have shown its association in young girls with chlorosis and anemia. It occurs in the aged also as the result of exhausting disease, like pulmonary tuberculosis and cancer.

Coagulation is favored by the trabeculæ which cross the cavity of the sinus, and by irregularities in the shape and lining of the latter. It may or may not be associated with phlebitis.

Very little is known of thrombosis of the cerebral *veins*, except that it may occur in veins of the convexity as the result of meningitis, and from the same causes that produce thrombosis of sinuses.

Secondary thrombosis occurs at any age, and is the result of disease adjacent to a sinus, commonly caries of bone, and is especially frequent as the result of disease of the internal ear. It spreads more frequently from the posterior wall of the middle ear, but also from the mastoid sinuses. Fracture, suppurative disease outside of the skull, especially erysipelas, and tumor compressing the sinus may produce it.

Symptoms.—There may be no symptoms in primary thrombosis, or there may be *nausea* and *vomiting*, *headache*, and *hebetude* increasing to *coma*. Dilatation of the pupils, choked discs, and paresis have been reported.

Secondary thrombosis is a septic process. It is commonly announced by a *chill*, followed by *fever* and *occipital pain*, succeeding on earache with suppurative otitis. The sinuses occluded are those near the ear, but the blood escapes by other channels, and the brain substance is not seriously invaded. The *symptoms of meningitis* are soon added. They are headache, somnolence, and stupor, or there may be active delirium and convulsions, rigidity, or optic neuritis, all the results of meningitis. Death is most frequently due to *suppurative pulmonary pyemia*, as was the case in 70 per cent. of Newton Pitt's cases, and the appearance of the latter disease under the circumstances is almost conclusive evidence of previous sinus thrombosis.

Prognosis.—This is always grave. The average duration of the secondary disease is about three weeks, and its termination is almost always fatal. Pitt reports a case of recovery in a boy of ten who had otorrhea for years, after removal of a foul clot from the lateral sinus by operation.

Treatment.—For primary thrombosis there is no treatment except

that for its cause. For secondary, operative treatment is indicated by trephining or other measures to give exit to pus. Quinin and restorative measures are indicated. Gowers lays particular stress on the use of the tincture of the chlorid of iron.

INTRACRANIAL ANEURYSM.

Definition.—Intracranial aneurysms are of two kinds, miliary and those of larger size. The former have been considered when treating of hemorrhage.

Distribution.—Larger aneurysms affect the larger arteries at the base of the brain in the following order:

1. Middle cerebral.
2. Basilar.
3. Internal carotid.
4. Anterior cerebral.

The anterior or posterior communicating and vertebral arteries are also occasional seats; the posterior cerebral and inferior cerebellar rarely. William Osler found 12 of these aneurysms in 800 autopsies, and Newton Pitt 19 in 1900. The aneurysm varies in size from that of a pea to that of a walnut.

Etiology.—Intracranial aneurysms are found rather more frequently in the male sex, and most frequently between the ages of from ten to sixty. Osler and Pitt each found one at the age of six. Heredity exercises some influence. Endarteritis and embolism, both of which weaken the vessels, are the chief causes. The former may be syphilitic or simple. The presence of endocarditis should especially invite examination for them at autopsies.

Symptoms.—*Death* from *apoplexy*, owing to rupture of the aneurysm, may be the first intimation. Not only are there often no symptoms, but when present they are vague. They may be those of tumor at the base of the brain, including optic neuritis and paralysis of the third and other cranial nerves. There are rarely *convulsions*. There may be *headache*, *vertigo*, *nausea*, *hebetude*, and even *coma*, *hemiplegia*, and *hemianopsia*. A *murmur* may be heard on auscultating the skull, while occasionally the patient himself is conscious of a murmur or recognizes the pulsations in his head.

Diagnosis.—This is usually impossible, but the foregoing symptoms, associated with endocarditis, may excite suspicion. *Syphilitic disease* being as likely to produce tumor, the history of its presence gives no assistance in diagnosis.

Treatment.—None exists which can be specifically directed to the disease.

THE CEREBRAL PALSIES OF CHILDREN.

Definition.—Referring to the division already made of the motor path into an upper cortico-spinal segment, extending from the cells of the cortex to the gray matter of the cord, and a lower spino-muscular, extending from the ganglia of the anterior horns to the motorial end-plates, the diseases now to be considered have their anatomical seat in the former, and

are characterized by paralysis, with spasm or disordered movements, exaggerated reflexes, normal electrical reactions, without rapid or extreme wasting. They result from a destructive lesion of the motor centers, or of the pyramidal tract in the hemisphere, internal capsule, crus, or pons. They are hemiplegic, diplegic, or paraplegic.

SPASTIC INFANTILE HEMIPLEGIA.

SYNONYMS.—*Hemiplegia spastica cerebialis* (Heine); *Hemiplegia spastica infantilis* (Bernhardt); *Acute Encephalitis der Kinder* (Strümpell); *Die atrophische Cerebrallahmung* (Henoch); *Agénèse cérébrale* (Cazauvielh); *Sclérose cérébrale atrophie partielle cérébrale* (other French writers).

Historical.—In 1834 Strümpell, in a paper, "Ueber die acute Encephalitis der Kinder," called attention to the possibility of encephalitis in children. Numerous papers on infantile hemiplegia have appeared in Germany, France, and America, among which may be especially mentioned those of Gaudard, Wallenberg, Jules Simon, Morse, Ross, Gowers, Sarah J. McNutt, Weir Mitchell, B. Sachs, Wharton Sinkler, H. C. Wood, J. Lewis Smith, and William Osler.

Etiology.—The disease is somewhat more common in girls than in boys, 63 out of 120 cases studied by Osler at the Nervous Infirmary in Philadelphia being of this sex. Of these cases 15 were congenital, 45 arose in the first year, 22 in the second, 14 in the third, 1 in the fourth, 3 in the fifth, sixth, and seventh, 1 in the eighth, ninth, tenth, and older. In 10 the age of onset was not given. The hemiplegia was right-sided in 68 and left-sided in 52 cases.

Among the causes may be mentioned abnormal conditions of the mother during pregnancy, including accidents, possibly disease, especially syphilis, in a few cases fright or distress, the effect of the last two being doubtful. Especially frequent causes are difficult or abnormal labor, injury with forceps producing flexures and fractures of the cranial bones during delivery. After birth are penetrating wounds of the head, ligation of the common carotid, and infectious diseases, including whooping-cough, diphtheria, scarlet-fever, measles, meningitis, typhoid fever, vaccinia, and mumps. Previous convulsions may cause the lesion on which the paralysis depends, and in a few cases embolism may be responsible.

Morbid Anatomy.—The morbid states of the brain found at autopsy are mainly *sclerosis* and *porencephalia*—defect consisting in arrest of development of the brain resulting in the absence of convolutions or even lobes, causing irregular subpial cavities. *Embolism* and *thrombosis* of vessels, especially of the Sylvian artery, and *hemorrhage* into the ventricle and substance of the brain, are found in a few cases. The sclerosis involves either groups of convolutions, an entire lobe, or even an entire hemisphere. The *skull* may be flattened on the affected side, broad and prominent above the mastoid processes, sometimes thickened. The *dura* may be thickened and adherent, and in one case contained extensive osseous plates. The *arachnoid* is turbid and thickened and the amount of cerebrospinal fluid is increased. The *pia mater* may be thickened and adherent, and drag portions of the cortex away on being removed, leaving a roughened surface, while there may be nodular projections of sclerosed tissue. The *reduction of weight* of the sclerosed hemisphere may be very considerable; in one case, referred to by Osler in his monograph, the atrophied hemisphere weighed

5 1-2 ounces (169 gm.), the normal being 20 ounces (653 gm.). The lateral *ventricle* may be greatly *dilated*, and the brain tissue over it very thin, while *cysts* have been found in the sclerosed areas—the remnants of old hemorrhages. The Rolandic area is that most frequently involved.

In 90 cases studied by Osler the lesions in 50 were atrophy and sclerosis, in 24 porncephalia, and in 16 embolism, thrombosis, or hemorrhage.

Symptoms.—The symptoms are complex and varied, but may be divided into three classes: those of the *onset*, those pertaining to the *paralysis*, and the *residual* symptoms.

The *hemiplegia* is usually preceded or accompanied by *convulsions* and *coma*, although the disease may come on suddenly, without spasms or loss of consciousness, in children apparently healthy. In the majority of cases, however, the disease begins with convulsions, partial or general. Loss of consciousness almost always accompanies the convulsions, and may last from a few hours to many days. Rarely coma occurs without convulsions. Among other symptoms may be mentioned *fever*, transient or persistent; according to Strümpell and Gaudard, it is an invariable accompaniment of the convulsions. *Delirium* is a common symptom, as is also *soreness* of the general surface. *Vomiting* and *screaming spells* are also noticed.

The *hemiplegia*, which is noticed as soon as the child recovers consciousness, is usually complete. Less commonly there is first, *paresis*, which gradually extends to complete loss of power; and in some instances a total *paralysis* is established after repeated convulsions. The *face* is not always involved, and, as a rule, in facial paralysis of cerebral origin the superior muscles are intact, and the child can close the eyes and elevate the brows. The facial palsy usually disappears rapidly and completely.

As to residual symptoms in adults, also, the *residual paralysis is most marked in the arm*, which is subject to slow wasting, and is commonly useless for the ordinary purposes of life. The *atrophy is moderate*, but there may be arrested development, leaving a wasted and withered member. In extreme cases the arm is held close to the side, the forearm strongly flexed at right angles and in a semiprone position, the hand flexed and the fingers contracted, the palm usually embracing the thumb. Motion may be almost lost in the arm and completely in the fingers, though in most cases there is considerable power of movement, the patient being able to lift the arm above the head, while flexion and extension can be made at the elbow and wrist. The finer and more delicate movements of the hand are rarely recovered. The *leg*, as a rule, *recovers more rapidly* and completely than the arm, and the palsy may disappear entirely in it, while it rarely does in the upper extremity. In the leg the wasting is also less pronounced, while arrested development is also less frequent. A persistent halt is apt to remain—indeed, almost always does—as evidence of impaired power; this may consist in simply favoring the affected side, noticeable only on rapid walking. A decided dragging of the limb is, however, more usual, and there may be tremor of the leg while moving.

The frequency with which *rigidity* is present has given rise to one of the names of the disease, *spastic infantile hemiplegia*. It is not, however, an invariable symptom, and the paralyzed limbs may be relaxed a long time after paralysis sets in. When rigidity is present, it is lessened during sleep, and is increased by emotion and forcible attempts to overcome the spasm. Contracture may ultimately result, after which relaxation is no longer

possible. A form of rigidity without much paralysis is known as *postoplectic hemi-hypertonia*, and has been previously referred to.

The *reflexes* are almost always *increased* in the affected limbs, ankle clonus being often obtainable in addition to exaggerated knee-jerk. The reflexes may even be increased on the sound side. Rectus clonus and clonus of the flexors of the fingers are rarely present, while in a very few cases the reflexes are absent.

Sensation is rarely affected, but vasomotor derangements are sometimes present. *Electrical reactions* are *normal*, as a rule.

Posthemiplegic *chorea*—*hemiataxia*—is not infrequent. More uncommon are *mobile spasm* and *athetosis* and posthemiplegic *tremor*. These interesting symptoms were first described by S. Weir Mitchell and Hammond in a study of cases of cerebral palsy.

Aphasia is present in a majority of cases almost invariably transitory, associated most commonly with right hemiplegia, very rarely with left.

Defects of intelligence are very common, the degree of feeble-mindedness ranging from low-grade imbecility to total idiocy. Psychoses may occur late in life, even when there have been no defects in childhood.

Epilepsy is very frequent, and is sometimes confined to the paralyzed side, but also tends to become general. The attacks usually begin within two or three years, sometimes within a few weeks, after the onset of the hemiplegia, but may be delayed from eight to ten years, or even longer. The seizures may present *three well-defined degrees*—the first, in which the child is simply dazed for a moment or two, or longer, without any motor involvement; second, Jacksonian epilepsy, without loss of consciousness, in which the spasms are confined to the affected side,* and third, general convulsions, beginning in the paralyzed limbs, and usually accompanied by loss of consciousness. The Jacksonian epilepsy is most common, but all forms may occur in any one case.

Diagnosis.—Infantile *spinal* paralysis, anterior poliomyelitis, most frequently must be excluded, usually without difficulty. The history of the case, including the presence of some of the causes named, the frequent onset with convulsions, the hemiplegia, the absence of rapid wasting of the affected muscles, the retained electrical reactions, are characteristic of infantile cerebral hemiplegia in its early stage; while rigidity of muscles, increased reflexes, the peculiar gait, and residual palsy, with mental imbecility and epileptic seizures, distinguish the latter stage.

Tumor of the brain sometimes produces similar symptoms. Tuberculosis and glioma are the forms most common in children. *Pressure paralysis* by obstetrical forceps affects the face and upper extremities, but other symptoms are wanting, and it is scarcely likely to be confounded with infantile hemiplegia.

Prognosis and Treatment.—The prognosis is favorable so far as life and the recovery of considerable locomotive power are concerned; unfavorable as to recovery from mental defect and epilepsy. An institution for feeble-minded children, in which the subjects have the benefit of training and watching, is the safest permanent home for them.

* Jacksonian epilepsy is usually without loss of consciousness, unless the convulsions are very severe or involve a large portion of the body.

BILATERAL INFANTILE SPASTIC HEMIPLEGIA.

SYNONYMS.—*Spastic Rigidity of the New-born* (Little); *Tonic Contraction of Extremities*; *Essential Contractions*; *Permanentes Kinder-Tetanus* (Stromeyer); *Spastic Paralysis of Children* (Adams); *Spastic Diplegia* (Gee); *Spasme Musculaire Idiopathique* (Delpech); *Birth Palsies* (Gowers); *Little's Disease*.

Historical.—Delpech was probably the first to describe the disease fairly correctly. To the German orthopedic surgeon, Heine, belongs the credit of first appreciating these conditions and their cerebral origin and separating them from common infantile paralysis. His paper was written in 1860. Little's paper, published two years later in England, so attracted attention that his name became applied to the disease. Stromeyer, Adams, and Rupprecht have furnished careful accounts.

Etiology.—Most cases of bilateral hemiplegia in children date from birth, and are the result of *injury during birth*. The infectious fevers are responsible for a certain number, and a few are direct results of convulsions. In a word, the causes are those of infantile hemiplegia.

Morbid Anatomy.—As may be inferred from the name, the lesions are bilateral and involve motor areas of the cortex almost solely. They consist in *sclerosis* or *porencephalous* defect, of which the most frequent primary cause is compression by a blood-clot due to meningeal hemorrhage from the veins or longitudinal sinus. A meningo-encephalitis may, however, be responsible for the sclerosis.

Descending degeneration of the pyramidal tracts or imperfect development of these tracts has been found in a few cases.

Symptoms.—These are to be distinguished from those of the next form, cerebral spastic paraplegia, which the disease closely resembles when the arms are so slightly affected that the palsy is scarcely appreciable. The cerebral spastic paraplegia of childhood is due to lesions similar to those of the bilateral spastic hemiplegia. In the diplegic state *all the extremities* must be more or less *spastic*, although the legs almost always are more so than the arms. These cases are further characterized, as are those of spastic paraplegia, by their occurrence *at or very soon after birth*.

There may be *convulsions* or a prolonged succession of convulsions immediately after birth. After this or without it there may be noticed a *limpness* or flaccidity of *muscles*, an expression of *paresis*, often overlooked, because present at a time when the muscular development of the child is so slight that little is expected of it. Soon, however, the *inability to hold up its head* may be observed, and when the time comes for it to walk, it is noticed that the limbs are clumsily used, and when examined, they are found to be *stiff*. As the child grows older it slowly acquires some power so as to be able to sit, but the *legs* are *crossed* and the head is not well supported by the neck muscles. If it is held up, the legs are extended and strongly adducted, and crossed with the feet in the pes equinus or equinovarus position. Occasionally the legs are partially *flexed*, while stiffness varies greatly, involving, in extreme cases, the whole body, sometimes one side more than the other. It is sometimes constant, at other times not. It may be greater on one side than another. The *arms* are usually *stiff* in flexion.

To the spastic symptoms described are added, in certain cases, *spasm* and certain movements known as *athetoid*. In the former, in an attempt at voluntary movement, as taking hold of an object, the fingers are thrown

out in a stiff, spasmodic, or irregular manner, or there may be constant irregular movements of arms and shoulders, movements which are usually characterized as choreic. In fact, such cases have been named *chorea spastica*, being differentiated from the congenital choreas by the spastic feature. Spasm rarely affects the muscles of the face, though it does occasionally, causing a continual *grimacing*, which does not always disappear during sleep.

The *athetosis* is double or bilateral, resulting in the most grotesque and distorted movements. They consist in a constant flexion and extension of muscles, more particularly of those of the fingers of one hand and forearm. Flexion of the fingers of one hand may take place, while those of the other may be extending, and the same may be true of different fingers of the same hand. The shoulder and trunk muscles may be also affected, producing a rhythmical and orderly twisting and bending of the body; or those of the neck, producing a turning of the head from side to side. These movements are all increased under excitement or with the effort to do anything.

Mental defect, consisting in imbecility and various grades of idiocy, is more or less characteristic of these cases, but is commonly less than in infantile hemiplegia.

The form resulting from premature birth should be distinguished from that caused by injuries at birth, or by lesions acquired later, as in the former convulsions and athetoid movements do not usually occur, mentality may not be affected, and improvement may be slowly progressive even after many years.

INFANTILE SPASTIC PARAPLEGIA.

SYNONYMS.—*Paraplegia cerebri spastica* (Heine); *Tetanoid Pseudoparaplegia* (Seguin); *Spastic Spinal Paralysis* (Erb); *Tabes dorsalis spasmodique* (Charcot).

Definition.—Spastic paralysis of the legs in children.

Historical.—A common affection of children, though only recently understood, was fully described and correctly named by Heine in 1849. Delpech and Stromeyer in Germany and Adams and Little in England described it. Erb and Seeligmüller in Germany and Gee in England brought the subject to the notice of physicians, and Erb contrasted it with the spastic paraplegia of adults. Ross, Hadden, Gowers, d'Heilly, Gilbert, and Osler have more recently treated the subject as one of the cerebral palsies of children. It must be distinguished from the spastic paralysis occurring in adults and found in a very few cases to be due to primary degeneration of the pyramidal tracts.

Etiology.—The causes are those of spastic diplegia and infantile hemiplegia, and also premature birth, the child being born at a period when the central motor tracts are very imperfectly developed; premature birth causes an arrest in the development of these tracts.

Morbid Anatomy.—This is less known than the morbid anatomy of the other forms of cerebral palsy. It may be due to cerebral lesion involving especially the centers for the lower limbs, to imperfect development of the motor tracts, or to other causes. A few cases with necropsy are recorded.

Symptoms.—These are almost *identical* with those already described as belonging to the *spastic paraplegia of adults*, with which the earlier writer classed it. Spastic paralysis of the lower extremities, dating from

birth or appearing within the first few years of life, with talipes equinus or equinovarus, adductor spasm, rigid stiff gait, the patient walking on his toes or by crossed-legged progression,—*all without wasting*,—these are, in a word, the symptoms. The order of sequence of events is very similar to that described under spastic diplegia. In attempting to walk the heels are everted and knees approximated, because of spasm of the adductors, which may be so strong as to make it impossible to separate the thighs. The spastically extended legs may, however, be gradually forced into flexion after the manner of the “lead-pipe” contraction. If, however, the attempt be made to extend the leg, the spasm returns. If the extension be gradually insisted upon, it often happens that when the extension is nearly complete, the spasm suddenly completes it, as the spring acts on the blade of a pocket-knife, whence the name “clasp-knife” rigidity.

Mental imbecility is not so serious as in spastic diplegia or even as in infantile hemiplegia, and may be entirely absent, especially in those cases resulting from premature birth.

Diagnosis.—The distinction between *spastic diplegia* and *paraplegia* is not a very important one. The two conditions are probably the results of different degrees of similar lesions having different locations. There is an affection of children known as *pseudoparalytic rigidity*, idiopathic contraction with rigidity, or tonic contraction of the extremities, with which it is sometimes confounded, but the following table of differences from Osler’s monograph will aid in separating the two conditions.

PSEUDOPARALYTIC RIGIDITY.	SPASTIC PARALYSIS; DIPLEGIA AND PARAPLEGIA.
Follows a prolonged illness. Is often associated with rickets, laryngismus stridulus, and the so-called hydrocephaloid state.	Usually exists from birth. History of difficult labor [or of premature labor], of asphyxia neonatorum, or of convulsions.
Begins in hands and feet as carpedal spasm; often confined to hands and arms.	Arms rarely involved without legs and not in so marked a degree.
Spasms painful and attempts at extension cause pain.	Usually painless.
Intermittent and of transient duration.	Variable in intensity, but continuous.

The spasm in the pseudo cases is altogether more severe and difficult to overcome. The disease is associated with rickets and other constitutional diseases.

Tetany is characterized by a different history and causation. Bilateral rigidity may also be produced by *tumors* of the pons and cerebellum.

Treatment.—The treatment varies with the stage existing at the time the physician is called. If in the stage of initial convulsion, there is no remedy like chloral, which should be given in doses sufficient to control the fits. In the mild degrees, or with a view to keeping up an effect first obtained by chloral, the bromids may be used. If chloral fails, chloroform may be inhaled.

In established paralysis medicines do not avail much and recoveries are rare. Hygiene and good food, gymnastics, manipulation, massage, passive motion, and surgical appliances may be used. Baths and electricity should not be forgotten.

The epileptic convulsions should be treated as when occurring under other conditions, though the cortical lesions occasioning the disease preclude any expectation of permanent relief. Operative procedure has been sug-

gested in certain selected cases and carried out, but with results which have been disappointing.

The mental deficiencies are best treated in an institution for feeble-minded children, where all such cases should be taken, whatever the circumstances of the parents.

SCLEROSIS OF THE BRAIN AND SPINAL CORD.

MULTIPLE SCLEROSIS OF THE BRAIN AND SPINAL CORD.

SYNONYMS.—*Insular Sclerosis; Disseminated Nodular Sclerosis; Sclérose en plaques.*

Definition.—A chronic affection of the brain and spinal cord, consisting in the presence of numerous sclerotic patches scattered through the nerve centers, characterized especially by intention tremor, scanning speech, and nystagmus.

Etiology.—Its precise cause is unknown. The infectious diseases, especially scarlet fever, are alleged causes; so are cold, exposure, mental emotion, and syphilis, but without definite foundation. Hereditary predisposition has been noticed. The disease is more common between the ages of eighteen and thirty-five, though Strümpell met a case which came to autopsy at sixty. Both sexes are equally subject. Prichard states that more than fifty cases have been reported in children, but it is doubtful whether the diagnosis was invariably correct. It has been thought that the disease depends on anomalies of the vessels, but this view is not held by all.

Morbid Anatomy.—The sclerosed patches are widely scattered through the brain and cord, rarely in the cord alone. They may generally be recognized by their gray color and unnatural firmness. On section, they appear as grayish-red areas. Histologically they consist of thickened neuroglia traversed by a few healthy nerve-fibers. In the vessels there is an increase of the nuclei and, later, a thickening of the walls. Fatty granular cells are present in fresh cases. Many of the axis-cylinders are preserved in the sclerotic patches for quite a long time after destruction of the medullary sheaths. The favorite seats of the plaques in the brain are the centrum ovale, the walls of the lateral ventricles, the corpus callosum, and the cerebellum; while they are quite numerous in the pons, less so in the medulla oblongata, but numerous in the cord, especially the white substance. The cortex is not often invaded.

Symptoms.—By no means every case of multiple sclerosis can be recognized, so often are the symptoms united with those of other lesions whose effects predominate, while the slowness of the onset necessitates delay in the recognition of even typical cases. Typical cases do, however, occur, and they present a set of symptoms whence their recognition is more or less easy.

One of the most important of these symptoms is *tremor*, known as “*intention tremor*,” because associated with any voluntary effort to perform an act, as picking up an object, raising a glass of water to the lips, or apposing the ends of the fingers of the two hands. This does not prevent the ultimate attainment of purpose. When the patient is quiet, the tremor ceases, and in this respect it can be differentiated from the trembling of paralysis agitans. It is not confined to the arms, but occurs also in the head and trunk,

so that the head trembles when it is raised from the pillow. It is increased by excitement.

Another characteristic symptom is what is known as *scanning speech*, a slow, measured, yet indistinct and obscure utterance, depending upon disturbances in the innervation of the tongue and larynx, probably due to the presence of sclerotic patches in the pons and medulla oblongata. There may be tremor in the tongue and lips when speaking. The third symptom is nystagmus—oscillatory or lateral movements of the eyeball when the eyes are directed to an object. In addition there may be *spastic symptoms* manifested chiefly in the presence of *increased reflexes*—including periosteal as well as tendon reflexes—in both upper and lower extremities, but the skin reflexes remain normal. There is ankle clonus, and the gait is often spastic. *Paresis*, at first absent, ultimately appears, amounting at times to complete *paralysis*. Indeed, spastic rigidity and paresis may be among the earliest signs of the disease. The sphincters remain intact, at least until toward the close. There are *no disturbances of sensibility* in the majority of cases. *Optic atrophy* is sometimes present, less commonly than in tabes dorsalis, and associated with such *derangements of vision* as amblyopia, achromatopsia, and even blindness. *Optic neuritis* may occur with subsequent atrophy, especially in the temporal halves of the optic nerve. There may be also derangements of innervation with diplopia.

Mental weakness and *imbecility* are sometimes present, more rarely *melancholia* or *exaltation*. *Apoplectiform* attacks also occur, following prodromal symptoms, such as *vertigo* and *headache*, and succeeded by hemiplegia, which, however, subsequently disappears.

Diagnosis.—This is not difficult in typical cases. The intention tremor, the scanning speech, and nystagmus are characteristic, and when associated with spastic weakness, the diagnosis of multiple sclerosis is probably correct. The apoplectiform seizures and mental weakness are also valuable signs. When the symptoms are mixed with those of other nervous lesions, diagnosis is not so easy. In *paralysis agitans* tremor occurs during rest as well as motion; in multiple sclerosis only when motion is attempted. Strümpell says: "The circumstance, indeed, that the anomalous cases will not properly fit the molds of any other form of disease should make us think of the possibility of multiple sclerosis."

The disease known as *pseudo sclérose en plaques*, described by Westphal, seems to have most of the symptoms of multiple sclerosis except nystagmus. The tremor movements are said to be more violent. Strümpell has found slight degeneration of the pyramidal tracts in a few cases of this kind.

Prognosis.—This is unfavorable after a long and tedious course, terminating in the bedridden state.

Treatment.—This is unavailing. The end may be delayed by galvanism and tepid bathing.

DEMENTIA PARALYTICA.

SYNONYMS.—*Chronic Diffuse Meningo-encephalitis; Paretic Dementia; General Paresis; Progressive General Paralysis of the Insane.*

Definition.—A chronic progressive meningo-encephalitis, or meningo-rachitis, with resulting mental and motor derangements, terminating in dementia and paralysis.

Historical.—Boyle in 1822 and Calmeil in 1826, by their descriptions, first separated paralytic dementia from other diseases which run a like course. The minute anatomical changes lying at the bottom of the symptoms are a matter of comparatively modern study, and have received valuable contributions from Bevan Lewis and others.

Etiology.—At least 75 per cent. of all cases are caused by syphilitic infection, and observations reported by Krafft-Ebing seem to indicate that the proportion is much greater. Starting out with this assumption, we have at once an explanation of its greater frequency in the male sex, though many women have it; while it is rather a sad commentary on the fidelity of man that it is much more frequent among married men. The fact that it occurs most frequently between the thirtieth and fiftieth years, that it is a disease of the better classes,—especially army officers and artists,—and that it is pre-eminently a disease of the cities, should be added. Although other factors apparently enter into the causation of general paresis, those who have most closely studied the subject are disposed to assign to them a predisposing rôle. Such influences are heredity and exhausting mental work, such as comes of public political life and ambitious financial ventures. Intemperance, chronic lead poisoning, and traumatism are included among causes.

Morbid Anatomy.—An *atrophy* of the brain, and especially of the frontal lobes, may be set down as the most important morbid change. The convolutions are wasted and pale in color, the fissures are wider, and the weight of this portion is reduced to one-fourth or one-third the normal, while the consistence is firmer and more resisting to section. Other macroscopic changes are a *thickening of the dura mater*, *pachymeningitis interna*, *edema of the pia* with thickening, opacity, and adhesion to the cortex. Minute examination of the cortex recognizes *thickening of the vessel-walls* and cellular infiltration of the adventitia of the arterioles and lymphatic sheaths—in other words, the effects of mild inflammation. To these are added demonstrable *destruction of nerve elements*, especially of the fine medullary nerve fibrils known as “tangential fibers” in the frontal convolutions, island of Reil, and elsewhere; also *atrophy of the ganglion cells*. Associated with this are neuroglia or proliferation and numerous Deiters’ spider cells. Here enters a contested question as to whether these nerve changes are primary or secondary to an interstitial encephalitis. Tuczek, Wernicke, and Strümpell hold to the former view; while Rindfleisch and Mendel adopt the latter, making the destruction of nervous tissue secondary to the overgrowth of neuroglia.

The white matter is also involved, the central ganglia as well. Coincident *changes in the spinal cord*,—first described by Westphal,—consisting in fascicular systemic degeneration of the *lateral columns* and *posterior columns*, either alone or jointly, are quite constantly present. To these is ascribed a large part of the ataxic and spastoparalytic symptoms. From this brief statement of the character and situation of the morbid changes it will be seen that they are widespread in their distribution through the nervous system, while they are also degenerative.

Symptoms.—So widely scattered a distribution of morbid phenomena naturally brings about corresponding differences in the variety and degree of the symptoms. As further characteristic, no absolute constancy is observed in the order of their development. As a rule, however, the *first stage* is characterized by abnormal mental processes, and these are at first what may be comprehended under the single expression *peculiarity* or “*queer-*

ness" of conduct. The patient will perform acts wholly unnatural to him, and will surprise his friends and family by breaches of decorum and morality. An *apathy* and *loss of memory*, causing the omission of obligations, are also constant. At first these may pass unnoticed as temporary, but their permanence is gradually established. In lieu of this may be present an irritability and intense *restlessness*, so that the patient cannot remain in one spot, but walks constantly to and fro. Not often in this stage is there much volubility, but rather a *morose silence* is observed. In this stage, too, the patient may make rash and ruinous financial ventures, and lose his own money and that of his friends, or he may become very generous, giving away freely all he possesses, and more, too. The power of arithmetical calculation is defective or gone. He may be self-satisfied and intensely egotistical. On the other hand, he may be conscious of these ills and be anxious about them, as well as experience a discomfort or malaise, for which he may consult the physician.

Nor are *motor disturbances* wholly wanting in the first stage. They are chiefly *derangements of speech and handwriting*, and are of no small diagnostic value. The speech is slow and hesitating, yet the patient stumbles over syllables, especially when the word is complex or rather difficult to enunciate. As to the handwriting, it is tremulous, characterized by the omission of letters and substitution of wrong ones, as well as erroneous spelling—all motor defects.

Other symptoms of the first stage are *inequality of the pupils, ocular paralysis*, and *absence of patellar reflex*, in tabetic cases often reflex immobility of the pupils, and in spastic cases increase of reflexes. There may be *neuralgic pain* and attacks of *migraine*.

The *second stage* is characterized by more *exalted mental symptoms* and excitement, with a *higher degree of motor disturbance*. The former consist in exaggeration of all previously maintained mental symptoms, amounting to noisy, boisterous, and maniacal excitement, and even uncontrollable violence. In this stage belong, too, those extraordinary delusions of grandeur—expansive delirium—in which the patient imagines himself or herself to be a person of great consequence and unlimited wealth. This is not, however, invariable, and there may be an exaggerated degree of the opposite condition of melancholy sometimes present in the first stage, or the two conditions of delirium and depression may alternate or may be absent. Sleeplessness may be added to restlessness and mental excitement, causing rapid decline of strength.

Motor disturbances are greatly increased in this stage, but a uniform order of invasion is by no means always observed, while remissions and temporary improvement are often noticed. *Speech* becomes almost impossible and incomprehensible. There is paraphasia—persistent repetition of words—and reading and writing are impossible. The voice can no longer be modulated, and is weak and rough from imperfect innervation of the vocal cords.

The *gait* becomes defective, and the patient often trips in walking. There may be *ataxia* and other tabetic symptoms; apoplectic seizures with *paralysis*; or *epilepsy* with grand or petit mal and aura, sometimes one-sided and followed by monoplegia or hemiplegia. There may be loss of *sensibility*, with bladder and rectum paralysis. The *tendon reflexes* may be lost and the pupil be immobile, or the opposite condition of spasm with increased tendon reflexes prevails. The paralytic attacks may occur in the earlier stages,

though in mild degree, manifested by vertigo or obscuration and loss of consciousness, lasting for a short time and then passing away. There may be local twitching in the face and extremities and even typical Jacksonian epilepsy. Finally, *bulbar* symptoms may appear with invasion of the medulla oblongata. Ultimately, the patient becomes helpless, bedridden, and completely demented, dying from exhaustion or intercurrent disease.

In a few cases none of the mental symptoms described are present, but a gradual decline of mental power takes place until complete dementia supervenes. An *acute variety* is also sometimes met, properly termed "galloping," in which the disease runs its whole course in a few months, and is especially characterized by emaciation and rapid loss of strength due to restlessness, sleeplessness, and insufficient food. The pulse and temperature are essentially normal, or at least there are not characteristic variations.

Diagnosis.—To recognize paretic dementia *ab initio* is perhaps impossible, but to watchful observation the disease commonly reveals itself after the symptoms have existed for a short time. The early symptoms resemble those of *neurasthenia*, but differ from those of the latter disease in their steady progression. Other affections possibly mistaken for it are *cerebral syphilis*, *tumors of the brain*, and *multiple sclerosis*. In *cerebral syphilis* the onset is usually more sudden, and paralytic symptoms appear earlier. Headache is more frequent and severe, and there may be convulsive seizures, but affections of the tongue and speech are wanting, while the train of mental symptoms is less complete and characteristic, and expansive delirium, as a rule, does not occur. The epilepsy is more commonly Jacksonian. It is to be remembered that the syphilitic virus produces both, and it is not unnatural that the two should sometimes merge. *Tumors of the brain* frequently, but not always, produce symptoms more localized, and often also optic symptoms, including choked disc. The symptoms of *insular sclerosis*, which include dementia, are often identical with those of paralytic dementia, and the two diseases cannot then be differentiated. Intention tremor is more characteristic of sclerosis. The cerebral symptoms of some forms of *plumbism*, it is said, also sometimes closely resemble those of paralytic dementia.

Prognosis.—The prognosis is almost always unfavorable, although the course of the disease varies somewhat. The most rapid cases of the galloping form may terminate in a few months, but two or three years is the more usual duration; sometimes much longer, it may be ten years or more. Death ensues from exhaustion, hastened by the complications and secondary conditions which naturally supervene on an illness so prolonged and in which nutrition is so interfered with; or it may be due to intercurrent disease.

Treatment.—In view of the general acknowledgment of the syphilitic origin of chronic diffuse meningo-encephalitis and the acknowledged efficiency of antisiphilitic treatment over tertiary manifestations of the disease, it is rather surprising that attempts at curative treatment are so futile. The treatment is confined mainly to iodids and mercurials. Mercurials are best used by inunction, and the iodids in ascending doses. These, however, do not arrest the disease.

As to the rest, treatment must be symptomatic. The bromids and chloral, with quiet, hygienic surroundings, and sometimes enforced retirement, are measures demanded for the relief of the nervous excitement.

For the opposite condition of depression and melancholia change of scene by travel and residence in different localities should be enjoined.

Further than this the use of a proper hygiene, with bathing, frictions, wholesome outdoor life, and an abundance of nourishing and easily assimilable food constitute about the sum of the means we can bring to bear against the disease.

TUMORS OF THE BRAIN.

SYNONYMS.—*Ncoplasmata cerebri*; *Intracranial Tumors*.

Definition.—Cerebral tumors, clinically considered, include not only tumors of the meninges and substances of the brain, but also all intracranial and even such extracranial tumors as ultimately invade the brain. Among the latter are tumors of the orbit or nasal cavity, of the antrum, and of the sphenopalatine fossa.

Varieties.—The principal varieties of cerebral tumor, approximately in the order of frequency, are:

1. Tyroma, or tubercular tumor. 2. Glioma. 3. Sarcoma. 4. Carcinoma. 5. Cystic, including parasitic cysts and cysts arising in sarcomata and gliomata. 6. Gumma. 7. Histioid tumors. After these occur in irregular order, cholesteatoma, lipoma, myxoma, angioma, fibroma, psammoma. Even dermoid cysts, as well as parasitic cysts—including the echinococcus or hydatid cyst—and the cysticercus cellulosæ, are met. Of these tumors, psammoma and glioma are peculiar to the brain. According to M. Allen Starr's tables, gliomata and gliosarcomata practically equal in number the sarcomata, but the term gliosarcoma is regarded by many unfavorably.

Etiology.—Except sarcoma, tumors are found in males more frequently than in females. Tubercle is more common in childhood; parasites, glioma, sarcoma, and gumma in early and middle life, and cancer in middle and late life, but is rare even then. Brain tumors of any kind are rare after sixty. Heredity appears to have slight, if any, influence. A few brain tumors are metastatic, especially carcinoma, and to a less degree sarcoma. Eichhorst relates several remarkable cases in which trauma seemed to be the exciting cause.

Certain tumors seek by preference special localities. Thus, *tuberculous* tumors are most numerous in the cerebellum and about the base of the brain. *Glioma* starts from the neuroglia in any part of the brain, but more frequently the cerebrum, and may also attain a large size—larger than any other brain tumor; it is further characterized at times by its great vascularity, leading sometimes to rupture and apoplectic symptoms. Glioma may also occur in the eye. *Sarcoma* develops also most frequently in the membranes of the brain and sheaths of the vessels; it may be primary or secondary; it is often encapsulated. *Myxoma* and *fibroma* occur in the same localities. *Carcinoma* is usually secondary, but may be primary; it arises more frequently in the membranes, but may be found in the substance of the hemispheres; it is especially secondary to primary cancer of the breast, lungs, or pleura. *Syphiloma* elects the hemispheres or the pons and vicinity; it is generally superficial, grows from the meninges, or is attached to arteries, attaining sometimes a large size. It may be multiple. *Parasitic tumors* are found in the membranes, the substance of the brain, and the ventricles. The hydatid cysts developed by the echinococcus are usually on the surface of the brain; the cysticercus, usually multiple, on the surface or in the ventricles.

Psammoma, or sand tumor, is found commonly in the neighborhood of the pineal gland.

Symptoms.—The symptoms of cerebral tumor are in no way specialized by the kind of tumor present, and depend entirely upon the effect exerted on the surrounding brain substance, chiefly by pressure. They do, however, vary somewhat with the part of the brain involved. It occasionally happens that a brain tumor may produce no symptoms whatever, being thoroughly latent, and disclosed only by the autopsy. On the other hand, apparently insignificant tumors cause very decided symptoms. Such differences may depend in part on the location of the tumor, and in part on the rapidity of its development.

As in all local diseases of the brain, two sets of symptoms usually present themselves: (1) Diffuse and (2) Focal symptoms.

1. *Diffuse or General Symptoms.*—These are symptoms which may be associated with various forms of nervous disease. The most constant of these is perhaps *headache*, which varies in intensity and constancy. Probably the severest headaches it is given human beings to suffer are caused by brain tumors, exhibiting every variety of pain—sharp, cutting, shooting, boring, or dull and pressing. At times it is moderate, producing a sense of discomfort only. It may be intermittent or constant. It may be over the entire head, or half of it, or be still more localized in the forehead or back of the head, extending also from the former over the face and the latter down the neck. It may be increased by mental excitement of any kind, by noise, or by alcoholic drink or strong light. There may be tenderness on pressure, or pain in percussing the head. The seat of pain is, however, for the most part, no indication of the seat of the tumor, though the presence of pain limited to the occiput and back of the neck suggests a tumor in the posterior fossa of the skull, the occiput, or the cerebellum. Localized pain on tapping the skull is a more reliable index.

Vomiting is another characteristic symptom of brain tumor. It may occur independent of headache, but is often associated with it. It is further characterized by being independent of food ingestion, may be without nausea, and is apt to be worse in tumors of the cerebellum and pons.

Dizziness is also a very frequent symptom, and often an early one. It is at times intermittent, at others constant, and it may be so severe as to make it impossible for the patient to walk. It is most serious in tumors of the posterior fossa and of the cerebellum. Along with vertigo may be *slowing of the pulse*.

Mental symptoms may be present. They may be intermittent, and variously manifested in peculiarities of temper, such as sullenness, indifference, absent-mindedness, and loss of memory; or the opposite condition of maniacal excitement or delirium; or there may be drowsiness and even coma. Such mental states may, indeed, be the only manifestations of tumor.

Speech.—The patient may *talk slowly*, and the facial expression is sometimes altered.

Apoplectic seizures and *epileptiform attacks*, especially of the Jacksonian variety, are distinctive symptoms. The former may be due to hemorrhages in the tumor or around it, and may be followed by transitory paralysis and paresis. Epileptic convulsions, especially if unilateral, point, though not unmistakably, to tumors in the hemispheres impinging on the cortex. *Choreiform movements* are sometimes present.

Choked disc or *papillitis* and *optic neuritis* are the most constant and

most valuable diagnostic symptoms of brain tumor. Choked disc consists, in brief, in a swelling of the optic nerve, with overdistention and congestion of the retinal veins, and narrowing of the retinal arteries. It is usually bilateral, rarely unilateral. There is still much difference of opinion as to the mechanism of choked disc, but it is thought by many to be the result of intracranial pressure forcing the cerebrospinal fluid from the subarachnoid space into the lymph sheath of the optic nerve, causing compression of the nerve and the vessels within it. The vision is not necessarily deranged in choked disc, and its defects are not uniform, varying from slight amblyopia to total blindness. The swelling may diminish and improvement in vision ensue, but retinitis or neuroretinitis may set in with consequent nerve atrophy, producing permanent impairment of vision. The choked disc is sometimes the only symptom of brain tumor, and its subject first consults the oculist for relief. On the other hand, it is not caused by brain tumor alone, but it may result from meningitis or abscess, in fact anything which produces intracranial pressure. Optic neuritis occurs in from 80 to 90 per cent. of all cases of intracranial tumor. It may be absent, even though a brain tumor of considerable size exists.

The *senses of smell and hearing* may be impaired by tumors impinging on the olfactory or auditory nerves, and there may be *pruritus* and other modifications of cutaneous sensibility; also *neuralgic pains*. If the tumor is on the floor of the fourth ventricle, there may be *polyuria* and *glycosuria*. Finally, sooner or later the *appetite* may fail and the *nutrition* suffer, although the opposite condition of large appetite and good nutrition may obtain. In the terminal stage there may be *irregularity of breathing* (Cheyne-Stokes) and slowing of the pulse, while the final issue is often preceded by a *febrile movement*. The local temperature in brain tumor is usually raised from 92° to 95° F. (33° to 34.9° C.), and even 98° F. (36.7° C.).

2. *Focal Symptoms*.—These are symptoms peculiar to the seat of irritation or destruction, and become, therefore, of value in diagnosis. They are the results either of irritation or destruction of nervous tissue, irritation causing contraction and spasm, while destruction causes paresis and paralysis. For convenience in localization the brain may be divided, as in Fig. 132, after C. L. Dana, into:

1. The prefrontal area, including all anterior to a line starting from the upper end of the ascending branch of the fissure of Sylvius at right angles to another drawn between the frontal and occipital ends of the brain.

2. The central region, bounded in front by the line just named and behind by a line limiting the posterior central convolution prolonged downward to the Sylvian fissure.

3. The parietal lobe.

4. The occipital lobe.

5. The temporal or temporosphenoidal area.

6. The pons and medulla oblongata.

7. The cerebellum.

The boundaries of these territories are shown, as far as possible, in the accompanying illustration.

In addition there are: (8) The corpus callosum; (9) the great basal ganglia and capsules; (10) the corpora quadrigemina, and pineal gland; (11) the crura cerebri; (12) the base of the brain.

1. *Tumors of the prefrontal area*, especially on the right side, often give no localizing symptoms whatever, motor or sensory, while general symptoms

may also be absent and the tumor truly latent. Then, again, general symptoms may be well marked, including mental torpor and imbecility, childishness, irritability, and emotional phenomena. These symptoms are the same whichever side of the brain is affected. If the tumor extends downward into the inferior frontal convolution, it may cause aphasia; or if backward, it may occasion irritative spasm or destructive paralysis. Involvement of the optic tract may cause hemianopsia and optic neuritis; of the olfactory system, anosmia; if the tumor invades the orbit, oculomotor paralysis and protrusion of the eye. Percussion tenderness may aid in localizing the tumor.

2. Tumors in the central or motor region may cause irritative lesions, resulting in spasm. If the tumor is in the upper third of this area, the spasm may begin in the toes, in the ankles, or in muscles of the leg; if in the middle third, spasm beginning in the fingers, in the thumb, in the muscles

Fig. 132.—Showing Focal Symptoms of Brain Tumor—(after Dana).

of the wrist or shoulder; if in the lower third, in the muscles of the face, the angle of the mouth, or tongue. In a word, the phenomena of Jacksonian epilepsy are present. All of these may be preceded or associated with sensory disturbance, such as numbness and tingling, and may be limited to one muscle group before extending to another, constituting the "signal symptom" of Seguin. There may be an aura, and the muscular sense is also sometimes affected.

Destructive lesions cause paralysis, and this may have the same distribution as the convulsions which sometimes precede. If on the left side in right-handed persons, aphasia and agraphia may result.

3. Tumors of the parietal area may produce no symptoms or sensory and motor phenomena, but there may be impairment of stereognostic perception. With the involvement of the angular gyrus and lower parietal lobule

may come word-blindness and mind-blindness. If the tumor is upon or near the central area, spasms and paralysis of the various muscular groups described under 2 may develop. Paralysis of the third nerve has occurred in connection with tumors in the neighborhood of the angular gyrus; no satisfactory explanation for this has been offered—possibly it is due to pressure at a distance.

4. *Tumors of the occipital lobe*, if in the cuneus or neighboring parts, may produce homonymous hemianopsia; and if double, total blindness; if elsewhere on the left side, there may be mind-blindness; and if the tumor extends also into the angular gyrus, word-blindness, along with hemianopsia; if obtruding further forward into the parietal lobe, hemianesthesia, hemiataxia, and perhaps some hemiplegia from involvement of the internal capsule may occur.

5. *Tumors of the temporosphenoidal area on the right side* rarely produce symptoms; on the left side, in the posterior part of the first and upper posterior part of the second gyrus, they cause word-deafness. Disturbances of the senses of smell and taste may result from involvement of the hippocampal convolution.

6. *Tumors of the pons and medulla oblongata* produce two sets of phenomena:

(a) Irritation or destruction of fibers in the pons and medulla oblongata.

(b) Pressure on the nerves emerging in this region.

Either may occur alone or both jointly. Lesions here are especially apt to produce alternate paralysis: that is, involvement of the cranial nerves on one side and the limbs on the opposite side.

If the tumor is in the cerebral peduncle, there may be a palsy of the third nerve on the same side and a hemiplegia on the opposite side; if lower down and in the pons, a palsy of the fifth on the same side and hemiplegia on the other; if still lower down, it may involve the sixth nerve, producing internal strabismus, the seventh producing facial paralysis, and the eighth causing deafness. If the tumor is very large, it may produce a hemianesthesia as well, and there may be forced movements of the body, either toward or from the side of lesion. Conjugate deviation of the eyes away from the side affected may also occur. This is in direct contrast to the conjugate deviation sometimes noticed in cerebral lesions, in which the head and eyes are turned toward the side of lesion.

Tumors of the medulla oblongata may produce hemiplegia and hemianesthesia, and, if the tumor is large, symptoms of bulbar paralysis. From irritation of nerves on the same side, the ninth, tenth, eleventh, and twelfth, difficulty in swallowing, irregular action of the heart, irregular breathing, and vomiting may arise. Sometimes also there is retraction of the head, or sensory symptoms including numbness and tingling and finally convulsion. If the cerebellum is impinged upon, there may be unsteadiness of gait.

7. *Tumors of the cerebellum* produce very characteristic symptoms, though here, too, there may be latency if the growth is limited to the hemispheres. If the middle lobe is invaded, vertigo, vomiting, headache, optic neuritis, and choked disc, with blindness and cerebellar ataxia, are present. Optic neuritis is more common in cerebellar than in cerebral tumors. The pressure causing choked disc is not directly on the occipital lobe or optic tract, but is generally on the cranial contents, and possibly interference with the circulation of fluid in the ventricles causes pressure on the optic chiasm by means of an excess of fluid in the third ventricle. More rarely nystag-

mus and neuralgic pains in the neck and occiput occur. The irregular and staggering gait of cerebellar ataxia is very striking, the patient reeling like a drunken man, or he may be thrown sideways or forward, rarely backward, by forced motion.

If the medulla oblongata is compressed by the tumor, vomiting from this cause may ensue, also bulbar symptoms and glycosuria.

8. *Tumors of the corpus callosum* are rare. The symptoms are similar to those of tumors in the third and lateral ventricles of the brain, extending peripherally. They cause general symptoms of brain tumor, with gradually developing hemiplegia, and later paraplegia. With this there are mental dullness and drowsiness and indisposition to speak. The cranial nerves are not involved.

9. *Tumors of the basal ganglia and the internal capsule* produce symptoms similar to those that occur in the corpus callosum. They are partly pressure symptoms. There is progressive hemiplegia, with which there is apt to be hemianesthesia. Sometimes there are choreic and athetoid movements if the tumor involves the optic thalamus and adjacent parts of the internal capsule. Tumors of the caudate nucleus alone, or of the lenticular nucleus alone, are generally latent; so are those of the anterior three-fourths of the optic thalamus, except that choreic and athetoid movements referred to may be noticed, due to irritation of fibers of the internal capsule, or, as supposed by some, to irritation of the anterior cerebellar peduncle. Tumors in these areas are very likely to give pressure symptoms. A large tumor of the thalamus may involve the fibers of the optic radiation and cause hemianopsia or sometimes hemianesthesia. This may be differentiated from hemianopsia due to lesions of the occipital lobe by the presence of the hemianopic pupillary reaction, in accordance with which a ray of light thrown on the insensitive part of the retina will not produce a reflex contraction of the pupil. Optic neuritis is apt to be an early symptom of tumors in this vicinity.

10. *Tumors of the corpora quadrigemina* usually involve the crura as well. They are characterized by inco-ordination, forced movements, and oculomotor palsies, to which may be added hemianopsia or blindness due to destruction of the primary optic centers; the pupillary reflex is lost and there is nystagmus.

11. *Tumors of the crus* from involvement of the third nerve are especially characterized by oculomotor paralysis on one (the same) side and hemiplegia on the other. Tumors of the crus are, however, rare.

12. *Tumors of the base*, if of the anterior fossa, produce symptoms much like those of tumors of the prefrontal area, adding, however, anosmia from destruction of the olfactory lobe; while there may be also involvement of the optic and oculomotor nerves and of the orbital contents. Tumors of the middle fossa and of the interpeduncular space produce pressure on the optic chiasm with consequent neuritis and bitemporal hemianopsia, by which lesions of this area are distinguished from those in the anterior fossa.

Diagnosis.—This consists first in the recognition of the presence of tumor from the general symptoms, and then the determination of its location in either hemisphere from the focal symptoms. The same symptoms may be produced by any agency causing pressure on these structures. *Choked disc*, which is so constant a symptom of tumor, may be caused by *Bright's disease*, *lead encephalopathy*, and *anemia*. The albuminuria, hypertrophy of the right ventricle, polyuria, and tube-casts usually help to recog-

nize the first. Other symptoms of lead poisoning indicate that disease, and the usual symptoms of anemia point to it. *Meningeal thickening, hemorrhage, aneurysm, and abscess* may also produce pressure symptoms.

The nature of the tumor may be determined in part by what has been said of the preference for certain localities and the age of the patient, and in part by the history, say of tuberculosis or syphilis or primary growths elsewhere. The surface temperature is of uncertain value in diagnosis. Death may be sudden, especially from growths near the medulla oblongata. It is usually the result of increasing pressure. The X-ray has recently been applied to the diagnosis of brain tumor with uncertain results; a change in the percussion note over a tumor is also of doubtful value.

Prognosis.—This is generally unfavorable. It is true that in some rare instances the brain tumors cease to grow after a time. Various observers find the ratio of removable tumors from 5 to 10 per cent. Of 1121 cases collected from different authors by M. Allen Starr in his article on "Tumor of the Brain" in Dercum's "Nervous Diseases," 80, or 4.25 per cent., were regarded as operable, but four-fifths of all persons operated on perish. When due to syphilis, they may in some cases be melted away by mercurials and iodids. Calcification is a rare, but happy, termination of tuberculous growths. The duration of tumor averages two or three years; the extremes average from a month to many years.

Treatment.—This is *medicinal, hygienic, and operative*. The first is limited in its purpose to the cure of syphilitic tumors and, perhaps, in a slight degree, to tuberculous. The astonishing effect of the mercurial and iodine treatment upon syphilitic new formations is nowhere so well shown as upon cerebral gumma. Unless syphilis can be excluded with absolute certainty, the *iodid of potassium* should be given in any case in ascending doses, limited only by their effects. In the absence of syphilis the larger doses are not well borne. In addition, *mercury* should be used, at first preferably by inunction until the specific effect is produced, after which it may be discontinued, to be renewed as indicated. Instead of inunction, the *bichlorid* may be given internally in doses of 1-12 grain (0.005 gm.) three times daily, or until the physiological effects are produced. When the tumor is once under control, it is still necessary to keep up the treatment in such doses as experience may determine to be necessary. Usually the iodid of potassium is sufficient for this purpose. When, however, the symptoms of tumor disappear and remain absent many years under iodids, the diagnosis of tumor may be doubtful. On the other hand, I have a patient in whom for thirty years the disease has been kept in check by a dose of sixty grains (4 gm.) a day, which must sometimes be doubled for a time. The evidence in this case seems as conclusive as possible, since following acknowledged infection there occurred secondary symptoms of syphilis, the full train of classic symptoms of brain tumor, including ophthalmic symptoms studied by an experienced ophthalmologist. If mercury is necessary in this stage, the *biniodid* may also be used in doses of from 1-24 to 1-12 grain (0.0025 to 0.005 gm.), as required, though I have not the confidence in it that I have in the separate use of the iodid of potassium and the bichlorid of mercury.

In tyroma the usual constitutional treatment of tuberculosis by cod-liver oil, iron, and other tonics, with nourishing food and healthful indoor and outdoor life, is to be carried out.

The usual remedies indicated to relieve pain are to be used, bromids, if necessary, in large doses, phenacetin, antifebrin, and antipyrin, and, if

necessary, morphin. The ice-cap may be used, and, above all, leeching tried. The most magical effect is sometimes produced by free leeching, though it is unfortunately temporary. Other symptoms should be treated by appropriate remedies.

The hygienic treatment is of the greatest importance. Excesses of every kind should be avoided, alcohol should be rigidly excluded, as well as all sexual excitement and mental excitement of any kind, for the slightest increment of blood in the brain may bring on a convulsion and cause death.

Exploratory operation being much less dangerous than formerly, with the aseptic precautions of the present day, should be made whenever the tumor can be localized with any approach to accuracy. Although cerebral localization has been developed to a very high degree, it must still happen that we frequently fail to locate a tumor accurately.

SUPPURATIVE ENCEPHALITIS.

SYNONYMS.—*Suppurative Inflammation of the Brain; Cerebritis; Abscess of the Brain.*

Definition.—By encephalitis is meant inflammation of the substance of the brain as contrasted with inflammation of its membranes. What is spoken of as inflammation of the brain in popular parlance is really inflammation of the membranes of the brain, or meningitis. A literal application of the term is here intended.

Etiology.—The causes of cerebritis are: (1) Traumatic; (2) an adjacent focus of inflammation extending to the brain substance; (3) pyemia.

Under traumatic causes are included blows upon the head and falls, more commonly those attended by fracture or punctured wound; although it is not necessary that there should be even a scratch upon the skin.

Under adjacent disease, whence extension of inflammation is especially frequent, is to be included caries of the petrous portion of the temporal bone due to disease of the middle ear or labyrinth, the most common of all causes of abscess of the brain. Disease of the orbit or of the nasal passages is another focus of the same kind. The route of such a communication may be through either the sinuses of the brain or the lymph paths.

Pyemic abscess of the brain is rare. Causal foci are malignant endocarditis, gangrene of the lung, chronic bronchitis with bronchiectasis, bone disease, supuration of the liver, and the specific fevers, among which may be included *la grippe*.

Encephalitis occurs most frequently between the ages of ten and forty, and about three times as often in the male sex as in the female.

Morbid Anatomy.—Abscesses of the brain are usually solitary, though there may be two or three, or even more. The abscesses may be from one-half to three inches (1 to 8 cm.) in diameter, rarely more, though an entire lobe has been involved. The abscess itself is a very interesting product. Unless very recent, it is surrounded by a distinct wall which is composed of *three layers*. The inner is smooth, made up for the most part of granular fatty cells. Outside of this is a layer of germinal tissue containing spindle cells and more perfect fibrillated tissue. Externally again is another layer of fatty cells. The pus within the abscess is usually greenish-yellow in color and acid in reaction, while its corpuscles are distinctly

nucleated. The *zone outside of the abscess is edematous*, the cells are swollen, sometimes disintegrated, with blood points scattered throughout, becoming sparser as the periphery is extended.

The locality of the abscess is preceded by the condition known as *red softening*, which is often spoken of as the first stage of the inflammation, but it is most important to remember that red softening is not peculiar to abscess. It consists simply of brain substance broken down into a reddish, blood-stained pulp. In this substance are found fragments of nerve-fibers, drops of myelin, pus-corpuscles, and granular fatty cells. The termination of cerebritis is not always in abscess. It is barely possible, before the stage of abscess is reached, for a condition of *yellow softening* to supervene, and the so-called apoplectic cyst may be the final result, or even cicatricial tissue may develop.

The *cerebrum is involved four times as often as the cerebellum*, the *left hemisphere* more frequently than the right, and the temporo-sphenoidal lobe more than any other. The cause has something to do with the location: Ear disease places the abscess in the temporal lobe or cerebellum: if in the tympanum, the cerebrum rather than the cerebellum; if the mastoid cells and labyrinth, the cerebellum.

Symptoms.—While inflammation of the brain is spoken of as acute and chronic, more strictly speaking it is rather primary and delayed, the symptoms of the so-called chronic form being essentially the same as those of acute cerebritis, but characterized by their late appearance after the cause which precedes them. In acute cases the symptoms develop rapidly and may run their course in a few days, while in the forms known as chronic the symptoms are scarcely less rapid after they once set in, which may be weeks, months, and even longer, after the operation of the cause.

These symptoms are the result of pressure,—direct or indirect,—of destruction of the brain substance, or of poisoning due to absorption of putrid matter. They are much the same as those of meningitis, with which, indeed, abscess is often associated, especially if there is injury. The most striking are *headache*, often severe and persistent; *vomiting*; *vertigo*; *mental dullness*, succeeded sometimes by *delirium* and sometimes by *coma*. *Convulsions* are often present, and are epileptoid in character. *Optic neuritis* is also one of the symptoms. There is usually *fever*, as shown by elevation of temperature. At other times the temperature is normal or subnormal. The *pulse* is usually slow—from sixty to seventy. The symptoms may set in with a *chill* after the latent period. The toxic symptoms are those usual to toxic states—viz., chill, irregular fever, prostration, emaciation, exhaustion. *Paralysis* in the form of hemiplegia sometimes occurs. The paralysis, however, is not always hemiplegic, and may be limited to the arm and face, especially in abscess of the temporo-sphenoidal lobe, which may compress the internal capsule. If on the left side, there may be *aphasia*. Other cranial nerves beside the optic are sometimes involved.

When the abscess is in the parieto-occipital region, there may be *hemianopsia*. It is especially in abscess of the cerebellum that *vomiting* occurs, and *staggering* if the middle lobe is affected.

Of the *chronic* form it has already been said that the symptoms, though long delayed, are the same as those of the acute form. Such delay, however, does not always cover all symptoms, since during the latent stage the patient may have headache or vertigo in a mild degree, and especially may he be irritable and depressed, while he may even have a convulsive seizure

during this preliminary period. It occasionally happens that there are no symptoms at all, and cases have occurred, more particularly of abscess in the frontal lobe, in which there were no signs or symptoms before death.

Phlebitis of the superior petrosal and lateral sinuses is especially common when the abscess is caused by disease of the ear, since the former receives a vein from the internal ear, and the latter receives the mastoid veins. *Edema about the ear and neck* and *hardness of the jugular veins* should suggest phlebitis, while *rigidity of the neck* and *cranial nerve paralysis* even more unerringly point to meningitis.

Diagnosis.—This is easy in acute cases, being substantiated by the history of injury, rigor, and fever, followed by the brain symptoms described. Almost as certain is the diagnosis when such symptoms follow chronic ear disease or localized putrid lung disease. It is to be remembered, however, that general cerebral symptoms may be produced by pus in the middle ear. These should be treated by puncture of the tympanum, and should the symptoms persist, after puncture abscess may be suspected. In like manner *meningitis* and *abscess* may be confounded, and with reason, because, in the first place, meningitis may be produced by the causes that produce abscess; and, second, meningitis may be caused by abscess, and both may occur together. Meningitis, however, affects the cranial nerves more than abscess, unless the abscess is seated in the pons, and usually meningitis succeeds more promptly upon its cause. It is to be remembered that *tumor of the brain* may produce symptoms identical with those described. The chief distinctive symptom in abscess is the presence of fever.

Prognosis.—This, unless we admit a curable form described by Strümpell, is always ultimately fatal unless we have the rare good fortune to reach it with the trephine.

Acute cases last from eight to fourteen days, rarely thirty days; the delayed cases may not show their first symptoms for months. In the curable form referred to, Strümpell says pronounced symptoms of focal disease exist for a time and suggest a tumor, but after some months or even a longer time they gradually abate, and recovery is complete. The nature of the symptoms is such as to suggest a seat in the cortex, for there is usually paresis of some part of the body, often associated with symptoms of motor irritation and impairment of speech.

Treatment.—A certain prophylaxis may be exercised in the proper treatment of disease of the ear, for it is often the neglect of this which leads to the abscess. Such prophylaxis includes measures which secure free discharge and antiseptics. Beyond this the only treatment for abscess which promises anything toward a favorable result is operation, on which account the surgeon should be promptly associated in the treatment of the case. The use of the trephine has saved a few cases. For the details of the operation the student is referred to text-books on surgery.

ENCEPHALITIS WITHOUT ABSCESS.—When, on the other hand, inflammation of the surface of the brain accompanying meningitis is eliminated, and, on the other, softening of the brain, formerly thought to be the result of inflammation, but now known to be due to the arrest of blood supply, a number of cases of encephalitis without abscess remain, in some of which a necropsy was obtained.

CHRONIC HYDROCEPHALUS.

Definition.—A collection of serous fluid either between the meninges or in the ventricles of the brain. The former constitutes intermeningeal hydrocephalus, or *hydrocephalus externus*, or *hydrocephalus ex vacuo*. The latter is ventricular hydrocephalus, or *hydrocephalus internus*. The seat of effusion in hydrocephalus externus may be either in the subdural space—*i. e.*, between the dura mater and the arachnoid—or in the subarachnoid space. The first was formerly regarded as the most frequent; later its occurrence came to be denied, but more recently, by means of frozen brain sections, it has been demonstrated. Since the subarachnoid space communicates with the ventricles of the brain, the two forms of hydrocephalus may coexist. Both external and internal hydrocephalus may be diffuse or circumscribed. When circumscribed there result in the case of the former cystic spaces in the membranes, and in the latter vesicular distention of portions of the ventricles.

EXTERNAL HYDROCEPHALUS occurs in connection with atrophy of the brain, and is not of much clinical importance.

INTERNAL HYDROCEPHALUS.

This is divided into congenital and acquired.

Congenital Hydrocephalus.—This pre-exists before birth, and may be present to such a degree as to retard the birth of the head. More frequently it is not recognized until some time after birth.

Etiology.—This cannot be said to be certainly known. Virchow early ascribed it to inflammation of the ependyma; Rindfleisch rather to an obstruction to the circulation in the choroid plexus. Drunkenness and syphilis in parents, and accidents in pregnancy, are held responsible; occasionally, also, tumors of the brain. More than one child in a family is sometimes affected.

Morbid Anatomy.—The head is characterized externally by its spherical shape and large size, its smooth eyebrows and protruding eyes, the last being due to depression of the orbital plate of the frontal bone. It is often so great that the eyelids cannot close over the eyes. The size of the head thus obtained is often enormous—from eight to ten inches (20 to 25 cm.) in diameter in a child of three or four years. On the other hand, the face appears very small. On closer examination the cranial bones are found separated and exceedingly thin, at times almost as thin as paper. In the membranous interspaces are often found Wormian bones. The veins may be seen beneath the skin, and fluctuation may sometimes be obtained through the scalp. On incising the brain a variable quantity of limpid fluid passes out. The quantity is sometimes enormous, reaching twenty pounds (40 kilos) or more. The cerebral cortex is greatly thinned, the thickness on the convexity being reduced to but a few millimeters. The gyri and the basal ganglia are compressed, and the ventricles are dilated. The commissures are stretched and even torn. The foramen of Monro is a wide opening, and the third ventricle is dilated and sometimes also the fourth. The ependyma is thickened, the choroid plexuses are vascular, sometimes little changed.

Symptoms.—These consist largely of the external morbid states just described, but in addition there is *slowness of physical and mental development*. The child learns to walk late and is very feeble and apt to be mentally deficient, although it is sometimes bright. Convulsions may occur and the reflexes be increased.

Diagnosis and Prognosis.—The rachitic head may be mistaken for the hydrocephalic, but the latter has not the broad forehead with prominent frontal eminences; it is rather spherical and smooth. The congenital case rarely lives to be more than four or five years old, though it may attain adult life.

Acquired Hydrocephalus.—Etiology.—This is also commonly ascribed to some inflammatory process, although it is said to be sometimes idiopathic. Especially is it a consequence of suppurative and tuberculous meningitis, when it is spoken of as acute acquired hydrocephalus, though chronic inflammatory processes may also cause it. Derangements in the circulation in the choroid plexus and in the ependyma of the ventricles may, however, be responsible. Especially may a tumor in the third ventricle, at the base of the brain, pressing upon the venæ Galeni or on the straight sinus of the dura mater, be a cause; or closure of the foramen of Monro, by which the ventricles communicate with the membranous spaces. Even lung or heart affections and growths in the mediastinum and neck may produce the needed obstruction.

Morbid Anatomy.—In cases of acquired hydrocephalus, even though beginning tolerably early in life,—say the seventh year,—as well as in adults, the skull does not necessarily expand, and the head may not enlarge. Indeed, the head may even be smaller than natural, as in cretins. In these instances the brain substance must yield, and is reduced in thickness, at times to a few millimeters only. In other cases the skull yields, its plates become thin, the fontanels grow larger, and an appearance like that of congenital hydrocephalus may result.

Symptoms.—The symptoms of acute acquired hydrocephalus are never distinctive, on account of the rapidity in the course of the disease which produces and obscures it.

Of chronic acquired hydrocephalus the most striking symptom is, as a rule, the *marked distortion in the size and shape of the head* already described. The weight of the head is sometimes so great that it inclines to fall to the side or backward or forward, and must be supported by the hands of the patient. Other symptoms may, at times, be decidedly delayed, and the child may make some progress in studies. At times there is early *headache*. Signs of *mental imbecility* sooner or later make their appearance, manifested first, perhaps,—as in congenital hydrocephalus,—by absence of development, but progressing until the child lives an almost vegetative existence, having to be fed and cared for like an infant, even though several years old. There may be *convulsive contractions, tremors, ataxic gait, paresis, and paralysis*; in fact, all the symptoms which succeed on irritative and destructive lesions of the nervous system. The symptoms of tumor of the brain may be quite closely simulated, especially when the cranium does not enlarge with the growing distention of the ventricles. There may be choked disc, atrophy of the optic nerve, and total blindness. There may be prolonged attacks of drowsiness, or coma, with slow pulse, while sudden death is not uncommon during epileptiform convulsions or apoplexy.

Spontaneous evacuation of the fluid sometimes takes place by the nose, mouth, ear, or orbit.

Diagnosis.—This is commonly easy. It is only in cases in which the cranium does not expand that the symptoms of *brain tumor* may lead to a diagnosis of the latter condition instead of hydrocephalus.

Prognosis.—This is usually unfavorable. Generally the child lives from two to five years, though it may perish in a few months or live for from ten to fifteen years, or, as in a case of Bright's, to twenty-nine years, or even longer. It has happened that spontaneous recovery has followed the evacuation of fluid previously described. The absorption of small amounts of fluid is also possible.

Treatment.—This consists primarily in the treatment of the disease which is responsible for the hydrocephalus if it can be discovered; secondly, in the treatment of the symptoms which may arise, and next, in attempts to cure the malady. Some favorable results have followed the removal of the fluid by puncture of the ventricles, although there has been failure in the majority of instances. Measures should be taken to make the removal gradual, if possible, thus attempting to imitate the spontaneous efforts of nature, which have occasionally been followed by recovery. To this end the slow removal of the fluid—by puncture of the subarachnoid space between the third and fourth lumbar vertebræ—has been recommended and practiced by Quincke. At this point, too, the spinal cord is not very likely to be injured. It is more particularly in congenital hydrocephalus that operation is indicated.

If operation is deemed undesirable, attempts may be made to get rid of the fluid by diuretics and purgatives, although with little prospect of success. Iodid of potassium may be tried, with the faint hope that the hydrocephalus is due to a syphilitic tumor which might thus be melted away. Blisters may also be applied.

GENERAL AND FUNCTIONAL DISEASES—NEUROSES.

The term neuroses is applied to nervous affections in which there are functional disturbances corresponding to which there is no known anatomical lesion.

ACUTE DELIRIUM.

SYNONYM.—*Bell's Mania*.

Definition.—An acute and violent febrile delirium of unknown cause and undetermined lesion, running a course of from two to three weeks, and usually fatal.

Historical.—The disease was first described in 1849 by Luther Bell, of the McLean Asylum.

Symptoms.—These set in suddenly and consist in violent, active *delirium*, in which the patient talks and moves incessantly, with a speech that is incoherent and unintelligible and movements which are aimless and irresistible or rhythmical as though with a purpose. This is kept up for hours and hours, notwithstanding the use of the most powerful anodynes, until the patient becomes exhausted, the whole presenting a picture which is at once revolting and pitiable. At times sleep is obtained for an hour or two, but immediately on waking the active movements and delirium begin. The rhythmical movements may be like those of the salaam convulsions, up and down, as of one chopping wood or working a pump-handle. Throughout there is *high fever*, the temperature ranging from 102° to 104° F. (38.9° to 40° C.).

The tongue is dry, the pulse rapid and feeble, the skin, in like manner, dry and often covered with petechial spots or pustules and bullæ or bruises, the result of the violent acts of the patient. There seems, however, no pain or tenderness other than is due to these causes.

Morbid Anatomy.—As stated in the definition, there is nothing definite. There may be venous engorgement of the meningeal veins and of the cerebral cortex, with perivascular exudation and cellular infiltration of the lymph sheaths and perivascular spaces. There is often engorgement of the bases of the lungs, and deglutition pneumonia has been found.

Diagnosis.—At first the disease may be mistaken for any of the acute fevers which sometimes begin with violent delirium, especially for *typhoid*, but the course of the temperature and absence of other distinctive symptoms soon eliminate any doubt.

The same may be said of certain forms of *puerperal mania*, and more rarely *pneumonia* of the meningeal type and of *cerebral meningitis* itself. The *incessant violence* is, however, peculiar to Bell's mania.

Prognosis.—This is almost always fatal.

Treatment.—This must consist of measures to control the mania, of which hypodermic injections of morphin are almost alone efficient, and these often only feebly so. Chloroform or ether must sometimes be employed, because of the dangerous doses of morphin which seem necessary.

Blood-letting has apparently been of service in some cases, and there certainly is no contra-indication to it in the early stage of most cases, the patients being commonly very strong and vigorous. The cold bath may be employed, but is not an easy treatment to carry out, because of the difficulty in controlling the patient.

PARALYSIS AGITANS.

SYNONYMS.—*Chorea scelotyrbē sive festinans* (Sauvages); *Chorea procursiva* (Bernt); *Shaking Palsy*; *Parkinson's Disease*.

Definition.—A chronic nervous disease characterized by muscular weakness, tremor, or shaking in the extremities, muscular rigidity, and forward-bent gait.

Historical.—The disease was first fully described by Parkinson, of London, in 1817, so accurately that nothing of importance has since been added to his description.

Etiology.—Shaking palsy is commonly a disease of the second half of life, but occasionally occurs between thirty and forty, and has been observed as early as the twentieth year. It is a little less frequent among women than men—11 to 14. Among the causes held responsible for it are exposure to cold and wet, fright, mental excitement, business worry, injury,—whether to nerves or other parts of the body,—alcoholism, sexual excesses, and the infectious diseases, including malaria, while heredity is said to have a certain influence. The etiology of the disease is largely a matter of conjecture and inference. Perhaps exposure to cold is the best determined cause.

Morbid Anatomy.—This is unknown so far as essential lesions are concerned. Various lesions have been described, while the brain, spinal cord, and peripheral nerves of the most typical cases have been examined with results not entirely satisfactory.

As the phenomena are similar in kind, if not in degree, to those of senility, it is held by Dubief, Borgherini, Koller, Sass, Jacobson, Ketscher, and Sanders that they have for their anatomical basis the lesions of senility somewhat intensified, and differs from true senility only in its earlier onset. Most recent studies conclude that this is not the case, and that paralysis agitans is a disease *sui generis*, although there are many changes in the spinal cord, brain, and nervous system which are common to the two affections, consisting essentially in increase in interstitial tissue and proliferation of neuroglia in the spinal cord, medulla oblongata, pons, and the motor cortex in a less degree. Charles L. Dana* says: "The most logical conclusion one can reach is that in paralysis agitans there is early a functional disturbance and later a destruction and degeneration of the dendrites of the anterior horn cells which interfere with the even flow of motor impulses, and finally lead to motor weakness and rigidity, owing to the cell being practically cut off from the brain." Dana continues: "The difference between this condition and that found in spastic paraplegia due to a sclerosis of the voluntary motor tracts is manifest, for there the dendrites of the anterior horns which subserve reflex purposes are normal, while in paralysis agitans all are somewhat affected. The rigidity of this disease is much like that found late after total transverse cord lesions."

* "Paralysis Agitans and Sarcoma," "Am. Jour. of the Med. Sci.," November, 1899.

H. C. Gordinier,* on the other hand, says the primary seat of the pathological changes is in the blood-vessels, starting with an endarteritis and peri-arteritis and consequent proliferation of the neuroglia in the immediate neighborhood, with the production of patches of perivascular sclerosis, which are characteristic of the disease. Also that "the alterations which have been observed in the nerve-cells of the anterior cornua and cranial nerve nuclei, together with the slight changes in the cells of the motor cortex, are secondary, due, in all probability, to a gradual diminution of nutrition dependent on the vascular changes." The truth is, the pathology of this disease is unknown, and is at present a subject for speculation.

Symptoms.—The disease is not a very rare one in this country, and the county almshouses almost always contain one or more cases—easily recognized by the characteristic shaking or tremulousness of the hand. Though commonly gradual in onset, the symptoms may come on quite suddenly, and at first only after exertion. Indeed, there may even be a *prodrome* in the shape of neuralgic pains, paresthesia, dizziness, and the like. The more sudden cases follow fright or trauma. The *tremor* is most marked in the fingers and hands, where it commonly begins, and whence it extends to the arms and lower extremities. The upper arm muscles are rarely involved. It most frequently passes from the right arm to the right leg, thence into the left arm, and thence into the left leg; or the course may be crossed—that is, from the right arm to the left leg. It may remain in one limb to the exclusion of the others. In the fingers the movement between the thumb and index-finger is frequently that of rolling pills, but the movement may not always be characteristic. At the wrist that of pronation and supination. In the feet it is most marked at the ankle-joint. It affects the writing, making it trembling, as in the aged, and ultimately it becomes impossible to write. The muscles of the head and face are last involved, sometimes not at all, and when present, the motion is vertical and quite rhythmical, usually about five times in a second. At first the tremor ceases during sleep, but continues during the waking state even when the muscles are at rest, but ultimately it continues also even during sleep—in fact, sleep is sometimes prevented thereby. It frequently is partially arrested by voluntary motion and is increased by emotion. Should rigidity become excessive, the motion may cease.

The rate of tremor varies greatly, being at first slower, and increases in rapidity as the disease advances. Roughly, it may be put down at from three to five times a second. There may be intermissions of the tremor of days and even weeks.

Muscular weakness is a less striking symptom, but may be estimated by the dynamometer, and increases with the duration of the disease and the intensity of the tremor. It is most striking at least in the extensor muscles, the *flexors* being disposed to *rigidity* and *spasm*, which early produce a slowness and stiffness of motion which is characteristic. It is this flexor spasm which brings the thumb and forefinger into the writing or pill-rolling position. At other times, hyperaction of the interossei muscles over that of the common extensors of the fingers results in the position so characteristic of arthritis deformans—that is, with the first phalanx bent, the second extended, and the terminal phalanx also bent. Ultimately extension is impossible. Occasionally the opposite state of fixed extension exists.

* "The Pathology of Paralysis Agitans," December, 1899.

The *attitude* and *gait* ultimately assumed by the subject of shaking palsy are also the result of rigidity, which sooner or later affects most of the muscles. The head is bent forward, the back is bowed, the arms are held away from the body and flexed at the elbows, and the knees are approximated so that they are often rubbed in walking; while the general appearance is that of a man in danger of falling forward. The position of the body due to flexion also gives rise to a "propulsive" gait, caused by carrying forward the center of gravity, so that, when started, the patient is apt to "get a-going" and cannot stop until he comes up against some object. On the other hand, a push backward, bringing the centers of gravity behind the point of support, is apt to make the patient fall, because he cannot move back fast enough to save himself by "retropulsion." Charcot regards both these phenomena as "forced movements," but Strümpell prefers to explain them by simple physical laws, as previously described. Sometimes the characteristic position of the patient exists without the shaking, and for this the name "*paralysis agitans sine agitatione*" has been employed.

The *facial expression* is also very strikingly altered. The face is indeed without expression, stiff and mask-like, giving rise to the name "Parkinson's mask." There is often a dribbling of saliva from the partially closed mouth. On the other hand, sometimes the mouth is kept closed, and is found full of saliva—a condition ascribed to delayed deglutition rather than to increased secretion. The speech is slow, hesitating, and monotonous, and the voice may be piping and shrill. On the other hand, if the lips and tongue share in the tremor, the speech is stuttering, as though the patient were in a hurry to speak—quite different from the scanning speech of insular sclerosis.

The remaining nervous and organic functions are essentially normal. Sensation is usually unaltered, and the bowels and bladder are unaffected, as is also the temperature, although it is said that the surface temperature is sometimes elevated. Charcot has noticed an alteration of the temperature sense. There is sometimes a tendency to unnatural perspiration.

Diagnosis.—This is usually very easy, and can generally be made at a glance. *Multiple sclerosis* resembles it in some respects. Both have tremor, but in multiple sclerosis this is shown more particularly when the patient attempts to do something, as to bring a glass of water to his lips or approximate his fingers. The speech is rhythmical, "scanning," instead of stuttering, as in shaking palsy; there is nystagmus, and the disease begins almost invariably in the lower extremities, while the attitude is not that of paralysis agitans. *Chorea* is characterized by movements, but these are irregular and more intermittent.

Prognosis.—A well-established case of paralysis agitans is not curable by medicines. On the other hand, the disease lasts indefinitely, the patient getting slowly worse, with perhaps the intermissions alluded to, until he dies of some intercurrent disease or from the effects of some accident growing out of his condition.

Treatment.—Under the circumstances this must, for the most part, be by tonics and general hygienic measures. As the disease advances the patient should be guarded against accident; and especially when in bed his position should be changed for him if he cannot change it himself, as is often the case.

Cases have improved under the use of the iodid of potassium and arsenic, and hyoscin has been especially recommended by Erb—hypoder-

mically, in doses of from 1-20 to 1-12 grain (0.003 to 0.005 gm.) of the muriate. Good results have also been reported from the use of atropin, of which from 1-100 to 1-60 grain (0.00066 to 0.0011 gm.) may be used subcutaneously or by the mouth.

Measures calculated to improve the general health are indicated, such as sea-bathing, massage, electricity, fresh air, and outdoor life.

OTHER FORMS OF TREMOR.

SYNONYM.—*Ballismus*.

In addition to the tremor in paralysis agitans, a similar tremor occurs under other circumstances, sometimes without assignable cause, when it is known as *simple* tremor, or it may be induced by fright or overexertion. A *hereditary* tremor has been described by C. L. Dana. *Senile* tremor is the well-known form of tremor which comes on with advancing years, at times earlier than others, but usually not until after seventy years. The existence of a tremor due to senility was denied by Charcot, but is accepted by most neurologists.

Toxic tremor is due to a number of toxic agents, among which tobacco and alcohol are the most frequent. Lead is another of these causes. Finally, *hysterical* tremor occurs as a part of hysterical phenomena in women. *As-thenic* tremor is due to simple weakness, and is especially seen in exertion during convalescence from acute disease.

ACUTE CHOREA.

SYNONYMS.—*Chorea minor*; *Mild Chorea*; *Sydenham's Chorea*; *St. Vitus' Dance*.

Definition.—A disease chiefly of the young, characterized by irregular, involuntary muscular contractions, associated at times with psychical disturbance, often with rheumatism and endocarditis. The term chorea is derived from the Greek *χορεία*, dancing.

History.—The term *chorea Sancti Viti* was first applied by Paracelsus (1493-1541) to an affection of a totally different nature, a sort of hysterical dancing mania which prevailed in epidemic form in the fourteenth, fifteenth, and sixteenth centuries in Germany and the Netherlands, for which the subjects sought relief by pilgrimages to certain shrines, among which was that of St. Vitus, in Zabern, whence the disease was called St. Vitus' dance. From other shrines it received other names, as St. John's and St. Anthony's dance. *Chorea minor* was first recognized by Sydenham in the sixteenth century, and was also called by him St. Vitus' dance, though a widely different affection from the St. Vitus' dance of Paracelsus.

Etiology.—The disease, though not confined to children, occurs far more frequently among them, notably from the time of the second dentition—the sixth or seventh year—to the fifteenth year. More than three-fourths of the entire number of cases occur during this period. Among adults it is relatively more frequent from the fifteenth to the twenty-fourth year. Occasionally it occurs in old age, when it is known as *chorea senilis*. *Chorea* is about twice as frequent in the female sex as in the male. Heredity has always been an acknowledged factor in its causation, but is probably less significant than was once supposed. It has even been claimed that the disease is sometimes congenital in the offspring of a choreic mother. It is more

frequent in neurotic families. As to temperament, it is well known that high-strung, excitable, nervous children, as contrasted with the dull and phlegmatic, are especially liable to the disease. It is principally in these that overstudy is seen to have a predisposing effect. Psychological influences are undoubtedly potent; thus, fright causes a large number of cases, while grief causes many, and even joy some.

The so-called Huntington's chorea, which is hereditary, is not the same as Sydenham's chorea, although Charcot did not make this distinction. Sydenham's chorea affects children of all social grades, but is more common among artisans and the lower classes. It is rare in the negro. Wharton Sinkler, who has especially investigated this point, has seen but one case in a full-blooded negro, while William Osler, at the Johns Hopkins Hospital, out of 175 cases found 5 in the negro race. It is apparently unknown among Indians in their natural state.

The season of the year appears to have an undoubted influence. Morris J. Lewis, whose studies have been most thorough in this direction, finds that the fewest attacks occur in October and November and the greatest number in March and April. Hermann Eichhorst, on the other hand, says that the greatest number of cases occur in the autumn and winter months. The disease prevails more generally in towns than in the country.

Imitation, commonly regarded as an exciting cause, has been shown by modern studies to play a less important rôle than was thought, many cases described as thus originating being really hysteria. Trauma precedes a certain number of cases. Reflex irritation, especially digestive disturbances, and intestinal worms were regarded as potent causes by the older observers; but here again Osler's studies have failed to find any causal relationship. The chorea of pregnant women has been referred to this category. The causal relation of eye-strain to chorea has been emphasized by Stevens, but is practically denied by George de Schweinitz, who concludes, from an examination of more than 100 cases, that, while ordinary chorea and many forms of facial spasm—habit spasm, etc.—are materially benefited by correcting refractive errors and anomalies of the ocular muscles, he does not believe there is any proof to show that eye-strain is of itself responsible for their origin, with perhaps the single exception of habit spasm affecting the orbicularis and adjacent facial area. It may be such chorea which Howard F. Hansell cured in Da Costa's clinic* by atropin, paralyzing the ciliary muscle and preventing the effort at accommodation until the habit was broken up.

The association of arthritis and chorea was observed by the earliest students of the subject, and was distinctly recognized in England as early as 1802, but the exact causal relation of the two diseases has, perhaps, not yet been made out. That they are frequently associated and that there is close connection between the two affections is admitted by English and French writers, but the Germans find the association much less frequent. Steiner, for example, found only four cases of rheumatism in 252 cases of chorea. English observers find from 20 to 70 per cent. of cases of associated joint affection, while in this country, where rheumatism is apparently less frequent in children, the range of percentage found by various observers is from 15.5 to 54 per cent. That the arthritis precedes the chorea in a large number of cases is generally conceded, the latter disease developing with the subsidence of the former, or not until convalescence has been well established. Hence

* Da Costa's "Medical Diagnosis," eighth ed., 1895, p. 221.

that the rheumatism is the cause of the chorea seemed at one time established, but recent views as to the probable infectiousness of rheumatism and the possible infectiousness of chorea changed the conditions. As the nature of the virus of rheumatic fever is unknown, it may be that chorea is caused by a similar poison. This theory is further sustained by the fact that the infectious diseases play an acknowledged rôle in the etiology of chorea. Scarlet fever, diphtheria, measles, typhoid fever, gonorrhœa, secondary syphilis, puerperal fever, pyemia, multiple suppurative polyarthritis, have all been followed by chorea; but with the exception of acute rheumatic polyarthritis and some forms of septicemia, the number of cases thus associated is not large. On the other hand, acute exanthemata developing in the course of chorea usually check the disease. Anemia has been held to be a cause, and probably is a predisposing cause, although frequently also a result. In fact, the studies of Charles W. Burr and others go to show that anemia is less frequently associated with chorea than has been commonly supposed. The relation of hysteria to chorea is interesting from the close resemblance, at times, of the two conditions. It has already been said that the cases of so-called imitation chorea are often hysteria, and, on the whole, the association of the conditions is rather coincidental than causal, but some cases may be truly imitation in children not hysterical. Poisons are acknowledged causes in a few instances. Carbon dioxid and iodoform are among those which appear to have caused acute attacks of chorea of short duration.

Morbid Anatomy.—There is no definitely ascertained morbid anatomy for chorea, and the lesions which have been found are the result of the complications or are incidental. The most constant of these associated lesions are endocarditis, in 85 per cent. of Osler's cases; pericarditis, 26 per cent.; combined heart lesions, 90.4 per cent.; pneumonia, 12 per cent.; less numerous were acute pleurisy, pyemia, and phlebitis, also noticed. As to the nervous system, the symptomatology would lead us to expect the essential lesions in the cortex of the brain, and C. L. Dana has analyzed the recorded autopsies, of which there were only 39 in which the state of the nervous system was accurately described. In 16 there were intense cerebral hyperemia, periarterial exudation, erosions, softened spots, minute hemorrhages, and occasional emboli. The changes were most marked in the deeper parts of the motor tracts, particularly in the lenticular nuclei and the thalami. These changes are the same as those described by W. H. Dickinson in 1876. Essentially similar were the lesions found in two of Osler's cases. In two reported by Bevan Lewis there was apoplexy, one cerebellar and one cerebral and extraventricular. The so-called chorea corpuscles described by Ellischer are in no way characteristic. The same may be said of the swelling and turbidity of certain of the large pyramidal cells in the deeper layers of the cortex in the Rolandic region described by F. C. Turner. The changes in the ganglion cells of the spinal cord described by H. C. Wood in canine chorea have been found also by Triboulet, but he agrees with others who hold that canine chorea is a very different disease from human chorea.

Nature of Choreæ.—This, it must be admitted, is as yet unknown. It has been intimated that the symptoms are of a kind which would naturally result from lesions in the motor cortical area. No constancy in such lesions is demonstrable. A cerebral seat for chorea is rendered likely by the existence of hemichorea, the association of chorea with mild psychical derangements, and by the fact that choreiform movements are sometimes symptoms

of undoubted brain lesions—*posthemiplegic hemichorea*. The embolic theory which was suggested by Senhouse Kirkes, and supported by him, Hughlings Jackson, Broadbent, Tuckwell, and others, was based upon the presence of foci of embolic softening found in a few instances in connection with endocarditis, but has gained few supporters.

The theory which is at the present day naturally attracting most attention is the infectious theory, but the limits of a text-book do not permit its developmental consideration. Suffice it to say that Pianese, of Naples, has apparently isolated from the nervous system of a choreic patient a bacillus which he was able to cultivate successfully, and the cultures from which caused death in animals; also that while the acuter forms present many, if not all, of the conditions necessary to the conception of an infectious disease, the course of the milder forms, their etiology, notably their negative morbid anatomy, seem to demand that the disease be regarded for the present as a neurosis—that is, a disease of functional derangement without known anatomical basis.

Symptoms.—*Premonitory* symptoms, both motor and psychical, usually precede the onset of chorea. They include *restlessness* and inability to sit still, and an *altered disposition*, manifested by irritability and perversity. These symptoms, often misunderstood by parents, are sometimes the occasion of reproof and even severe punishment to the child—a course which accelerates and aggravates the disease.

A close study of the symptoms permits of their division into three separate groups, determined chiefly by their severity:

1. A *mild* form, including the majority of cases in which the affection of the muscles is slight, the speech scarcely involved, and the general health slightly disturbed.

2. The *severe*, in which the choreic movements are general, power of speech is lost, and the patient is unable to go about and help himself.

3. The *maniacal*, or *chorea insaniens*, characterized by intense cerebral excitement.

It is, however, unnecessary to separate the symptoms of each variety.

The *motor phenomena* are those first observed. They consist in peculiar jerky movements which begin most frequently in the upper extremities, especially in the right hand, rarely in the legs. They may even be general from the first, though the earliest symptoms often escape notice. *Speech* is affected, sooner or later, in one-fourth of the cases. The extent varies greatly from slight hesitancy to incoherency—the difficulty being in the muscles of articulation rather than in phonation. As a rule, the movements cease during sleep, though they sometimes persist even then. It is not generally believed that the movements extend to the muscles of organic life, though associated irregular and rapid action of the heart has been ascribed to choreic spasm of the papillary muscles. As the disease continues *muscular weakness* becomes manifest in a general want of strength rather than paralysis, though the weakness may be distributed hemiplegically or even monoplegically. It may even precede the jerking movements. Very rarely the pulse may be slow in the feeble state that follows chorea.

Sensory symptoms are less conspicuous than motor. Pain is rare, though its presence has been characteristic enough in some cases to obtain from them the name “painful chorea” from Weir Mitchell. Painful points over the sites of emergence of spinal nerves have been pointed out, though they must be rare. *Numbness*, *tingling*, and *pricking* sensations are

occasionally met, and may be a part of the phenomena of multiple neuritis sometimes present. *Headache*, sometimes very severe and paroxysmal, may occur, while epileptiform seizures are also a rare symptom, and when they occur are probably not a part of the chorea. The *reflexes* are variously affected, the knee-jerk being normal in about half the cases, in the remainder increased or absent. Trophic lesions are almost unknown. *Mental symptoms*, in the majority of cases, are not very conspicuous, though there are in some severe cases extreme manifestations, including melancholia, hallucinations, and even mania, which have their climax in *chorea insaniens*.

Most important are the *symptoms of cardiac disease*, in regard to which William Osler makes the startling statement: "There is no disease in which endocarditis is so constantly found postmortem as chorea. It is exceptional to find the heart healthy." The symptoms which are, therefore, to be always carefully sought include a *systolic apex murmur*, *palpitation*, and *irregular heart action*, although the child rarely complains of the latter or of pain about the heart. It is further important to note that in a majority of these cases the endocarditis is independent of acute arthritis, unless we hold with Bouillaud that in young subjects the heart acts as a joint. Organic *murmurs at the base* are very much more uncommon, most of the murmurs here being functional. They are heard with greatest intensity in the area of the pulmonary artery, but are audible sometimes in the aortic area as well. In a large proportion of all cases in which a murmur is heard at the base or along the left margin of the sternum in the second, third, and fourth interspaces it is functional, but a soft systolic murmur in this area with systolic pulsation in the cervical veins may be caused at the tricuspid orifice.

On the other hand, *endocarditis* sometimes occurs *without symptoms* or physical signs, while the disappearance of physical signs does not prove that endocarditis was not present. A *presystolic murmur* is also at times present, indicating mitral stenosis—in 19 per cent. of Osler's cases. On the other hand, the comparative rarity of simple aortic valve involvement is conspicuous, this being more uncommon than combined aortic and mitral disease, or even combined mitral and tricuspid disease. The tricuspid valves may alone be attacked.

A to-and-fro murmur, indicating *pericarditis*, may be present in from 8 to 25 per cent., and in more than half of these it is associated with endocarditis. It is to be remembered that both forms of organic heart disease, and especially endocarditis, may occur in chorea without rheumatism,—*e. g.*, in 66 per cent. of Osler's cases,—also that such endocarditis may lay the foundation of permanent organic disease.

Occasional *skin affections* make their appearance in chorea, the larger proportion being due to the prolonged administration of arsenic, so much used in the treatment of this disease. The forms for which the arsenic treatment is more or less responsible are erythematous and papillary eruptions, herpes, and the pigmentation frequently resulting from the prolonged administration of this drug. Eruptions also occur independent of arsenic administration. They are usually purpuric and associated with arthritis, similar in form to the purpura so often associated with rheumatism, and include some of the forms of multiple erythema—as erythema nodosum, purpuric urticaria, or simple purpura. C. H. Brown* has reported

*"Journal of Mental and Nervous Disease," August, 1893.

a remarkable case of subcutaneous nodules composed of young granulating tissue in a case of chorea in a boy of eleven.

Fever is a rare symptom in chorea, except as the result of complications, of which arthritis is the most common, but endocarditis and pericarditis may also cause fever. The rare instances are cases of *chorea insaniens*, in which the temperature may rise to 105° F. (40.5° C.).

Diagnosis.—This is usually easy. *Simple tremor, athetosis, paralysis agitans*, as well as *alcoholic, senile, saturnine*, and *mercurial tremor*, are not likely to be confounded with the movements of chorea. The symptomatic choreiform movements due to cortical irritation by *meningitis, tubercle, hemorrhage, softening, tumor*, or *parasites*, are attended by other symptoms which distinguish them from chorea. In multiple and diffuse *cerebral sclerosis* the so-called *chorea spastica* movements may be very similar, but the early onset,—usually in infancy,—impaired intelligence, increased reflexes, rigidity, and chronic course of the disease characterize it. *Friedreich's ataxia* might be mistaken for chorea, but it is easily recognized by the lost knee-jerks, the slowness and inco-ordination of its movements, talipes, nystagmus, and family distribution. Huntington's chorea is characterized by its hereditation, its limitation to adult life, and ultimate gradually developing dementia.

Prognosis.—Except in *chorea insaniens*, which is always fatal, recovery is the rule in from eight to ten weeks. It happens, too, sometimes that the severest cases of the ordinary forms are intractable, and rarely that they terminate fatally after a few days' illness, it may be from exhaustion or it may be from the complicating heart disease. Chorea of the pregnant woman is more serious than the chorea of children.

The *duration* of the disease may be from eight to ten weeks for the ordinary cases and from three to six months for the very severe ones. *Remissions* occur, and *relapses* as well, pointed out by Sydenham. A disposition to vernal recurrence has been noticed.

Treatment.—All cases should be carefully examined for causes of reflected *irritation*, which should be *removed*; then *rest* is essential. It is not necessary that the very mildest cases be put to bed, but they should be withdrawn from school and guarded from excitement and the curious gaze of friends and strangers, for the movements almost invariably increase when the patient is under observation. More serious cases should be put to bed—a more thorough exclusion as well as rest is thus secured. Not only is recovery thus facilitated, but a diminished liability to heart complication is also attained.

Of drugs, *arsenic* and *iron* hold the first place. The former is given in slowly ascending doses of Fowler's solution until its physiological effect is produced, after which the dose should be gradually diminished. Some one of the preparations of iron should be given continuously in moderate doses. The bromids are also indicated, especially when there are restlessness and want of sleep, when chloral may also be added, and in severe cases may be given continuously. Opiates should, however, never be employed. An old remedy in this country is black snakeroot or *cimicifuga racemosa*, first recommended by the late Dr. Hiram Corson, who wrote me that he had used it for fifty years without a failure. I have sometimes used it in the shape of the infusion in mild cases, with apparently satisfactory results, in doses of one or two fluid ounces (30 to 60 c. c.). Modern remedies are anti-pyrin and physostigma. The former is given to adults in doses of from

seven to fifteen grains (0.5 to 1 gm.), much reduced for children. Physostigma has been given in doses of from 1-70 to 1-35 grain (0.0094 to 0.0188 gm.) hypodermically. Hyoscyamin in doses of 1-100 grain (0.00065 gm.), three times a day, has apparently been followed by good results. The oxid of zinc, valerianate of zinc, nitrate of silver, and sulphate of copper, formerly much recommended, have fallen into disuse. In consequence of the close relations between chorea with its attending arthritis and rheumatic arthritis it is reasonable to expect that the salicylates might be useful, but such expectation has not, as yet, been realized.

CHOREIFORM AFFECTIONS.

There remain to be considered several forms of convulsive contractures included under the term "habit spasm" or "habit chorea," or "tic." The term *tic*, as usually understood, means *facial spasm*. It has, however, been extended by the French school (whose lead in these affections seems at present acknowledged) to include "an habitual, conscious, convulsive movement, resulting in the contraction of one or more muscles of the body, reproducing, most frequently in an abrupt manner, some reflex or automatic action of common life" (Guinon). It is characteristic of these motions that they are more or less under the control of the will, in which respect they differ from the contractions of chorea minor.

I. SIMPLE TIC.

SYNONYMS.—*Habit Spasm; Habit Chorea.*

Simple tic may be localized or general.

Localized tic begins usually in young persons, most frequently in girls from seven to fourteen years of age, and may persist through life. The spasm is confined to a single muscle, a group of muscles, or a group of associated muscles, *most frequently the muscles of expression*. The mild forms are looked upon as simply peculiarities of the individual; but the more severe forms, in which nearly all the muscles of the face are affected and even the depressors of the jaw and the tongue are often thrown into action while speaking, are manifestly pathological. It differs from the *idiopathic facial spasm* of adults in that the latter is rarely seen until after the fortieth year, and is slower than is the habit spasm of the facial muscles. It is possible for the simplest forms to be a perpetuated childish trick; such may be a blinking of the eye or the act of sniffing. In other simple forms there is a drawing aside of the mouth or a jerking of the head to one side, or a simple shaking of the head, while the eye is winked at the same time; or there may be a shrugging of one shoulder. More rarely the contraction occurs in the legs, as in the very characteristic "string-halt" tic, in which at times the leg is suddenly drawn up. Localized tic may be transient, gradually disappearing after a few months.

Generalized Tic, Electric Choreia (Hench).—In this there is sudden electric-like spasm of the muscles of the trunk and limbs, but especially of the neck and shoulders, causing an instantaneous start, which affects the patient for an instant only, when it passes off and leaves him quiet and motionless. The contraction is like that produced by a galvanic shock. It

may be associated with facial spasm. It occurs especially in children, but also in adults, particularly in women, and may persist for years.

Paramyoclonus Multiplex; Myoclonia.—This term was applied by Friedreich in 1882 to a disease first observed by him, in which there are clonic convulsions in symmetrical muscle groups in the arms and legs without loss of consciousness. It occurs usually in males, and follows emotional disturbances like fright or straining. In addition there is a considerable increase in the tendon reflexes. In order that a case may be one of true paramyoclonus it is necessary that the contractions in the single muscles should be sudden—lightning-like. The muscles affected are commonly those of the trunk and extremities. The contractions are usually bilateral, and vary from 50 to 150 a minute. There are no sensory symptoms. Between the attacks there may be tremors. These cases are allied, on the one hand, to the electric chorea just described, and, on the other, to the different forms of convulsive tic, clonic facial cramp, and clonic accessory cramp. Some cases of so-called paramyoclonus are really cases of hysteria. This view is sustained by Arthur Conklin Brush,* who reports three cases and reviews several.

Dubini's Disease.—The term electric chorea is applied to an acute infectious disease occurring in Lombardy, and known as Dubini's disease, in which there are sudden contractions, first usually in the arm, but passing thence into all the extremities, followed in several weeks or months by paralysis and muscular atrophy, occasionally by epileptiform convulsions and fever. No morbid anatomy has been determined.

II. TIC WITH EXPLOSIVE UTTERANCES, CORPORALIA, ECHOLALIA, FIXED IDEAS, ETC.

SYNONYMS.—*Maladie de la tic convulsif; Gilles de la Tourette's Disease.*

Definition.—In addition to motor spasm, this form of tic is characterized by explosive utterances of certain words and sounds, such as "fire," "murder," "hah," "bow-wow"; or profane words, such as "God damn," "Jesus Christ"; or filthy and obscene words, when it is known as *coprolalia*. There may also be mimicry of words, when it is called *echolalia*; or mimicry of action, *echokinesis*; or the patient may be possessed of a fixed idea of the variety known as *arithmomania*, *délire du toucher*, *onomatomania*, and *folie pourquoi*. In *arithmomania* almost every action is preceded by performing a certain number of acts, as in a patient of Osler's, who before she went to bed had to tap her heel upon the bedstead a given number of times; before drinking a tumbler of water, to rotate the glass nine or ten times, and the same thing when setting it down; before opening a door a certain number of knocks had to be given, and the greatest difficulty was experienced in getting her to brush her hair, as it took so long to count before she began. In the *délire du toucher* there is the constant fear of contamination from contact with objects; in *onomatomania* to repeat over and over again names which arise, and in the *folie pourquoi* to demand a reason for every one of the simplest acts. In other instances the patient imagines that some one is talking to her. All these are in addition to the convulsive acts.

* "The Nature of Paramyoclonus Multiplex," "American Jour. of the Medical Sciences," December, 1899.

The involuntary movements themselves vary greatly from trifling tic of any one or more of the muscles of the face to contractions involving all the muscles of the body. This condition, which is neither chorea nor habit spasm, is at times mistaken for both. It is commonly easy of recognition, and although of uncertain prognosis, recoveries take place.

III. COMPLEX CO-ORDINATED TIC.

Definition.—This includes a number of forms of habit movement differing from ordinary tic in the more complex nature of the actions performed. It includes tricks and habits, such as those of one who in writing stops at every few words and looks intently at his finger tips; the “head nodding” of children (not to be confounded with the *epilepsia nutans* of children), “thumb sucking,” “rocking in bed,” and similar actions. Of the same nature is the so-called “head-banging,” in which the child, asleep or awake, while in bed, will turn over and bang the head violently into the pillow, repeating this act five or six times or for two or three hours at a time; or the child may strike the head repeatedly with the fist—*krouomania*; or it may rotate the head violently from side to side, balancing or gyrating the body with great rapidity. This practice is sometimes communicated from one child to another. These movements are met especially in feeble-minded children, in whom it may be accompanied by nystagmus, and is sometimes the result of injury after birth. When these phenomena do not occur in the feeble-minded or after injury early in life, the prognosis is said by Gee and Haden, who have especially studied the subject, to be favorable.

IV. SPASMS OF THE MUSCLES OF RESPIRATION AND DEGLUTITION.

Definition.—The spasm affects the muscles of respiration and phonation, the muscular contraction being accompanied by more or less noise, as a “sniffle” or “hiccough” during inspiration, or some noisy or explosive sound during expiration. Such spasms are sometimes part of a hysterical state. Among those described as thus occurring is a sort of rumbling which comes from low down in the abdomen, passes up the stomach, and out of the mouth as an explosive loud noise—something like belching, but louder. In another instance there was a peculiar clucking noise in the throat accompanying motions, particularly those of swallowing, which disappeared only during sleep. Again, there may be a loud inspiratory cry preceded by three or four deep inspirations and followed by a deep, hoarse, expiratory sound.

V. CHRONIC PROGRESSIVE CHOREA.

SYNONYMS.—*Huntington's Chorea; Chronic Hereditary Chorea.*

Definition.—A disease of adult life, commonly hereditary, characterized by irregular movements, deranged speech, and ultimate dementia gradually developing.

Historical.—The affection was first described by C. O. Waters, of Franklin, N. Y., in Dunglison's “Practice of Medicine,” in 1842; again in the “American Medical Times,” 1863, by Irving W. Lyon; fully in 1872 by George Huntington, of

Ohio, in the "Medical and Surgical Reporter," in whose paper the following three marked peculiarities were presented and dilated upon:

1. Its hereditary nature.
2. A tendency to insanity and suicide.
3. Its manifesting itself as a grave disease only in adult life.

Subsequent to Huntington's description little is found in literature until 1884, when C. A. Ewald reported two cases in Germany, and 1885, when Clarence King, in this country, reported another family. Then followed numerous reports; and finally, in Paris, in 1889, the monograph of Huet, and another by Osler, in 1894, in which the history of two families is detailed. Numerous cases were reported between 1889 and 1894.

Etiology.—Its frequent hereditary origin has been mentioned. Indeed, heredity is one of its most striking features, 25 per cent. of certain families having been victims, and even more than 50 per cent. of the adults in families. It is especially when both parents were affected, and seriously, that one or more of the offspring almost invariably have the disease if they live to adult age. The two sexes are about equally affected, though in some families males are oftener affected. It is further characteristic that if a generation is skipped, the disease never manifests itself again in that family, and that it *rarely* presents itself *before thirty years* of age. Huet has, however, collected seven cases of earlier onset. It is said, also, that it is not invariably hereditary, being sometimes due to emotional causes. In all the families in which this choreic tendency has been found the nervous temperament prevails.

Morbid Anatomy.—This is somewhat more definite than that of chorea minor. At least, there has been found at necropsy quite frequently a condition of pachymeningitis and hematoma of the dura mater with atrophy of the cortex, and less frequently a disseminated *encephalitis*, evidenced by sub-cortical foci of round cells. Nothing has, however, been found which can in any way be regarded as peculiar or as accounting for the disease occurring at a certain age or for its affecting certain individuals, though the lesions do explain the motor phenomena. It should be stated that Charcot and his pupil Huet do not separate this chronic progressive chorea from chorea minor, but all other writers do.

Symptoms.—The *onset is gradual* in hereditary cases, although it may be sudden in cases arising otherwise. As in chorea minor, *motor symptoms* are the first to appear: first usually in an unsteadiness of the gait or slightly irregular movements of the hands. Occasionally only the *mental symptoms* are the first to appear, not usually manifesting themselves until the motor are well established. Motor symptoms include also *spasm* of the muscles of the face. The movements differ from those of chorea minor in being *slower* and in *absence of co-ordination*, strikingly manifested in walking. The station may be good, except for a slight swaying of the trunk, but an attempt to walk is followed by an unsteadiness characterized by marked lateral deviation from the straight line, by swaying of the body, and sometimes by precipitate falling movement from which the patient may, however, recover himself—in brief, a typical drunkard's gait. This unsteadiness ultimately makes locomotion impossible, and the patient takes to his bed. Yet before this stage is reached, although ataxic, he may be able to walk long distances. While at rest the movements cease altogether. They are aggravated by emotion and excitement, while in the beginning they may to a degree be influenced by the will. Thus, a patient said to me lately: "If I put my mind to it, I can stop it."

Speech is affected in most instances, being at first slow and hesitating

and interrupted by interjections; later it is indistinct. The handwriting is likewise involved, the letters being irregular and badly formed, running into one another and off the line, and ultimately writing becomes impossible. Sensation and the special senses remain intact, as does the muscular sense, until the disease is advanced. The reflexes are usually increased.

The *tendency to insanity and suicide* has been referred to as an acknowledged symptom. Beginning as a simple irritability or moodiness with depression, it passes slowly over into feeble-mindedness. The suicidal impulse is sometimes carried out.

Diagnosis.—This is easy in the hereditary cases only. *Friedreich's ataxia* resembles it slightly, but begins earlier. *Idiopathic double athetosis* also occurs in elderly persons, but in it the movements are associated with rigidity and are of a peculiar character, and the gait is also spastic, while neither rigidity nor spastic gait plays any part in progressive chorea.

Prognosis is ultimately fatal. The progress of the disease is progressively and irresistibly from bad to worse.

Treatment is of no avail.

VI. CHOREA MAJOR.

SYNONYMS.—*Pandemic Chorea; Automatic Chorea; St. Vitus' Dance; Rhythmical or Hysterical Chorea; Lata; Miryachit; Jumpers; Jerkers; Holy Rollers.*

I prefer to include under this heading all the different varieties of saltatorial spasm of which the historical St. Vitus' dance of Paracelsus, prevalent in the fourteenth, fifteenth, and sixteenth centuries, is the most familiar illustration.

All are varieties of tic, in which strong contractions take place in the leg muscles when the patient attempts to stand, causing a jumping or springing action. All are endemic neuroses, illustrated by the "jumping Frenchmen" of Maine and Canada, the subjects of which are liable, on any sudden emotion, to jump violently and utter a loud cry or sound and obey any command or imitate any action without regard to its nature. The jumping prevails in certain families. Similar were the "jerkers" who appeared during the religious revivals in Kentucky in the early part of the present century; and the "holy rollers," in New Hampshire and Vermont. The disease known as *lata* among the Malays, and *miryachit* in Russia are similar. In the true St. Vitus' dance, chorea major, or *chorea Germanorum*, the paroxysm arises spontaneously; so, also, in the *salaam* convulsions of children, in which the muscles of the abdomen are affected, and in which there is a bowing forward of the head and body as many as a hundred times or more. The paroxysms may occur several times a day, lasting from a few seconds to as many minutes. In the others, as the American jumpers, etc., it is in response to some external impression. During the paroxysm the affected person sings, dances, jumps from the ground, rolls from side to side, hammers with his hands, stamps with his feet, or whirls madly around until he falls exhausted to the ground.

VII. POSTCHOREAL PARALYSIS AND POSTPARALYTIC CHOREA.

SYNONYM.—*Posthemiplegic Mobile Spasm* (Gowers).

Definition.—By this are meant choreiform movements which are the result of cerebral disease, most frequently hemorrhage. They may immediately precede or follow the stroke.

History.—Weir Mitchell* first called attention in 1874 to certain choreiform movements which sometimes occur in partially paralyzed limbs after an attack of hemiplegia. Later, Charcot recognized the condition and described it.

Symptoms.—The prehemiplegic form is rarer and more serious in significance. The movements vary greatly, and the milder degrees can be recognized only on close examination. In this form the symptoms precede, usually by a few days, the apoplectic stroke, and cease as soon as paralysis appears.

Posthemiplegic chorea, on the other hand, ordinarily appears in the limbs previously paralyzed, at the time when they again begin to be capable of motion. It is generally sudden, and either continues throughout life or disappears gradually. Often it is associated with contractures. Not infrequently the affected side of the body is anesthetic, and even the organs of special sense may take part in the hemianesthesia, in which cases it is probably a hysterical hemianesthesia.

The movements are more frequent in the hand than in the leg, though sometimes they occur in both, most marked in the fingers and toes, and diminish toward the shoulders and hips. They are really more athetoid than choreic, but quicker, consisting mainly in inco-ordinate gyrations of the fingers and thumbs, flexion and extension of the wrist and elbow, shrugging and other movements of the shoulder. They always cease during sleep. Charcot considers posthemiplegic chorea as identical with athetosis.

The lesion causing these symptoms is regarded as cerebral, and in that portion of the cerebrum within the internal capsule in which the fibers of the pyramidal tract pass between the lenticular nucleus and the optic thalamus. Sometimes, however, similar phenomena are associated with disease elsewhere, as in the pons or even in the spinal cord; but under any circumstances it would seem to be necessary that there should be irritation of the pyramidal tracts somewhere in their course.

EPILEPSY.

SYNONYMS.—*Morbus caducus sive sacer; Morbus divinus; Falling Fits.*

Definition.—Epilepsy is a chronic paroxysmal disease, characterized in its typical form by sudden loss of consciousness and by violent general convulsions (*grand mal*); but both unconsciousness and convulsions may be so fleeting as to be barely recognized (*petit mal*); while convulsions may be localized and unattended by loss of consciousness (*Jacksonian* or *cortical epilepsy*); finally, seizures may be substituted by conditions of uncontrollable violence or somnambulistic acts (*psychical epilepsy*).

Epilepsy is, strictly speaking, a syndrome or group of symptoms of

* "American Jour. of the Medical Sciences," October, 1874, p. 342.

which the morbid basis is not always the same. Formerly it was considered essential to the diagnosis of epilepsy that the convulsions should not be toxic, reflex, traumatic, the result of previous brain disease, or heart failure. At the present day toxic convulsions, which are essentially covered in actual practice by uremic convulsions, are not regarded as epileptic, nor are pure reflex convulsions which are due to such causes as teething, constipation, worms, and other forms of peripheral irritation. On the other hand, certain convulsions due to cortical brain lesions, which will be further considered, are acknowledged to be epileptiform in addition to those of which the anatomical basis is still unknown.

Etiology.—From one to six persons out of every 1000 have epilepsy. The tendency of modern studies is to diminish the importance of heredity, formerly so conspicuous as a supposed cause of epilepsy. Gowers' statistics, which may still be regarded as representing the older pathology, drawn largely from his own practice, ascribe to heredity a percentage of 35, while the range in the older statistics is from 9 to 40. Osler's observations, on the other hand, on cases at the Infirmary for Nervous Diseases in Philadelphia, and in the Institution for Feeble-minded Children at Elwyn, Pa., give the percentage in the two institutions as a little over 1 per cent., and in five cases out of 435 in which the epileptics were children of epileptic parents it was traceable to the mother in every instance. The comparative unimportance of heredity as a cause is upheld by the modern French school, notably by Marie. On the other hand, the disease is of frequent occurrence in neurotic families, including those subject to insanity, hysteria, and neuralgia. So, too, vices of constitution and habit in parents, especially alcoholism and syphilis, are acknowledged causes. The intermarriage of relatives is also an element. More certainly responsible is local disease of the brain *cortex*, including tumors and traumatic disease, such as are produced by fractures, and the conditions described as causing the cerebral palsies in children.

All of these are causes which may be both essential and exciting. Among the more purely exciting causes are fright, irritation by worms in the intestinal tract, dentition, constipation, and the like, all of which may provoke attacks in an epileptic. Some would regard the reflex epileptiform attacks excited by these causes as true epilepsy, and call it reflex epilepsy. But at present these cases should not be called epileptic, since they do not recur after the exciting cause is removed. Such were the two striking cases in my own experience, one of which disappeared entirely after the removal of a tape-worm in a girl of eighteen, and another after the cure of constipation in a young man of twenty. These are very different from others in which attacks are brought on by like exciting causes, but occur also independently of these causes.

True exciting causes are infectious diseases, alcoholism, and syphilis. The influence of infectious diseases is thus shown: Given an epileptic who is subject to seizures once a month, who acquires typhoid fever, the prodromal symptoms are almost always sure to include frequently recurring epileptic seizures. *Masturbation* is included among the true causes, but is probably only an exciting cause. Ocular and aural irritations are exciting causes. Cardiac epilepsy is a variety in which there is disturbance of the heart's action, either palpitation or slowing, prior to attacks; but such derangements are cosymptoms rather than causes, or they may be a mode of manifestation of the aura to be presently described.

Epilepsy is pre-eminently a disease of childhood and youth, and after twenty it is most unlikely to arise. Most cases begin between the ages of ten and fifteen. Yet idiopathic epilepsy may occur after sixty. It seems to be slightly more frequent in boys than girls, although all statistics do not point this way, whence it may be concluded that the numbers in each sex are nearly equal.

Morbid Anatomy.—The cortical lesions described as causing the cerebral palsies of children and some resulting from trauma are found in connection with most cases of Jacksonian or focal epilepsy. *Tumors*, especially those involving the motor layer of the cortex, are among these causes; so are localized *syphilis*, *pachymeningitis*, and *tyroma* or tuberculous tumor, and sometimes tuberculous meningitis, pointed out by J. Hendrie Lloyd. Lloyd would, however, exclude the gross deformities, such as porrocephalia; and diffuse processes, such as lobar sclerosis, which manifest themselves by idiocy and arrest development, and are not infrequently provocative of epileptic seizures.

Sclerosis of different parts of the brain and medulla oblongata is also found in cases of epilepsy, especially in the hippocampus major, this being probably a conspicuous local focus of a more diffuse lesion. Similar sclerosis is sometimes found in the cerebellum. A *nuclear degeneration* and vacuolation of the cells of the second layer of the cortex has been claimed by Bevan Lewis as a distinctive lesion of epilepsy. Many cases of so-called idiopathic epilepsy are still without a demonstrable morbid anatomy.

Mechanism of the Convulsion.—The epileptic seizure itself is regarded in the light of our present knowledge as an explosion or *discharge of nerve force*, the seat of discharge, in the severe seizures, at least, being the large motor cells in the deeper layers of the cortex, the function of which is to store up and discharge nerve force. The same mechanism exists in sensory and psychical epilepsy. The explanation is not entirely satisfactory.

Symptoms.—These vary in the four varieties known as grand mal, petit mal, Jacksonian, and psychical epilepsy.

1. *Grand Mal.*—In a large number of cases the epileptic attack is preceded by what is known as the *aura*, a peculiar sensation which differs greatly in different individuals. Occasionally it is like what the word literally means, a breath of air, which starts from a particular part of the body, as the extremities or a single finger or toe or a part of the surface of the body, such as the neighborhood of the stomach or the heart. At other times the aura is a simple epigastric sensation, a sense of discomfort or uneasiness emanating from the stomach or the feeling of a ball arising therefrom, and this is not a very uncommon form. It may be a flash of light, which may be of different colors; an object, as a face or faces, and even a coffin—as in one of M. Allen Starr's cases. Auditory auræ are manifested through the sense of hearing, and may be subjective sounds of any kind, including musical tones or even voices. Gustatory and olfactory auræ include subjective tastes and smells, mostly of an unpleasant character. Auræ are represented also by tingling, numbness, or simple flushing or chilliness anywhere in the body. "Intellectual auræ," so called by Hughlings Jackson, are certain mental conditions, such as the "dreamy state," and the consciousness of a certain algebraic formula, which always presented itself to a patient of Starr's.

In other cases there is a more prolonged *prodrome*. For several hours or for a day the patient may be the subject of sensations. He may feel generally miserable, dispirited, timid, irritable, or dizzy, or he may be pale or

quiet, and wait patiently for the dreaded event, known to him rather by its consequences than its phenomena, of which he is unconscious. There is pathetic sadness often in this patient expectation. *The aura is by no means always present*, indeed, perhaps in the majority of cases of epilepsy there occurs no warning of the attack. The aura may be substituted by certain movements, such as running rapidly for a few minutes either forward or in a circle,—the so-called *epilepsia procursiva*,—or the patient may stand on his toes and rotate with great rapidity.

Following the aura or independent of it occurs the *convulsion* or “*fit*,” of which the initial event is often the *epileptic cry*. This is succeeded by the *fall*, which may be sudden, as if the patient were shot, while serious injury may be a consequence. Following this the phenomena of the fit may be quite sharply divided into *three stages*, that of tonic spasm, of clonic spasm, and of coma.

(a) *The Tonic Spasm*.—In this the head is drawn back or to the right and the jaws are fixed; the arms are flexed at the elbow, the hand is flexed at the wrist, and the fingers are clinched into the palm, while the legs and feet are extended. The muscles of the chest are involved and respiration is suspended, and the face becomes dusky, livid, and swollen, contrasting with the initial pallor. The muscles of the two sides are not equally affected, so that the neck is twisted and the spine curved. This stage lasts but a *few seconds* and is succeeded by clonic spasm.

(b) *The Clonic Spasm*.—Now the muscular contractions become intermittent. At first tremulous and vibratory, they soon become strong and general, until the arms and legs are thrown about in the most violent manner, sometimes so violently as to produce dislocation, usually of the shoulder. The muscles of the face are also involved in distorting contractions, while the eyes roll and the lids open and close. The jaw muscles contract violently, and the tongue is apt to be caught and bitten. A frothy saliva, often blood-stained, escapes, and the patient is said to “*froth at the mouth*.” There may be involuntary discharge of feces and urine. The lividity supervening in the first stage diminishes somewhat during this stage. The temperature rises 1-2° to 1° F. (0.28° to 0.55° C.). Very soon the contractions become less violent, finally abate, and this stage terminates, in *one or two minutes*, in the stage of coma.

(c) *Coma*.—In this the limbs are relaxed and there is profound unconsciousness, but the breathing is noisy and stertorous. The face remains congested, but is no longer cyanotic. The patient may, after a time, be aroused, but if left alone, commonly sleeps several hours, awaking after a time in a remarkably natural state, feeling bruised and aching, but otherwise quite himself; or there may be some mental confusion and even headache.

These are the phenomena of the attack in the vast majority of cases of grand mal. There may not be another attack for several days or a month or more. In severe cases, on the other hand, there may be daily recurrence, though not until the disease has lasted for several years. In a few instances the attacks may follow one another in rapid succession without a return of consciousness, lasting from twelve hours to a day or more, producing the *status epilepticus*, in the course of which the patient may die from exhaustion. In this state there is often decided fever.

After the attack the *reflexes* may be increased and ankle clonus may be obtained; at other times the reflexes are absent. The urine is also often

increased, and a small amount of albumin is quite common after the fit. There is also sometimes an increase in the amount of uric acid in the urine *after* the convulsion in *grand mal*.

Inequality of pupils (anisocoria) has been considered a symptom of epilepsy. This symptom,* however, occurs in healthy individuals, and too much value should not be attached to it.

2. *Petit Mal*.—The symptoms in minor attacks vary somewhat, but commonly the patient stops in the midst of what he may be doing, the eyes become staring and fixed, the pupils dilated, the countenance pale, there may be some twitching of the facial muscles or the limbs, and consciousness is lost, but there is no convulsion. Anything that is in the hand may be dropped, but in a minute or two consciousness returns and the patient resumes what he has been doing as though nothing had happened. Here, too, though rarely, there may be auræ of various kinds and even an epileptic cry; also forced movements—procurive epilepsy. There may be dizziness without unconsciousness, and the patient may fall. An increase of uric acid in the urine is said also to be quite frequently associated with this form of epilepsy. As the disease continues the attacks of *petit mal* generally become *grand mal*, or the two forms of attack may alternate.

3. *Jacksonian or Partial or Cortical Epilepsy*.—In this, *consciousness is retained*, though it is thought by some that there is always a momentary period of unconsciousness while convulsions occur, though circumscribed to a single group of muscles or to a single limb. It is almost always symptomatic of some focal lesion in the cortical motor area, which may be a tumor, an injury or inflammatory process in the membranes or brain substance, softening, hemorrhage, abscess, or sclerosis. It is especially apt to be a sign of a growing tumor. Hence it is also called symptomatic epilepsy. Previous to the twitching there may be a numbness or *tingling in the part to be involved*, which has been called the "signal symptom" by Seguin, because it ushers in the attack. It may remain during the attack, and is of value in determining the seat of the lesion, and therefore the place for operation. Its seat is usually the same in the same patient in all the attacks.

The spasm or convulsion begins uniformly in one part,—it may be the face, the thumb, the toes,—thence slowly invades an entire limb. It continues sometimes for three or four minutes or longer. The movement is tonic and clonic, extending from the part in which it begins to other parts in a definite order of extension. Thus, if it begins in a part of the face, it extends thence to the whole face, then to the shoulder, arm, forearm, and hand, and possibly the leg from the trunk down to the toes; or it may start in the fingers and go in the opposite direction. Jacksonian epilepsy also occurs in uremia and progressive paralysis of the insane, and it has already been spoken of as following the hemiplegia of children. After the convulsion, the parts convulsed and especially that in which the spasm begins may be partially paralyzed and awkward in movement, and quite often the numbness and palsy continue for some time, with a moderate degree of tactile or thermal anesthesia. More rarely this paresis is permanent, when it is evidence of changes in the cortex such as may be caused by a growing tumor. Rarely the opposite side of the body is affected, and if this occurs, consciousness may be finally lost.

4. *Psychical Epilepsy*.—This occurs either as a later symptom follow-

* See a paper by Wendell Reber, "The Pupil in Health and Epilepsy," "Med. News," August 24, 1895.

ing the more common forms of *grand mal* and especially *petit mal*, or as an independent state or as what is known as a "psychical epileptic equivalent," where the usual seizure is substituted by a somnambulistic state in which the patient performs various acts, sometimes of great complexity, including driving, walking, and the like, of which he is totally oblivious after he passes into the natural condition. Some striking instances of psychical epileptic equivalent are related by M. Allen Starr in his book on "Familiar Forms of Nervous Disease." Other manifestations of psychical epilepsy are represented by violent maniacal excitement and uncontrollable violence, in which criminal acts, including even homicide, are committed.

Relative Frequency and Time of Attacks.—The major form of attack is the most frequent, after this, mixed forms of major and minor, and then minor and Jacksonian; the most infrequent are the psychical forms.

Two-thirds of the attacks occur between 8 A. M. and 8 P. M.; many attacks occur early in the morning after awaking, some between 3 and 5 A. M., and others in the night at unknown hours—nocturnal epilepsy. In true epilepsy the patient generally feels perfectly well between the attacks—indeed, he not infrequently feels better for a time after the spell.

Diagnosis.—The epileptic fit is of itself in no way characteristic of the disease. The uremic convulsion is identical, as is also the reflex convulsion due to teething and other causes. Even hysterical convulsion closely resembles it, but there are points of difference. Something more, therefore, than the convulsion is necessary to prove the presence of the disease. The *aura* is distinctive, and when present, is almost conclusive. Scarcely less so is the *epileptic "cry,"* although it is less constant than the *aura*. The *relaxation of the sphincters* belongs rather to the epileptic fit, while the bitten tongue, the dilated pupil, and sudden unconsciousness belong to uremia as well; and it is from *uræmia* that it is most important to distinguish epilepsy. The occurrence in the midst of apparent health of a convulsion with the features described, followed by prompt recovery without albuminuria or casts, can hardly be anything but epilepsy. At other times, when other signs of Bright's disease are absent, it may be necessary to defer the diagnosis a little longer in order to examine the urine. Finally, epileptics may have *Bright's disease*, when errors are still more likely and sometimes unavoidable.*

The *reflex convulsion* in children is apt to be repeated until the cause is removed, and in this respect the condition resembles the *status epilepticus*, but in the former a little careful searching will probably discover the cause. The isolated reflex convulsion may be more difficult to account for at first, but in these cases immediate decision is less important, and we may await time to help us. The very short duration of the *petit mal* separates it sharply from the uremic fit. Nocturnal convulsions, occurring as they do often without the knowledge of the patient, are usually epileptic.

The *hysterical convulsion* sometimes simulates closely the epileptic. But the hysterical patient rarely loses consciousness completely, the fall is not so sudden, the victim rarely if ever hurts herself, and never bites her tongue; nor is there any rise of temperature, while even the pulse and respirations commonly remain quite normal. There is rigidity, but it is unlike that of epilepsy—it is not more conspicuous in the beginning of the attack. Opisthotonos, or arching of the back, does not occur in the epileptic convul-

* See two interesting cases reported by me in the "Transactions of the Association of American Physicians," vol. vi., 1891.

sion. Finally, the hysterical convulsion is of longer duration, lasts ten minutes or more, while the duration of the epileptic fit is not usually more than three or four minutes.

The *petit mal* is most frequently mistaken for *fainting*, but after two or three occurrences it should be recognized. The vertigo of *Ménière's disease* and of attacks of *indigestion* resembles it, but in the former there is deafness, while in neither is there actual unconsciousness, as is always the case in *petit mal*.

Jacksonian epilepsy is *sui generis* and is not simulated by any except the rare instances of *circumscribed uremic convulsions* and similar spasms in *general paresis*; however, it has been described as occurring in hysteria. A further study of each instance must quickly dissipate the error. While the approximate seat of the lesion may be inferred in many cases of Jacksonian epilepsy, the precise cause cannot generally be determined, because all sorts of lesions produce the same symptoms. Recurring epilepsy in persons over thirty is probably due to organic causes, and in nine cases out of ten, according to H. C. Wood and also Fournier, is due to syphilis.

The highest refinement of diagnosis in the study of epilepsy attempts to determine from the character of the aura the seat of beginning cortical irritation. Thus, a visual aura, it is claimed, might indicate that the nervous discharge began in the occipital lobes; a vertigo might indicate that it began in the cerebellum; a sense of numbness, the sensory motor area of the cortex. The "intellectual auræ," as they are called by Hughlings Jackson, are regarded by him as affording evidence of a nervous discharge from the highest cerebral centers.

Prognosis.—The true epileptic rarely gets well. I believe I have seen two cases of recovery in my experience. In such statement epileptiform attacks due to peripheral irritation are rigidly excluded as not being true epilepsy. These invariably get well with the removal of the irritation, while true epilepsy, in which attacks are readily excited by such irritation, is benefited but not cured. The chances of recovery are said to be greater in the young, and in the male sex than in the female. One of my cases of apparent recovery was a man who had his last fit after forty; the second a woman who had no attack after fourteen. Both live. C. L. Dana places the recoveries at from 5 to 10 per cent., which appears to me large. Even cases of combined *petit mal* and *grand mal*, of which the prognosis is most unfavorable, are said to get well. The prognosis of *petit mal* is more unfavorable than that of *grand mal*; of the mixed forms still more unfavorable, and post-hemiplegic epilepsy most unfavorable of all.

On the other hand, an epileptic rarely dies of his disease. He may fall in the water during an attack and drown, or may choke to death if attacked while eating. Death sometimes occurs from exhaustion in the *status epilepticus*, but this is not frequent. The health of epileptics usually deteriorates slowly, and life is shortened accordingly, few surviving the age of forty or fifty. They rather frequently die of tuberculous phthisis. Especially frequent is mental deterioration; indeed, it may be said to be the rule when the patient lives long enough, and about 10 per cent. become demented or insane. Much may be done by treatment to control the number of attacks, and the less numerous they are, the less serious is the effect upon the health. Many epileptic persons earn a living, and more could if properly helped.

The more infrequent the attacks, the better the prognosis. Pure nocturnal epilepsy and the pure diurnal form are each more easily cured than the

mixed forms. Cases, too, which arise after twenty years of age are more likely to get well.

Treatment.—No fact in therapeutics is better established than that the *bromids* control epilepsy in varying degree—it may be completely, it may be simply to render infrequent the seizures. There is probably no important difference in the efficiency of the various preparations, but the bromid of potassium has been most extensively used. The bromid of sodium is preferred on account of its greater solubility. Bromid of ammonium is slightly more stimulating. More recently bromid of strontium has been highly recommended. Causes of *peripheral irritation* should first be sought, and if possible *eliminated*. Gastro-intestinal irritation should be removed. Phimosi should be cured. The possible practice of masturbation should be inquired into. These eliminated, the bromid treatment may be commenced. The doses required vary greatly and must be determined by trial. Scarcely less than fifteen grains (1 gm.) four times a day are required for adults, and from this point the dose may be increased until the desired effect is produced. The massive doses sometimes given, amounting to ounces in a day, are ultimately harmful, but doses of a dram (4 gm.) are sometimes necessary and well borne. It is sometimes of advantage to combine the various bromids of sodium, potassium, and ammonium. Greater efficiency is secured if the drug is given on an empty stomach, half an hour before meals or two hours after, and smaller doses suffice when thus administered, and the omission of sodium chlorid from the diet is believed to lessen the amount of bromid necessary and to increase its efficiency. Bromism, shown by drowsiness, mental torpor, gastric and cardiac distress with acne, sometimes results. It is doubtful whether it can be obviated in any way except by omitting the drug. The bromid eruption may sometimes be averted by combining arsenic, but this does not always succeed, and on this account, too, the drug must be omitted. In a few cases the bromids are absolutely useless, more especially in cases in which they produce gastro-intestinal derangement, perhaps in about five per cent. of cases. *Chloral* adds to the efficiency of the bromids, and is sometimes necessary to produce the desired effect. It may be given in doses of from ten to thirty grains (0.66 to 2 gm.).

To treatment by the bromids should, of course, be added proper hygienic measures. Suitable food, especial attention to the bowels, fresh air, and outdoor life are indispensable. Bathing is important, and cold baths—particularly douches and shower-baths, cold sponge-baths or wet packs should be judiciously used. Vasomotor tone and circulation are thus strengthened.

Food should be simple and easily assimilated, overeating should be especially avoided. Stale bread, wheaten grits, and similar foods, rice, potatoes, fresh succulent vegetables like string beans, peas, and tomatoes, with an abundance of milk, are suitable. Water should be freely drunk by the patient, and a glassful is advised between meals and at bedtime.

Of other remedies recommended may be mentioned *antifebrin* and *antipyrim*. A trial of the former in the Vanderbilt Clinic in New York, by M. Allen Starr, was unsatisfactory. On the other hand, in the hands of Charles S. Potts, at the Dispensary of the University of Pennsylvania, it was apparently useful. Especially efficient at the latter proved a combination of antipyrim and bromid of ammonium, suggested by H. C. Wood. For adults a dose of six grains (0.39 gm.) of the former and ten grains (0.66 gm.) of the latter, three times a day, in a number of cases averted the seizure for months. Continuous exhibition seems necessary. These drugs at least merit a trial

where the bromids are for any reason unsatisfactory. The *monobromated camphor* has been recommended quite recently by Hasle. The best mode of administration appears to be in a capsule or emulsion, the dose being two to five grains (0.13 to 0.32 gm.).

Starr has also used the tincture of simulo (*Capparis coriacea*) at the Vanderbilt Clinic with the effect of reducing the number of attacks in *grand mal*, but to no purpose in *petit mal*. It was used in doses as large as 1-2 ounce (13.5 c. c.) daily. In *petit mal* the same observer found *nitro-glycerin* the only remedy of any service. He appears to have used it in doses of 1-100 grain (0.00065 gm.) three times a day. In my experience this regulation dose fails in a large number of cases to produce the physiological effect, and larger doses—from 1-50 to 1-25 grain (0.0013 to 0.0026 gm.)—may be given. It is to be remembered that epilepsy is one of the diseases which are nearly always influenced for a time by new remedies. The preparations of *valerian* may also be tried in the event of failure with the bromids. Others which have been used are borax, iodid of zinc, and sulphonal.

The nitrite of amyl has been employed to abort the attack in cases where there was an aura, and in a certain number of cases—about 25 per cent. in Starr's experience—has proved efficient.

Operation, usually trephining, is increasingly practiced, and many successful cases have been reported, chiefly of Jacksonian epilepsy. When a well-defined lesion can be located, operation should promptly be done. Even in doubtful cases operation may be justified, as with modern surgical precautions it is attended with much less risk. It should be remembered, too, that operation *per se* has proved curative—that is, cases have apparently recovered after trephining where no lesion was found after removing the disc.

Asylum Provision.—It is exceedingly important that some systematic provision should be made for epileptics either by the State or by private charity. They are, as a rule, unwelcome inmates of hospitals because of their incurability. Doubtless the neglect to which they are subjected at home aggravates in many cases their condition, while it makes even more unhappy their lot. Provision should be made to enable them to pursue some vocation, the tendency of which has been shown to be curative. A hospital with such provisions has recently been inaugurated near Philadelphia, and they exist in some other States. The mind should be kept occupied; nothing is more baneful to the epileptic than idleness, and it is said that cures have been effected by giving the patient something to do.

Treatment of the Convulsion.—Of no small importance is the treatment of the eclamptic attack. The first measure is to secure protection against biting the tongue. Unfortunately, this is often the initial event in the convulsion. The end of a towel may be twisted and inserted between the teeth, or a suitable piece of wood or a clothes-pin may be similarly used. A small object like a cork is unsafe, as it may be swallowed or drawn into the larynx and cause death by suffocation. Some patients carry such an appliance ready for use. The patient should be controlled sufficiently to protect him from injury.

Given a case that under the bromids has yielded to treatment, what course shall be pursued as to its interruption? The most experienced clinicians urge that the drug should be continued at least two years after the fits have disappeared, and Seguin even advises that there should be no reduction in the bromids until three years have elapsed without symptoms. My

own practice has been to continue a dose of from fifteen to twenty grains (1 to 1.32 gm.) at bedtime for an indefinite period after cessation of the fits. The friends of the patient should be impressed with the importance of such a course, as he himself is almost sure to grow indifferent after the long absence of attacks.

REFLEX CONVULSIONS OF CHILDREN.

SYNONYMS.—*Infantile Convulsions; Eclampsia; Epilepsia acuta.*

Definition.—Convulsions due to peripheral irritation in children.

Etiology.—There is some confusion in the use of the word eclampsia. Some would use it as simply synonymous with the word convulsion, an application, I think, altogether the best. Others apply it to convulsions due to peripheral irritation only; others seemingly to puerperal convulsions only; others, notably Hermann Eichhorst and C. L. Dana, define eclampsia as acute epilepsy. Eichhorst further says: "Epileptiform convulsions, which have the same genesis as true epileptic attacks, are excited by irritation of the cortical motor brain areas." He then names, among the causes of these, toxic agencies, including uremia and lead poisoning, but also says he will treat only under eclampsia of the convulsions of infants (five to twenty months), among the causes of which he names heredity; psychical causes, as fright or anger; but most frequently reflex irritation, as of the skin or gastro-intestinal tract (dentition, intestinal worms, inflammation, and the like); foreign bodies; fecal accumulation; stone in the bladder, etc.; and finally, the infectious fevers and rickets. This class of cases I have taken great pains to exclude from the epilepsies, and prefer to include at present under the heading of Reflex Convulsions of Children. The convulsions which attend diseases of the brain are a part of the symptomatology of these affections, and do not require separate consideration.

Debility and malnutrition may be considered as predisposing causes of the form of convulsion under consideration.

Symptoms.—These demand no detailed consideration, since the convulsion is epileptiform and has been described. It is much more often partial than the typical fit of true epilepsy, but it has the same stages of the tonic and clonic spasm followed by drowsiness. It is most frequently single, but the fits may follow one another in rapid succession, and though rarely, terminate fatally. As in epilepsy, the temperature rises slightly during the fit. It may come on suddenly without warning, or be preceded by restlessness and fever.

Diagnosis.—This is usually easy, the convulsion coming on suddenly in the midst of health, yet traceable to some such event as the ingestion of some indigestible food, to teething, or to some other source of peripheral irritation.

The convulsion is distinguished from that of *infantile hemiplegia* by the absence of hemiplegia. A transient paresis does, however, sometimes follow the reflex convulsion.

These convulsions most frequently occur between the fifth and twentieth months, and toward the end of the second year, though they may occur as late as the fifth year. Convulsions occurring after this period are more likely to be true epilepsy.

Prognosis.—Cases of infantile convulsions are always alarming, yet most get well, and doubtless many cases among the poor recover which do not come under the notice of the physician. On the other hand, not a few deaths are caused by them—according to Morris J. Lewis, 8.5 per cent. of all deaths in children under ten; and according to West, 22.35 per cent. of all who die under one year. Cases of infectious disease ushered in by convulsions are almost always serious, but the convulsions themselves are rarely fatal. Convulsions due to gastric derangement are generally followed by recovery.

Treatment.—The first step in the treatment must always consist in finding and *removing the cause*. If it be undigested food, an emetic and an enema are indicated; if dentition is at fault, the lancet should be promptly applied to the gums. The next step is immersion in a *warm bath*, say at 95° F. (35° C.), increased to 100° F. (38.8° C.), to which mustard may be added. At the same time *cold* should be applied to *the head* by means of an ice-bag or cold water. To control the convulsion, *chloral* is the remedy *par excellence*, but while waiting for its effect, it may be necessary to permit the child to inhale a few drops of chloroform. The dose of chloral should be sufficient—2 1-2 to five grains (0.165 to 0.33 gm.) to a child of one year, frequently repeated until the effect is produced. It may be given in enema in double this dose, the buttocks being compressed until it is absorbed. The *bromids* may be given in combination with chloral, but they are altogether too feeble to be relied upon alone. Should these measures fail, *opium* may be used and even morphin, hypodermically, in minute doses; but these drugs should be used only as a last resort. Generally, the attack is relieved the moment the peripheral irritation is removed.

MIGRAINE.

SYNONYMS.—*Sick Headache*; *Bilious Headache*; *Hemicrania*; *Megrim*; *Migrän*; *Paroxysmal Headache*.

Definition.—Migraine is an intermittent, sensory neurosis, of which headache, commonly hemicranial, is the most invariable symptom. Almost as constant are aggravated nausea and vomiting, to which may be added other sensory symptoms, especially deranged vision. Ophthalmoplegic migraine is a rare form, in which paralysis of ocular muscles occurs.

Etiology.—This is obscure. The disease is more common in females—apparently three times as frequent as in males. It begins early in life, commonly at puberty, and even earlier—as early, in fact, as at two years. It affects vigorous and strong as well as nervous and anemic subjects. Exciting causes are fatigue, mental and physical, including eye-strain, digestive derangements, and menstrual disorders. What is known as the uric acid diathesis plays an undoubted rôle in certain cases. As often none is discoverable.

It is usual to speak of migraine as a vasomotor disturbance, because there are symptoms which point to involvement of the sympathetic system, but this is a matter of inference rather than demonstration. The attacks are characteristically paroxysmal. It appears to be more frequent in the winter season in this climate, when it is not infrequently associated with a

gouty or rheumatic attack. Caries of the teeth and nasal troubles are a cause in children.

Morbid Anatomy.—No lesions other than those described as causal are found. The precise seat of the pain is not known, but is believed to be in the meninges of the brain.

Symptoms.—The attack is often ushered in without any warning, at others with *prodromal* symptoms familiar to the patient. They are various and not distinctive of the disease, but so characteristic for each case that the individual foretells the attacks on their approach. They include general discomfort, vertigo, a sense of pressure, tinnitus, spots before the eyes, chilliness, and the like. Hemianopsia and scotoma may be among them.

Then the *pain* starts in suddenly and is continuous, usually in one side of the forehead, but it may also be in the occiput, whence it extends to the half or whole head. It is extremely severe, sometimes described as blinding, at others sharp and boring or shooting. It is sometimes attended by flashes of light. Light and noise aggravate it, and a darkened room is always sought. Hemianopsia is not infrequent.

Along with pain generally is absolute want of appetite, and intense *nausea* succeeded by *vomiting*. The vomited matter includes first the contents of the stomach (if the stomach is empty, mucous matter), and later yellow and bitter bile, whence the term “bilious headache.” If the stomach happens to be full, the pain may be relieved by the vomiting.

The *vasomotor* symptoms are conspicuous in some cases, and are assigned by some an important rôle in its causation. From this standpoint two subdivisions are made, *angiospastic hemicrania* and *angioparalytic hemicrania*. In the first form, described by Dubois-Reymond from observations on himself,—some of the best descriptions have been by sufferers,—the forehead and ear on the affected side are pale, the skin is cool, the temporal arteries are contracted, the *pupil is often dilated*, and the secretion of saliva is increased—in a word, the symptoms of irritation of the sympathetic. In hemicrania angioparalytica, described by Möllendorff, also from observations on himself, the face is reddened on the affected side, it feels warm, the temporal arteries are dilated and pulsate strongly, there is sometimes unilateral sweating of the face, with the *pupils contracted*—symptoms suggestive of paralysis of the sympathetic. By no means all cases are capable of being thus classified, and mixed forms are met.

The frequency of the attacks varies greatly; usually they do not occur oftener than once in two weeks or once a month. They may, however, occur every ten days or even weekly.

The duration of the attack varies. Very often the patient goes to bed at night, and in the morning, or at the end of twelve hours, is relieved; or the attack may last twenty-four hours or even two or three days. The attacks continue over a period of many years, sometimes ceasing in women after the climacteric is passed, and in men after fifty.

Further speculation as to its true nature would be unprofitable here, though mention should be made that the arteries on the affected side sometimes becomes the seat of arteriocapillary fibrosis, a condition giving some force to the view of vasomotor origin.

Diagnosis.—The symptoms of *brain tumor* sometimes closely simulate migraine. One case of supposed migraine under my observation turned out to be brain tumor. Ophthalmoscopic examination may discover choked

disc in cases of brain tumor and thus settle the diagnosis. Such examination should always be made.

Prognosis.—This is favorable so far as life is concerned, but it is not always easy to prevent the attacks or diminish the frequency of their occurrence. It often happens that they cease after middle life.

Treatment.—Before treatment is instituted every case should be thoroughly investigated with a view to discovering causal conditions. Should such search be successful, their elimination may result in a cure. Such accessible causes are eye-strain, affections of the nose, mental and physical fatigue, and indiscretions in diet.

The attack itself is more likely to be warded off the earlier the treatment for it is instituted. Sometimes a dose of salts, taken as soon as the first symptoms appear, wards off an attack. *Phenacetin* in from ten to fifteen-grain (0.66 to 1 gm.) doses relieves some attacks. After the first dose it may be continued in smaller doses. *Antipyrin* and *antifebrin* are similarly successful, and I am informed by apothecaries that many women purchase these drugs regularly to relieve their attacks. Such practice should, however, be discouraged.

Sometimes a hypodermic injection of *morphin*, even so small a dose as 1-8 grain (0.011 gm.), acts magically, and on the whole it is the most reliable remedy, although it is one to be put off if others succeed. *Caffein* is a less efficient remedy, but may be used in conjunction with morphin or immediately after it to counteract the unpleasant effect of this drug. It may be given in three to five-grain (0.2 to 0.33 gm.) doses, and is sometimes administered hypodermically. *Salicylate of caffein* is also recommended in like doses. *Cannabis indica* is a remedy much recommended, but is unfortunately of uncertain strength. We may begin with 1-4 grain (0.016 gm.) and increase rapidly. *Bromids* may be tried. *Guarana* is more efficient in from thirty- to sixty-grain (2 to 4 gm.) doses of the powder and similar doses of the fluid extract.

If the spastic form can be distinctly recognized as present, *nitrite of amyl* may be expected to be serviceable—three to five drops by inhalation. In the opposite or paralytic form *ergot* has been advised, and may be given in doses of from fifteen minims to one dram (1 to 4 gm.). *Nitro-glycerin* in doses of from 1-100 to 1-50 grain (0.00066 to 0.0013 gm.), and *nitrite of sodium* in doses of from three to five grains (0.2 to 0.33 gm.), may be useful in the class of cases benefited by nitrite of amyl. *Cold* to the head is sometimes grateful, and when there is nausea, *cracked ice* or cold carbonated or apollinaris water or small doses of iced champagne are sometimes efficient.

Electricity is said to have been useful in a few cases, but I have had no experience with it. It is recommended that in the spastic form the anode should be applied to the sympathetic, and in the paralytic form the cathode, the other pole being applied to the cervical cord as high as possible on the occiput.

Preventive Treatment.—General treatment between attacks should not be neglected. When there is anemia, the judicious use of *iron* and *arsenic*, continued for some time, has occasionally been followed by a disappearance of the tendency to the disease.

The urine should be carefully examined, and if concentrated and tending to deposit uric acid or oxalates, diluents and the alkaline mineral waters are indicated. In a few instances in my practice the daily use of natural

Vichy water, to the extent of a bottle a day, had the effect of diminishing, and in one instance of eliminating, the attacks. The conditions of a healthful life, bathing, fresh air, and simple wholesome food, should be observed. Many persons are totally free from attacks while traveling. A course at Contrexville, Vichy, or Carlsbad may be of service in averting attacks.

OCCUPATION NEUROSES.

SYNONYMS.—*Professional Spasm; Copodyscinesia.*

Definition.—A term applied to a group of diseases characterized by symptoms excited by an effort to perform some oft-repeated muscular act, commonly one involved in the occupation of the patient. The most usual symptom is cramp or spasm in the muscles concerned, whence this word is preceded by that of the various occupations, to indicate its special variety. Thus we have writer's cramp or scrivener's palsy, telegrapher's cramp, pianoforte-player's cramp, typewriter's cramp, seamstresses' cramp, milker's cramp, etc.

WRITER'S CRAMP.

SYNONYMS.—*Graphospasmus; Cheirospasmus; Mogigraphia; Scrivener's Palsy.*

Definition.—The professional neurosis of clerks and scriveners. It is the most frequent of the occupation neuroses and may serve as the type for all.

Historical.—The first notice of writer's cramp appears to have been by Bernhart Ramazini in 1746. It was first fully described by Sir Charles Bell in 1830, and called scrivener's palsy by Samuel Solly, who published three admirable clinical lectures in "The Lancet" in 1864-65. Other monographs are those by G. V. Poore, in "The Practitioner," in 1872-73 and 1878, also in his "Text-book of Electricity," 1876, and "Med.-Chir. Trans.," vol. lxi., 1878; W. H. Erb's article in "Ziemssen's Cyclopedia," 1876, and O. Berger's article, "Beschäftigungsneurosen," in Eulenberg's "Real-encyclopädie," first edition, 1880, third edition, 1894.

Etiology.—There is no predisposition to sex, the disease being more frequent in men in occupations where more men are employed, and more frequent in women in occupations where more women are employed; and it is likely that since an increasing number of women have become telegraph operators, more cases may be expected among them, in whom, perhaps, also, the neuropathic temperament may favor it. The majority of all cases occur between twenty and fifty—154 out of 177 cases collected by Berger from Gowers, Poore, and himself. Predisposition is caused by previous injury and a neurotic disposition, while even heredity is said to predispose. An especially important factor is a faulty method of writing, while cases have occurred which were apparently independent of the usual exciting cause. Steel pens are said to be responsible for an increased number of cases since their introduction. The disease is becoming less frequent as clerical exactions grow less.

Morbid Anatomy and Pathology.—No distinctive anatomical changes have ever been discovered in writer's cramp. Three theories are held regarding its nature. According to the *first*, it is essentially a local disease: weakness in certain muscles permitting overaction on the part of their

antagonists, an overaction which increases to spasm. According to a *second* theory, the spasm is reflex and due to an irritation of the sensory nerves concerned in the act of writing. The *third*, and usually accepted theory, makes the affection primarily and essentially central, due to deranged function in the centers concerned in the act of writing, and therefore in the central nervous system.

The only discoverable morbid change is an occasional atrophy of muscles concerned.

Symptoms.—*Spasm* is almost always the initial disturbance, commonly affecting the forefinger and the thumb; but the onset is gradual, and the first effect is an awkwardness in which the pen does not move quite as intended. It is irresistibly grasped too tightly, yet the forefinger has a tendency to slip off, the pen passing between it and the middle finger, while an attempt to mend matters by taking a new hold only increases the difficulty, and the hand labors as if tied down. It feels tired, and there is often an aching pain throughout, extending even to the arm. The writing is irregular and uneven. These symptoms may continue, with more or less impairment of the power of writing, for weeks or months, coming earlier, however, after each effort, with gradual increasing severity until the intolerable spasm sets in. This may be so violent in a combined movement of flexion and adduction in the thumb that the pen may be wrested from the grasp and thrown to a distance, or there may be a lock spasm, described by S. Weir Mitchell, in which the pen is firmly locked between the fingers. The spasm is almost always tonic in character, although it may now and then be varied by a slight start or jerk. It is sometimes associated with *tremor*. Rarely tremor occurs alone, and it may be the premonitory symptom of *atrophy*. The spasm may be limited to the act of writing, while other actions are well performed; but absolute limitation to this act is seldom met in severe cases.

Special difficulty attends the performance of acts requiring delicate co-ordination of the muscles. Sometimes a patient can write with a pencil, but not with a pen. *Paresis* and *paralysis* may occur with spasm or alone. On the other hand, the strength of the hand may be quite unimpaired. Such loss of power varies greatly, being sometimes trifling, at other times considerable.

Sensory symptoms are almost always present in various degrees. They may even exist alone, producing a sensory form. They are manifested at first by the distressing fatigue alluded to, or by dull pain often referred to the bones or joints, very often to the metacarpal bones or to the wrist, ceasing with cessation of writing. Sometimes there is local tenderness or a tingling sensation. Again, the pain is more severe, neuralgic in character, and distributed along the course of the nerve, induced at first by the act of writing, later by any muscular act of the part. There may also be tenderness in the course of the nerve.

Vasomotor disturbances are seen in severe cases, manifested by hyperesthesia, a glossy, shining skin, or a cyanosed, chilblain-like appearance; or the hand may become blue and hot on attempting to write.

In the beginning the *electrical reactions* are normal, but in advanced cases there is a diminished faradic and sometimes increased galvanic irritability of the motor nerve endings distributed to the muscles. It is to be remembered that the radial, ulnar, and median nerves all supply muscles employed in writing.

Diagnosis.—This is usually easy, the initial limitation of the symptoms to the act of writing sufficiently indicating the nature of the case. More frequently other paralytic and painful affections of the arm and hand are mistaken for writer's palsy. Among these may be included *hemiplegia* of gradual onset, *commencing insular sclerosis*, early *tabes dorsalis* affecting the arms, or *pressure palsy of the musculo-spiral nerve*.

In most of these cases, however, other symptoms are present or are soon added. More frequently nervous persons *imagine* they have writer's palsy. In some cases the condition is really one of *muscular rheumatism*.

Prognosis.—A well-established case of scrivener's palsy rarely gets well. There are, however, exceptions, even under the most unfavorable conditions. The prognosis is more favorable when sensory symptoms predominate. Relapses are prone to occur when the patient returns to work.

Treatment.—*Prevention*, as usual, is much more effectual than curative treatment. The disease is confined almost exclusively to those who write in a cramped manner, and is said to be unknown in those who write from the shoulder. The curative treatment consists essentially in *rest* promptly adopted—a long rest being often sufficient to effect a cure, while no other treatment can take its place. Various *mechanical devices* to aid in writing while the cure is going on have not accomplished much, and the patient may learn to write with the left hand, although the disturbance may occur in this hand also. Typewriting is, as a rule, as easily learned with the affected hand as before disability. The devices referred to may be such as a very thick penholder which can be directed by the whole hand; or a pen attached to a ring, which is slipped over the index or middle finger, and the thumb is thus permitted to rest. The typewriting machine has, however, rendered all such devices of less consequence. The usual nerve tonics, such as strychnin, may be given. Hygiene of the part, including hydrotherapy, frictions, especially massage, and sometimes electricity, are useful.

The important position assigned by all neurologists to the *electrical treatment* of writer's cramp demands some special consideration, especially as the methods advised are by no means uniform. The preference given to the galvanic current over the faradic is, however, almost unanimous, and unless the latter is especially mentioned, the former is intended. Berger recommends a *stable current*,—*i. e.*, a current in which the electrodes are not moved about,—with the positive pole in the neck and the negative partly in the fossa supraclavicularis, partly on the affected nerves and muscles of the arm; the length of sitting, from five to ten minutes daily, or every other day.

Benedict recommended galvanization along the spinal column, with especial reference to sensitive vertebræ, but also localization of the galvanic current, as recommended by Berger; duration of sitting, three to four minutes, current strong enough to be easily felt. He also found subsequent faradization to the muscles most affected useful. Eulenberg also advised galvanization of the muscles affected with chronic cramp and of the involved nerve-trunk with the positive pole. In cases with tremor and rapid exhaustion the negative pole is to be applied to the spinal column and the positive on the peripheral nerve-trunks and muscles affected. Erb advised galvanization of the cervical vertebral column, with ascending stable and labile currents combined with peripheric galvanization. In several cases it appeared to him that transverse and longitudinal currents through the head were followed by favorable results.

Onimus used an ascending current through the affected arm, with the negative pole in the neck and the positive pole upon the muscles of the forearm, especially the ball of the thumb, in addition to a current of moderate strength along the cervical vertebræ. M. Meyer employed a stable galvanic current with the anode on the tender spots on the vertebral column when these were present, and the cathode on the sternum. Althouse sought to reach the cervical cord by placing the anode upon the cervical spine and the cathode on the depression between the angle of the jaw and the sternocleidomastoid muscle—a position corresponding to the superior cervical ganglion of the sympathetic. The current should be mild, uniform, and uninterrupted for from three to five minutes at a time. The method should not be reversed. In cases of paresis of certain muscles it is sometimes of benefit to have the patient make voluntary movements of these muscles simultaneously with the closing of the galvanic current applied to the nerve innervating these muscles.

Testimony is united to the effect that the galvanic treatment must be kept up for a long time, even for months continuously, with a current of moderate strength, say a maximum of four milliamperes, and section electrode of about three qcm.

Faradization is recommended only in cases where there is demonstrable paresis and anesthesia, and then in weak currents. In anesthesia the brush may be used. Erb found that many of his patients were benefited by wearing on the arms, for several hours daily, a simple galvanic element, such as a zinc and copper plate, united by wire, and under it a moist piece of linen.

Gowers has much less confidence in electricity, especially in the spasmodic form of the disease, and is probably right when he says if the patient goes on writing electricity has not the slightest influence on the disease. My own experience with electricity has not been very encouraging.

The position accorded to *gymnastic exercise* of the arm and hand muscles is scarcely second to that of electricity—indeed, it is preferred by some. Especially efficient appears to be that of a German writing-master, Julius Wolff. The gymnastics are of two kinds: First, active, in which the patient moves the fingers, hands, forearms, and arms in all directions possible, each muscle being made to contract from six to twelve times with considerable force, and with a pause after each movement, the whole exercise not exceeding thirty minutes; and repeated two or three times daily. Second, passive, in which the same movements are made as in the former, except that each one is arrested by another person in a steady and regular manner. This may be repeated as often as the active exercise. Massage is practiced daily for about twenty minutes, beginning at the periphery; percussion of the muscles is considered an essential part of the massage. Combined with this are peculiar lessons in pen-prehension and writing. Priority for this method is claimed by Roman Vigoroux and Th. Shott. The testimony of some of the best authorities in Europe is given in behalf of this method. Poore secured good results by combining gymnastic exercises with the use of electricity. Tenotomy and nerve-stretching have been attempted and abandoned as useless.

ATHETOSIS.

SYNONYM.—*Hammond's Disease.*

Definition.—Athetosis consists in a peculiar rhythmical contraction of the fingers and toes.

Historical and Nature.—It was first thoroughly studied by W. A. Hammond in 1871, also by Charcot, who considered it identical with posthemiplegic chorea or a modified form of it. This may be regarded as correct in cases where there has been hemiplegia, and athetosis occurs in the muscles of the side which was hemiplegic. It occurs in connection with hemiplegic weakness and contraction due to tumor of the brain. Frequently it is seen as a sequel of infantile palsy. Epileptics, idiots, and alcoholics also exhibit it in the bilateral form. Rarely, it is an independent affection, said to be the result of cold or psychological derangement, and is even held to be congenital.

Symptoms and Diagnosis.—It occurs preferably in the fingers and toes. In the fingers it is seen as a slow, though sometimes rapid flexion and extension, adduction and abduction, with the appearance as though the fingers were attempting to grasp something. The thumb, index-finger, and little finger are those most frequently involved, the muscles particularly concerned being the external and internal interossei. The wrist-joint may also share in the motion, and not infrequently the opposite to that of the fingers. The patient may resist the motion but for a short time, and it even continues during sleep, though in a less marked degree. Excitement, mental and physical, causes an increase in the motion. Subluxation of the phalangeal articulations may take place in long-standing cases, while contractions have been known to occur in parietic extremities. Sometimes there has been hypertrophy of the front of the arm as a consequence of the constant muscular movements; in other cases the muscles are unaltered, or there may be atrophy. The electrical condition is unaltered. Similar motions occur in the toes and feet, but they are not, as a rule, so active. Even the muscles of the neck and face and tongue may share in the process. As a rule, athetosis is one-sided,—hemiatheosis,—but bilateral cases have been described.

TETANY.

SYNONYMS.—*Tetanilla; Intermittent Tetanus; Contracture des nourrices.*

Definition.—A disease consisting in continuous or intermittent tonic spasm of the extremities, usually symmetrical, but occasionally confined to one limb or rarely even becoming general.

Historical—A knowledge of the symptom complex of tetany was gradually acquired. The name is said to have been suggested by L. Corvisart, whose book, published in 1852, was, however, preceded by one by Imbert and Gourbeyre in 1844, and another by Drepech in 1846. Dance in France and Steinheim in Germany described it about the same time. Trousseau (1860) first discovered the effect of pressure on the large vessels and nerves of the arm in producing the contraction in the hand muscles. F. Chvostek (1877) described the markedly increased motor excitability of nerves known as Erb's symptom; Chvostek and N. Weiss (1880) discovered the phenomena of facial and lip muscle contraction, elicited by tapping the facial nerve. Hoffmann (1887) showed that in tetany even sensory nerves are over excitable, and L. von Frankl-Hochwart (1887) that only galvanic excitability is increased and faradic not. Later L. von Frankl-Hochwart published a second monograph on the disease in Nothnagel System of Medicine.

Etiology.—Tetany occurs in children and in adults, and when present in the latter, it has usually made its appearance in comparatively early life. It has been supposed to be rare in North America, but J. P. C. Griffith, in a noteworthy paper read before the Association of American Physicians in 1894, collected 72 cases occurring in this country. Of these, five happened in his own experience. It is rather more frequent in girls than boys. The disease is more common in Vienna and Heidelberg than anywhere else, especially in the late winter and early spring.

Among possible causes may be mentioned digestive derangement, including dentition, dilatation of the stomach, hyperchlorhydria, and diarrhea; rheumatism, whence this form is sometimes called rheumatic tetany; rickets; open wounds; laceration. Removal of the thyroid gland (13 cases followed 37 operations in Billroth's clinic, and removal of the thyroid in dogs) has been followed by tetany. Pregnancy, acute fevers, and diphtheria are also alleged causes. Trousseau suggested the name *contracture des nourrices*. L. von Frankl-Hochwart has shown that it occurs quite frequently among the shoemakers and tailors of Vienna.

Symptoms.—The characteristic *spasm* is usually limited to the hands and feet, arms, and legs. In the hands the thumbs are flexed into the palms, the fingers firmly bent at the metacarpophalangeal articulation, but straight elsewhere. The fingers are adducted, the ring and middle fingers sometimes overlapping. The wrists are flexed, the elbows bent, and the arms folded over the chest. The hand is described as the obstetrical hand, from the position caused by the cramp. In the lower limbs the knees and hips are stiff and extended, the feet extended, and the toes adducted. Sometimes there is dorsal flexion of the foot and flexion at the knee. Contractions may last from a few hours to several days. The term *continuous* may be applied to those cases in which the contractions have lasted uninterruptedly for over two days, and *intermittent* when they do not last longer than two days without permanent or temporary disappearance. Following this standard, Griffith found 38 cases intermittent and 25 continuous. The spasm is always associated with *tenderness* or *pain*, the latter being often extreme. At other times these symptoms are present only in the beginning of the attack or when the members are handled. Rarely the muscles of the back, neck, and face are involved; and there may be *trismus*, the angles of the mouth being drawn out.

Associated symptoms are *stridulous respiration*, regarded by some as an essential part of the disease or as a manifestation of the disease in the larynx. Further interesting phenomena, especially studied and called cardinal symptoms, are *contraction caused by tapping the muscles*; as, for example, the pectoralis or the facial muscles, known as Chvostek's symptom. Another is Trousseau's symptom—the production of *spasm by pressure* upon a *large artery or nerve*, especially in the arm; and still another is Erb's symptom—*increased electrical excitability*. *Inability to urinate* may be present, and anesthesia has been recorded among symptoms. There may be *slight elevation of temperature* and *frequent pulse*.

Diagnosis.—The rarity of this disease sometimes causes it to be overlooked, while differences of view as to what constitute its essential symptoms also cause a different diagnosis. Thus, some would exclude the *carpopedal spasm* of children; while Gowers, Dana, and Griffith include these cases under tetany. Many cases of *mild spasm succeeding gastro-intestinal irritation* and the like would be regarded by some as tetany and by others not. It

possesses nothing in common with *tetanus*, whose name it so closely resembles, but whose symptoms are totally different.

Prognosis.—This is usually favorable, recovery taking place in from a few days to months. The fatal cases are those associated with dilated stomach, gastric carcinoma, and thyroidectomy. The disease has a marked tendency to return, and is most common in late winter and early spring.

Treatment.—The *cause* of the condition should be sought and, if possible, eliminated. After this, *remedies calculated to diminish nervous excitement* should be administered; also wholesome hygienic measures availed of, including massage, *passive motion*, and *electricity*. *Warm baths* are especially recommended. The cases attended with severe pain may require the hypodermic use of morphin, and delayed response to the latter may even demand chloroform inhalation.

Thyroid extract should be administered in those cases in which the disease follows removal of the thyroid gland, beginning with five grains three times a day. A portion of the thyroid may be transplanted.

HYSTERIA.

Definition.—Hysteria is a morbid state of the nervous system in which may be manifested every variety of nervous symptom due to deranged function of the cerebral, basal, and spinal centers, associated with lowered will-power and exaggerated emotional tendencies.

Etiology.—Hysteria is a disease of civilization and of certain races. It is unknown in the barbarian, and is more rare in Northern races, while the volatile Southern temperament favors its development. Thus, the French and Italians of the Latin race furnish many subjects, while it is rarer among Germans, English and Americans. The disease is also frequent among Hebrews.

The sexual organs of women have been held responsible for hysteria in the female, and the name hysteria is derived from *ὑστέρα*, a womb; but this conception is erroneous. In males the disease assumes more the form of hypochondriasis, but in them also convulsions, contractures, and paralysis occur. It is found in boys as well as in adult males, especially in alcoholic males. About half of all cases occur in the second decade, especially after puberty, though it may also occur earlier; one-third between twenty and thirty, while boy subjects are commonly under the age of puberty. Masturbation and adherent prepuce are held responsible for many cases in boys. Heredity plays a certain part, while the neurotic constitution especially favors hysteria.

Among the exciting causes are included diseases of the generative organs in women, but their influence as compared with other illnesses may simply grow out of their frequency. Ovarian disease has been held responsible, and tenderness in the ovarian region is undoubtedly a frequently associated symptom, but it is questionable whether this tenderness is of ovarian origin. Association with others similarly affected is an undoubted factor, and it is not unusual for the disease to spread itself from one to a number of girls living under the same roof. Various diseases other than those mentioned also predispose to hysteria. Even local affections, including injuries, may thus operate, and hysterical joint affections may follow trauma of a joint. Strümpell relates an instance of a girl who, from having inhaled

smoke, acquired hysterical paralysis of the vocal cords. General disease of an exhausting kind, such as fevers, nervous diseases, functional and organic, predispose to hysteria. Hysteria is common in prostitutes. Cerebral tumors, tuberculous meningitis, multiple neuritis, chorea, infantile hemiplegia, often cause conspicuous hysterical phenomena. Diphtheritic paralysis may pass into hysterical palsy, while Gowers has known hysterical convulsions to attend the onset of embolic hemiplegia, as shown by autopsy. Among psychological nervous causes are fright, such as attends a runaway or a fire; an angry scene; the constant operation of trifling mental causes, including worry and anxiety.

Symptoms.—An idea of the number and variety of the symptoms of hysteria has probably been obtained from the definition given—a variety which belongs to no other disease, and which may include almost all symptoms excited by any of the numerous nervous diseases. The hysterical patient is, however, characterized by certain general, corporeal, and mental peculiarities which should be first considered. Such persons are emotional, irritable, capricious, sensitive, often willful, sometimes because of indifferent early home training and overindulgence. They exaggerate every illness, and demand an inordinate amount of sympathy. If women, they are at times disagreeable and petulant or doggedly silent, while at others they are charming and fascinating. They are often intellectually bright. Hysteria does occur, however, among intellectual degenerates. Other hysterical cases present no mental peculiarities. As to physical development, the hysterical patient is by no means always delicate; indeed, some of the most stubborn cases are those which appear in blooming health, rosy, well nourished, and handsome.

There are also certain symptoms which are so characteristic of hysteria and possessed of such diagnostic significance that they have been called by Charcot "hysterical stigmata." They include, especially, modifications of sensibility, but in addition to these are derangements of motion, the maximum expression of which is the hysterical convulsion. There are also characteristic vasomotor symptoms.

I. DERANGEMENTS OF SENSATION.—The symptoms in this category are, as a rule, only elicited by the special examination of the physician, being rarely discovered by the patient. They include, especially, alterations of cutaneous sensibility, manifested by anesthesia or hyperesthesia. Most striking is insensibility to painful impressions, known as *analgesia*. It is usually tested by thrusting a pin deeply into the flesh—an act which is often totally unfelt. Less invariably is there failure to appreciate the sharp irritation of the electric current. Such analgesia may be confined to definite parts of the body, half the body, or may be general. It may extend to the mucous surfaces as well, and even to the deeper tissues, as those of the muscles and joints. While analgesia is the most common manifestation of deranged sensibility, there may be absence of the sense of temperature, of pressure, and even of the muscular sense.

Hyperesthesia is almost equally characteristic. The areas involved may be exquisitely sensitive or but slightly so, requiring, sometimes, considerable pressure to develop the tenderness, while at other times it is elicited by the slightest touch. The hyperesthesia is especially noticeable when the attention of the patient is directed to it by such remarks as, "This will hurt you very much when I touch you." The sensitive areas may also be limited or extended and anywhere—on the head, thorax, limbs. Inguinal

tenderness is especially frequent on the left side. Even more characteristic is the hyperesthesia of the spinal column,—the so-called “hysterical spinal irritability,”—which affects the column as a whole or in segments, not infrequently a single vertebra. The sensitiveness may be so extreme that the slightest contact may cause the patient to cry out, while strong pressure may be necessary to cause it. Of special interest also are the hysterical zones, to be again referred to.

The *special senses* are variously involved. There may be simple dimness of vision or narrowing of the field, due to anesthesia of the peripheral part of the retina. There is often total amblyopia, but never hemianopsia. Hysterical achromatopsia is not infrequent. According to Charcot, the loss of the appreciation of violet is the most common, then of green, and, lastly, of blue and yellow. Loss of hearing is not infrequent, and still more frequent is anesthesia of taste and smell, even bitter substances, like quinin, or pungent ones like vinegar, producing no impression or but a trifling one.

2. DERANGEMENTS OF MOTION.—The most striking of these is *paralysis*. It commonly comes on suddenly, apparently as a result of fright or other suddenly acting cause. It may, however, be gradual, and take weeks for its development. It is most frequently hemiplegic, but may be monoplegic, rarely diplegic, while every form of organic paralysis may be simulated. Hemiplegia is more usual on the left side—according to Weir Mitchell, four times as frequent as on the right. The face is not usually affected, the neck and arms rarely, the legs oftenest. The patient can sometimes move the legs in bed or even when sitting up, while all attempts at walking are unsuccessful; or she may be able to move the arms when the eyes are open, but not when they are shut. It is a paralysis of the will. Sometimes one leg only is paralyzed, giving rise to a peculiar gait, the free leg making long strides while the paralyzed one is dragged along with a shuffling noise, and not swung outwardly in a circle as in true hemiplegia. Sometimes there is ataxia with paresis. Paralysis may be both flaccid and spastic. Though far more frequently a symptom of hysteria in women, it may be as striking in men. Paralysis of the vocal cords is one of the most frequent symptoms of hysteria, giving rise to aphonia. The paralysis is easily demonstrable by laryngoscopic examination, because of anesthesia of the pharynx. It may be so marked that the vocal cords actually open with an attempt at phonation. Anesthesia and motor paralysis are commonly associated.

Contractures and *spasms* are a form of motor derangement; they may occur alone or with anesthesia and paralysis. They exhibit every variety, and may attack any group of muscles; they may be tonic or clonic, and sudden or gradual in development. The tonic contracture is most usual in the arm, which is flexed at the elbow and wrist, while the fingers grasp the thumb in the palm tightly. In the feet, also, flexures predominate, the feet being inverted and the toes flexed. In the larger joints, on the other hand, the extensors are involved, as a rule. Rarely extensor contractures occur in the small joints; all disappear with chloroform narcosis unless they have persisted a long time and shortening of the muscles, ligaments, etc., has occurred. The reflexes may be very much exaggerated and the condition closely resemble spastic paraplegia. Extreme emaciation may occur in connection with these contractures, as witness a remarkable case related and illustrated by Weir Mitchell in the “Medical News,” August 24, 1895.

Even hysterical trismus may occur, and a very striking result of abdominal contracture is the *phantom tumor*, which is found usually just below and

in the neighborhood of the umbilicus, often simulating a firm and solid growth. The mechanism of its production, according to Gowers, is a relaxation of the recti and spasmodic contraction of the diaphragm, together with inflation of the intestines and an arching forward of the vertebral column. Women have even been prepared for surgical operation on such tumors when the delusion was dissipated by the anesthetic, and the abdomen has been opened for purely hysterical conditions. Such tumor is not infrequently associated with symptoms of spurious pregnancy—pseudocyesis. Visible tremor may be present, rarely hysterical athetosis.

3. VASOMOTOR DERANGEMENTS.—A striking *pallor* is often present, at other times hyperemia, and even a hot skin. *Hemorrhage* from internal organs, especially the stomach and lungs, often alleged, is usually at least apocryphal. Commonly, the blood is derived from the gums, and its amount is never considerable. Yet such symptoms have been the basis of a diagnosis of pulmonary disease or gastric ulcer. Hysterical stigmata or hemorrhages in the skin are also alleged, but are very rare.

Hysterical fever belongs also to vasomotor symptoms. A temperature of 106° F. (41.1° C.), and even more, has been reported. Such temperatures are characterized by their irregular occurrence. Actually they are extremely rare, being in most instances traceable to deception.

Anomalies of secretion include profuse and scanty perspiration, the latter resulting in a peculiar dryness of the skin; the salivary secretion is similarly influenced, and modifications in the urinary secretion are some of the most characteristic phenomena of hysteria. They include ischuria, but especially polyuria, the patient passing a large amount of very light-colored urine of low specific gravity. *Excessive thirst* is also frequent, further augmenting the polyuria. The chemical composition of the urine is altered in many severe cases; thus, the phosphates and urates have been found diminished, while the ratio of earthy to alkaline phosphates may be changed to 1 to 2 or 1 to 1, instead of 1 to 3. Such changes are held by Charcot's school to be diagnostic of convulsive hysteria as contrasted with epilepsy.

4. VISCERAL DERANGEMENTS.—The *digestive system* is especially disturbed by simple indigestion, depraved appetite, flatulence, and gastric pain. Not infrequently there is spasm of the esophagus, causing difficulty in swallowing: in some instances expulsion of food before it reaches the stomach. Hysterical vomiting is very common, and alleged vomiting of impossible substances is one of the most characteristic symptoms. An antagonism to food is sometimes present, so extreme that death by starvation has been barely averted; indeed, is said to have occurred. Constipation is a frequent and troublesome symptom. Much more rare is the opposite condition of diarrhea.

Cardiovascular and *pulmonary* symptoms exhibit every variety, including irregularity of the heart's action, tachycardia and bradycardia, precordial oppression and sense of suffocation, with extreme frequency of breathing and deranged rhythm. Laryngeal spasm, hysterical cough, and hysterical hiccough are frequent symptoms. *Hysterical cries* with inspiration or expiration, and imitation of the sounds produced by various animals are described by the French neurologists.

Joint affections, purely hysterical, were early studied by Sir B. Brodie, and later by Sir James Paget. They involve the knee and hip and consist of fixation, tenderness, and even swelling.

The *mental symptoms* are a prominent feature of hysteria, and vary

greatly in their manifestations. Irritability and capriciousness of temper, maniacal excitement, hallucinations, and even insanity may occur. The hysterical trance is a well-known condition. It may come on spontaneously, but more frequently it follows one of the forms of hysteroid attacks to be later described. The cataleptic state may be associated with this symptom.

5. CONVULSIVE SEIZURES.—Hysterical convulsions are a recognized symptom, while in some they are the only manifestation of the disease. Their severity varies greatly; but two degrees are described, a milder or minor, and a severer or major.

(a) *Minor Form*.—This may come on suddenly or be preceded by a *prodrome*, including hysterical behavior, such as laughing and crying; a sense of constriction about the throat, or that of a ball rising in it (the so-called *globus hystericus*); a feeling of anxiety with shortness of breath; or pain and discomfort in the chest or abdomen.

In the *actual seizure* the *patient falls*, with this striking feature: that she rarely fails to find a soft spot, such as a sofa or bed, to receive her. The convulsion consists in clonic contractions of a disordered and irregular kind, in which all four extremities and even the trunk may take part. Though seemingly unconscious, the patient still gives to the careful observer the impression of a certain method in her madness. The convulsion lasts usually a few minutes, when it passes off spontaneously, or the patient may be aroused by some powerful impression, such as the dashing of cold water in the face, or by a sharp galvanic shock. She may remain emotional for a time, but the period of torpidity, so characteristic of the epileptic fit, is rare.

(b) *Major Form (Hysterical Epilepsy)*.—This has become widely known, more particularly from the graphic descriptions and vivid pictures furnished by the French school of neurology. It is much less common in this country; indeed, it is rare outside of hospital walls, where prostitutes are the usual subjects. The attack may be preceded by *prodromata* similar to those that precede the milder attacks. The convulsion is described by French writers as having four distinct stages:

1. The epileptoid state, closely simulating a true epileptic attack, with apparent unconsciousness, tonic spasm, even *opisthotonos*, grinding of the teeth, livid face, succeeded by clonic convulsions, relaxation, and coma; lasting rather longer than the true epileptic attack.

2. The period of "contortions and grand movements," called by Charcot "clownism," characterized by emotional display, striking contortions, or cataleptic poses.

3. The period of plastic positions and passionate attitudes, including those of ecstasy, fright, beatitude, or erotism.

4. The return to consciousness and a stage characterized especially by manifestations of delirium with extraordinary hallucinations and by hypnotic "suggestibility." In it visions are seen, voices heard, and conversations carried on with imaginary persons. Imaginary events are related as actually true. These hallucinations sometimes persist even after recovery. These periods are not sharply separated from one another.

Suggestion and Hypnosis.—At this point it is suitable to say something of these conditions, so closely associated with the hysterical state and which have attracted much attention of late. By suggestibility is meant the susceptibility of a person to the production of a definite psychical or physical state dependent upon the arousing of corresponding ideas in the mind. It is really a further development of the hysterical mental constitution already

referred to, in which the patient permits himself to be dominated by his imagination. Suggestion is merely the artificial fostering of the psychical peculiarity. It is most easy during the part of the hysterical attack when the patients speak, hear, and answer. At such times a definite direction may be given to the patient's ideas. If he is told in an emphatic, convincing manner that he is in a certain situation, be it one of a pleasurable kind or a state of suffering or danger, he believes it, and at once, by behavior or expression, shows that he believes it, and is actually experiencing the conditions named. Physical states may be similarly suggested, such as paralysis, contractures, and anesthetics, while severe pain may be inflicted without exciting sensibility. After the attack is over the subject is totally ignorant of what has transpired, but during another attack may remember the events of the previous one, or, what is still more strange, supposed events, furnishing thus an instance of double consciousness.

Hypnosis is closely allied to suggestion. It is regarded by many as nothing more or less than the intentional production of a hysterical attack, or a hysterical psychosis by suggestion. As Strümpell graphically puts it, "Hypnosis is an artificial hysteria." This view, however, is not held by all. The French school makes four principal forms of the hypnotic state with many transitions:

1. The cataleptic state, in which the limbs retain all the positions artificially given them.

2. The state of suggestion or artificial hallucination, in which patients are induced to eat tasteless and unnatural food with a gusto.

3. The lethargic state: a state of apparent unconsciousness, with the eyes closed, the muscles relaxed, yet with a markedly increased excitability in the muscles and nerves, in which a light tap on a nerve like the facial is sufficient to put all the muscles supplied by it into a tetanic contraction far outlasting the irritation.

4. A state of hysterical somnambulism, in which the patient, while remaining half unconscious, still answers automatically questions put to her, obeying orders or giving them, and sometimes exhibiting certain sensory hyperesthesias. It will be seen that each of these corresponds with one or another of the different manifestations of the hysterical attack.

Hysterogenous Zones.—In this connection some further reference should be made to the so-called hysterogenous zones already alluded to. These are hyperesthetic areas especially studied by Richet, on which persistent pressure will sometimes excite a hysterical attack. While the submammary areas, especially the left, and the inguinal region are favorite hysterogenous zones, the zones may be in any part of the body: as, for example, the sides of the trunk. Pressure in such a zone may cause an existing attack to subside. Hysterical spasm may be localized or limited to groups of muscles.

Diagnosis.—This is not usually difficult. There is something indescribable in the bearing and appearance of a hysterical patient which enables the experienced physician often to recognize the disease at a glance. While, as stated, every phenomenon of any organic nervous disease may be present, yet the essential symptoms of organic lesion are still wanting, and there are symptoms which are peculiar to hysteria alone. The anesthetics are peculiar in their area of distribution, and hysterogenous zones are nowhere else found. The hysterical convulsion is quite *sui generis*, the throat and pharyngeal symptoms are not found elsewhere, and the emotional symptoms

are tell-tale. Cases occasionally occur in which the diagnosis between hysteria and organic disease is very difficult.

Prognosis.—This is very rarely serious, though the course and duration of the disease vary greatly. The milder cases may be of very short duration, while the more serious may last for weeks or years, often, however, with intermissions and changes. Only in very rare instances does a fatal result occur, and reports of death from hysteria demand very critical examination.

Treatment.—A proper prophylactic treatment, so commonly overlooked, would prevent many cases of hysteria. The counteracting of all that is mentioned under the head of predisposition constitutes such treatment. Wholesome discipline or training in youth, the inculcation of self-denial as contrasted with overindulgence and the gratification of fancy, and careful exclusion from the companionship of hysterical persons make up the sum of these.

The successful curative treatment of hysteria also more frequently depends upon the individuality of the physician than on the remedies employed. Indispensable, however, is the removal of the causes which predispose to the disease, whether they be of the nature of moral influences or bodily ailment. Among the most difficult to eliminate of the former are those which arise from the fondness and sympathy of relatives who have, from long habit, become almost slaves to the fancies of the hysterical subject, and with whom, in consequence, firmness has become impossible. It is in consequence of such difficulties that the isolation plan of treatment, which has become inseparably associated with the name of Weir Mitchell, has been so successful. Originated for neurasthenic cases, it is as applicable to the hysterical in whom neurasthenia is likewise often present, while hysteria also often forms a large factor in the neurasthenic state. Whenever possible, the patient must be removed from her previous surroundings, her family, and even her friends. This accomplished, the details of management largely depend upon the peculiarities of the case, but in a general way the Weir Mitchell plan may be said to be as follows :

First, and indispensable, is the care of an intelligent and sensible nurse. Under her charge the patient is put to bed and kept in a condition of absolute rest, even reading being prohibited, and also at first self-feeding. Massage is used daily, at first for short periods, which are gradually lengthened, until an hour is thus consumed. With massage is associated electricity, the faradic current with slow interruptions being usually preferred. Thus, with a small electrode, the motor nerve points can be picked out, and the contraction of individual muscles produced. Massage and electricity both have for their purpose the substitution of exercise, to which end the former is by far the more useful and important. Both are discontinued during menstruation. The food at first is milk, which has been usually skimmed, but in my own experience good milk unskimmed and diluted with one-fourth its bulk of water, or aerated water, answers the purpose better. The proportion of casein is less, and the oil, which is so valuable for the nutrition of the patient, is retained in more nearly its normal quantity. At first from four to six ounces of milk are given every two hours. After a week or ten days a chop or a few raw oysters are added at luncheon, with a cup of coffee or tea, and later at breakfast an egg, bread and butter or biscuit with the milk, the latter being continued at two-hour intervals. The patient should have a thorough sponge bath daily at the hands of the nurse. It is convenient to make out a schedule including the hours for nourishment, massage, and electricity, of

which the last two should be separated by several hours. Massage should be followed by a full hour's rest. Under this forced feeding the patient gradually fattens, and concurrently with this the excitability of the nervous system usually grows less. In a month or six weeks the patient is allowed to sit up, at first for a few minutes only, but each day a little longer, until the whole day is thus spent, interruptedly by periods of rest. Later she is taken out to drive, and then to walk for gradually increasing distance, until, in the vast majority of instances, she is enabled to perform enormous amounts of physical exercise without fatigue. I have known patients bedridden for months and even years, women whose relatives had been worn out with nursing, who, after a few weeks of this treatment, acquired the most vigorous health, walking many miles a day and presenting an appearance of health and strength which would be considered absolutely impossible by one unfamiliar with the results of this mode of treatment. As a rule, three months should be asked for its fulfillment. As has already been said, the individuality of the physician has much to do with the success of the method. One who has a firm, earnest, yet gentle manner will do more with such cases than one who is vacillating and disposed to yield to the caprice of the patient. An element of "suggestion" must perhaps be acknowledged in the power of the physician thus constituted, yet the full application of this principle of treatment by hypnotic suggestion is to be deprecated. The nurse in charge must be similarly constituted, and it not infrequently happens that a nurse otherwise excellent is totally unadapted for the management of a case of this kind.

As to medicines, the number that are useful are few. Iron and arsenic, in very moderate doses, are the only ones which are actually curative. The various nervous sedatives, including valerian, asafetida, the bromids, the milder hypnotics, such as phenacetin, rarely chloral, may be used as occasion requires; morphin should never, or almost never, be given. A convenient form in which to use asafetida is the suppository; 10 grains (0.66 gm.) may be put in a single one.

The paralysis and contractures generally require some time to overcome, and in some cases are persistent in spite of all treatment. Cure is accomplished mainly by manipulation aided by electricity, under the use of which the symptoms gradually disappear and the patient, induced at first to walk for a few steps, will slowly acquire full power of locomotion. Anesthesia is best treated by faradization and the electrical brush. Paralysis of the vocal cords is also best treated by electricity, suitable electrodes having been devised for that purpose.

Allusion should be made to metallotherapy, a treatment instituted by a French physician named Burq, who years ago ascertained that by laying plates of metal upon a cutaneous surface affected by hysterical anesthesia, sensation is sometimes at once restored not only in the immediate region, but also sometimes in a much larger area. The cases so treated were, for the most part, hysterical hemianesthesias. Iron is the metal most frequently efficient, but sometimes copper, zinc, or gold are employed. The process of determining the metal essential to each individual case was called *metalloscopy*, and Burq held that this metal would also have the same effect if given internally. A committee of the Paris Society of Biology tested these statements in 1876 and confirmed them, except as to the internal administration of the metal. A similar discovery was that of Charcot, also substantiated, that the return of sensation to an anesthetic area as the result of applying a

metal plate is accompanied by a simultaneous development of anesthesia upon the opposite side previously normal and in an exactly corresponding place. This is known as transfer. Other hysterical symptoms than anesthesia have been found to exhibit analogous phenomena. Thus, transfer can sometimes be observed in hysterical amblyopia, achromatopsia, deafness, loss of the senses of smell and taste, contractures, and paralysis, while such transfers may be induced by other means than metal plates, known as esthesiogenous remedies. They include large magnets, feeble galvanic currents, static electricity, vibrating tuning-forks, and sinapisms. It must be plain to any thinking person that these phenomena are merely the result of suggestion produced by ideas similar to those already described. Their career will doubtless end like that of Perkins' tractors. Hypnotism has also been employed of late for the treatment of hysteria, and has acquired some popularity in France, where it has been especially practiced by the school at Nancy. Wonderful cures have doubtless thus been accomplished, but based as it is upon mysticism and imagery, and being already much abused by charlatans, it is to be hoped that its fate will be that of metallotherapy and Perkins' tractors.

NEURASTHENIA.

SYNONYMS.—*Nervous Exhaustion; Nervous Weakness; Encephalasthenia; the American Disease.*

Definition.—A term originally suggested by George M. Beard, in 1879, for a complexus of symptoms without anatomical basis, in which muscular weakness, nervous irritability, and pain are variously manifested. Beard defined nervousness as "Deficiency of nerve force, manifested chiefly by undue sensitiveness to external impressions," and neurasthenia as "A sign and type of functional nervous disease" evolved out of this general nervous sensitiveness. The line of demarcation between neurasthenia and hysteria is not always definite. Not only do the two conditions sometimes merge, but certain cases of neurasthenia are in no way distinguishable from the minor forms of hysteria. The condition is called *spinal, cerebral, cardiac, or gastric*, according as the symptoms dependent on one or the other of these systems predominate, but the line of demarcation is not sharp.

Etiology.—The same class of persons who are predisposed to hysteria are predisposed to neurasthenia, and such predisposition may be inherited or acquired. So, too, many of the exciting causes of the former become the exciting causes of the latter. Among these are overstrain of mind and body, overwork, especially overwork associated with care and anxiety. It is distinctive of neurasthenia as contrasted with hysteria that it is more frequent among men, on whom business care and financial worry fall more severely. It is well known that men differ greatly in their power to bear the mental strain incident to the struggle for existence or business success. From the special prevalence of this disease in America it has been called "the American disease," and is reasonably ascribable to the fact that mental and physical strength in this country is more taxed than in any other.

Morbid Anatomy.—Although Beard took great pains to prove that neurasthenia is a physical and not a mental state, and that these phenomena do not come from emotional causes or excitability, but from nervous debility

and irritability, there has been found no distinctive morbid change associated with its complexus of symptoms any more than with hysteria. It is barely possible that the investigations of C. F. Hodge and others, demonstrating changes in nerve-cells during functional activity, may result in some further knowledge in this direction.

Symptoms.—It has already been said that the symptoms of the minor forms of hysteria are the symptoms of many cases of neurasthenia. The *appearance* of the patient may be that of perfect health; less frequently he looks worn and worried. In the *spinal* form motor phenomena are the most conspicuous. Of this and, indeed, of all forms, the most constant symptom is *muscular weakness*, as a result of which the patient complains of being tired and weary, even too weak at times to keep out of bed. Such weakness may affect the gait, making it uncertain and trembling, and the acts performed by the upper extremities may be similarly embarrassed. There may be *hyperesthesia* and *paresthesia*, and even the special senses may be affected, especially *vision* and *hearing*. The latter is more frequently oversensitive, and vision may be obscured by the presence of scotomata or muscæ volitantes. In the *cerebral* form especially characteristic is a low-spiritedness or *despondency*, often painful to witness, and which may alternate with *irritability* or *moodiness*. Another symptom is *sleeplessness*, though many patients sleep well; indeed, there is occasionally an irresistible disposition to sleep. A disposition to seek *solitude* is characteristic, while at other times the patient fears to be alone. Again, he is *restless*, unsettled, and impelled to move about from place to place, while there is sometimes a pronounced disposition to *suicide*. *Confusion of mind*, and especially a difficulty in dealing with figures, is a very common symptom, sometimes an initial symptom, the simplest arithmetical problems being quite impossible with one so affected.

The *cardiac* form is characterized by *palpitation* and frequent irregular action of the heart and *precordial pain*, which give rise to the belief in the patient's mind that he has cardiac disease, arteriocapillary fibrosis, or "hardening of the blood-vessels," as it is called by the laity. Of vasomotor phenomena there may be *flashes* of heat, *sudden sweats*, even night-sweats, and a relaxed state of the peripheral blood-vessels to an extent which may cause the "*water-hammer*" and even *capillary* pulse, similar to that of aortic regurgitation. *Epigastric pulsation* is often an annoying symptom in women. In the *gastric* form are, especially, *gastric pain*, the distinctive symptom of "nervous dyspepsia," but there are also distention and discomfort after eating, or a constant noisy motion of gases—*borborygmus*. *Polyuria* is a conspicuous symptom. A slight degree of glycosuria and even intermittent albuminuria have been reported. The opposite condition of urine—a dark hue and high specific gravity—is more rarely present. *Hoarseness*, *aphonia*, and very frequent breathing are regarded as symptoms of hysteria.

Diagnosis.—This is generally easy, and is arrived at by the exclusion of the objective symptoms of organic disease and by the etiology, for it will be observed that all of the symptoms which have been narrated are subjective in character. The so-called *spinal irritation* is a condition which resembles neurasthenia, and probably some of the cases so named which are not hysteria are cases of nervous exhaustion. Sensitiveness of the vertebræ is not apt to be present in neurasthenia, whereas it is the most distinctive symptom of spinal irritation.

Prognosis.—Recovery from neurasthenia may be confidently promised to almost every patient who is in a position to meet the indications of a successful treatment, which, unfortunately, are apt to be expensive, though the modern hospital affords to even the poorer classes an asylum where the treatment may be successfully carried out. On the other hand, it is mostly the rich who suffer from neurasthenia, and they are in a position to meet these requirements.

Treatment.—The first essential condition of a successful treatment is *removal of the causes* which are responsible for the illness. To this, in the case of women, and sometimes of men, the most successful adjuvant is the *rest treatment* of Weir Mitchell, the technique of which has been already described under the treatment of hysteria. After this and, in the case of men, often even before this, *removal from the scene* and surroundings which attended the development of the disease is most useful. *Travel* away from home, especially in foreign countries, a sojourn at a sanitarium or health resort, the seaside, the woods, the mountains, for prolonged periods, have always, in my experience, sooner or later been followed by recovery. For the poor, the rest-cure as carried out in hospitals may be substituted for the more expensive methods of home treatment.

The treatment of the *insomnia* of neurasthenia calls for brief special consideration, and what is said here may apply to the treatment of any form of simple insomnia, by which I mean insomnia not the result of pain. Modern therapeutics has added to our resources a number of drugs which are more or less efficient to this end. The best of these, considered from all standpoints, is *sulphonal*. Not less than from ten to fifteen grains (0.66 to 1 gm.) should be given to an adult, while twice as much may be given if needed. I prefer to give this dose and repeat it in an hour if no effect follows. It is bulky, soluble with difficulty in cold water, but readily so in any hot menstruum, and especially suitable is hot milk. It should be given an hour or two before sleep is desired, but associated quietude is necessary to secure its effect. Nearly the same may be said of *trional* in the same doses. It is rather more conveniently administered, and may be placed dry on the tongue and washed down with a mouthful of water. *Paraldehyd* is an excellent remedy, but very disagreeable, and is more prompt in its action than sulphonal or trional, and should be given in dram (4 gm.) doses. *Chloralamid* is also a good hypnotic; its dose is thirty grains (2 gm.). It should be dissolved in some alcoholic menstruum diluted to 1-2 ounce (13.5 c. c.). *Phenacetin* may be used in doses of from fifteen to thirty grains (1 to 2 gm.). *Chloral*, as a simple hypnotic, is better, perhaps, than any of those named, although it has yielded its former high place to those just mentioned because of their harmlessness. It has the further disadvantage of sometimes causing drowsiness the next day, and occasionally it is exciting. From ten to thirty grains (0.66 to 2 gm.) should be given at a dose. It is especially useful when combined with morphin, making a much smaller dose of this drug efficient, but morphin should not be used if it is possible to get along without it. Hydrobromate of *hyoscin* may be used in doses of 1-100 grain (0.00066 gm.) if the drugs named fail. Sometimes it acts like a charm, at other times it produces the opposite effect—exciting the patient. One trial suffices to settle the question.

It is true of all the drugs named that their effect is apt to wear off, and increasing doses must be used. It is, therefore, desirable to obviate the necessity of their use as early as possible, and, if possible, substitute other

measures. Often the patient simply needs a start to put him in the way of sleeping, while sometimes the simple feeling that there is something at hand which he can use if he wishes gives him the needed confidence and he goes to sleep at once. A warm *bath* before retiring, or even at times a cool bath or cool sponging, and again a hot bath, promote sleep. To persons residing in cities sleep is often favored by a sojourn at the seaside, many being able to sleep there when they cannot do so at home. The same is true of the country or the mountains.

It is important, too, in our efforts to secure sleep for our patients to investigate the various functions, derangement of any of which may keep a neurasthenic patient awake. Irregularities of digestion and circulation should receive attention. An undigested meal or a loaded bowel often keeps one awake, while an excited heart, by its ceaseless beating, repels the restful sleep without which life is wretched. Often a light meal or a single glass of wine seems to furnish the brain-cells the right amount of stimulus to enable them—

“To shut the banging doors and windows wide
Of restless sense.”

TRAUMATIC NEUROSES.

SYNONYMS.—“*Railway Brain*”; “*Railway Spine*”; *Traumatic Hysteria*; *Erichsen's Disease*.

Definition.—A neurasthenic or hysterical state, the result of shock from railroad accident or accident of similar alarming character.

Historical.—The condition was first studied by Erichsen in 1868 to 1875, under the designation of “railway spine.” Erichsen regarded it as an inflammation of the spinal meninges. Leyden, in 1875, made important contributions to the literature of the subject in treating of spinal concussion. Spitzka, in a review of “*Spinal Injuries as a Basis of Litigation*,” in 1883, referred the symptoms to the category of spinal irritations. J. J. Putnam and G. L. Walton, in 1883, first pointed out the hysterical nature of the affection, a view which is commonly accepted to-day. H. W. Page, an English railway surgeon, published in 1885 a considerable volume directed against Erichsen's view. There still remain a few, and among them S. V. Clevenger, in a work on “*Spinal Concussion*,” published in 1889, and Gowers in his 1892 edition, who hold that railway spine is something more than a purely mental condition. W. A. Hammond suggested the anemic origin.

Etiology.—Profound nervous shock, however induced, by railroad accidents, shipwreck, boiler explosions, and the like, even when the sufferer himself is not a victim, but is profoundly impressed by it, is capable of producing this nervous state.

Morbid Anatomy.—In the vast majority of cases, anatomical changes are not discoverable; in fact, as most cases recover, there is little opportunity to seek them. In a few, however, morbid alterations have been found in the brain and spinal cord, including *degeneration* of the pyramidal tracts of the cord, demonstrated by Edes in four cases; *multiple sclerotic areas* in the white matter, and *arteriosclerosis* in the vessels of the brain, with scattered areas of degeneration, but the study of concussions in man has not led to very definite results. The effects of concussions of the brain and spinal cord have been studied in animals, and changes in the nerve-cells and nerve-fibers have been found.

Symptoms.—These are not essentially different from those of neuras-

themia from other causes. The most remarkable fact with regard to them is that they do not necessarily immediately follow the accident, and there may be some interval of time between the two events—the accident and its result. In some cases the symptoms appear suddenly, in others they are gradual in their invasion. All the symptoms detailed under neurasthenia may be present, especially spinal tenderness and pain in various parts of the body, principally in the back and head; there may be numbness and tingling in the extremities, increased muscular irritability, and increased knee-jerk. The latter varies from day to day, and may be exhausted by repeated stimulation. Extreme depression of spirits is another symptom. Other patients exhibit active hysterical symptoms, including modifications of sensation and motion, hemianesthesia, anesthesia, paresis, and even paralysis.

In the more severe cases in which there is actual concussion the symptoms suggest organic changes, which are, indeed, actually found at times in the shape of pachymeningitis. Such cases exhibit diminished superficial reflexes, with exaggeration of the deep ones. There may be severe pain, variously distributed. Other symptoms are alterations in the temperature sense and in the muscular sense, both of which may be bilaterally distributed. There may also be modification of the special senses, including those of smell, taste, and vision, with inequality of pupils. There may be monoplegia with or without contracture. Symptoms which imply true organic change are optic atrophy, bladder symptoms, paresis, and exaggerated reflexes. Such cases are sometimes, though rarely, fatal.

Prognosis.—Most cases get well. The effect of litigation is often to delay recovery, while successful litigation does not always relieve the symptoms, and when it does, it is by no means always speedily—months and even years elapsing before the cases recover. A few cases, where there is true organic disease, perish.

Treatment.—Rest, mental and physical, is the first essential condition of recovery. It may be aided by the measures useful in other forms of neurasthenia, such as massage, electricity, and proper feeding. Medicines avail little, except for their moral effect. Narcotics should be avoided.

OTHER FORMS OF FUNCTIONAL PARALYSIS.

ABASIA-ASTASIA.

Definition.—Abasia (α privative; $\beta\alpha\sigma\iota\varsigma$, a step) is a term given by P. Blocq, in 1888, to a difficulty in starting the act of walking from a state of previous rest. Astasia (α privative; $\sigma\tau\alpha\sigma\iota\varsigma$, a standing) is an inability to stand, contrasted with integrity of sensation, muscular strength, and co-ordination of other movements of the legs.

Nature.—The phenomena are thus far inexplicable in the absence of discoverable lesions, and are usually regarded as hysterical. It is a condition occurring in adults, equally frequent in men and women—as determined by Knapp's study of fifty cases, of which half were in either sex.

Symptoms.—These occur in connection with a variety of morbid states, and a large majority of them are doubtless hysterical.

In the "unconscious" variety the patient is without any idea that he

cannot walk or stand, when he suddenly finds that he cannot do either. Another variety of abasia-astasia is the "hypochondriacal," in which the patient acts under "conscious" erroneous impression that he cannot walk or cannot stand. It is sometimes associated in the hypochondriacal paranoiac with paresthesia, and in the neurasthenic with abnormally increased sense of fatigue. A third form is associated with some suddenly acting "shock," as fright, which acts inhibitorily on the motions of the patient. Finally there is the "coercion" variety of abasia-astasia, in which the patient, while in the act of walking or standing, is suddenly seized with the idea that he cannot walk or shall not walk. This differs from the hypochondriacal form in that the patient is conscious of the erroneousness and absurdity of the idea, but is nevertheless coerced by it.

These different forms are not always sharply defined. Suddenness is especially characteristic in the "unconscious" form. In other cases the patient may walk a few steps and then suddenly break down. Sometimes he stands rooted to the ground, as it were. At other times the development is slow, requiring even years to reach its acme. Sometimes it is preceded by trembling or staggering, as associated symptoms, the result of the effort of the patient to stand or move forward.

Closing the eyes usually increases the difficulty. On the other hand, sometimes, with the eyes closed the patient can walk in the normal manner, when it is impossible to do so with the eyes open. The latter is especially true of the hypochondriacal variety. In these cases, too, the natural gait is sometimes restored after attempting an unusual method of walking, as walking backward or with the legs crossed or by leaping or in military step. So, also, abasics can walk on all-fours. The morbid state is also influenced by certain surroundings, as broad open surfaces or long narrow corridors or standing without special support. Th. Ziehen refers to a case in which it came on when the patient walked under a tree, the moving leaves of which produced moving shadows. There is sometimes associated tachycardia; at other times evident hysterical symptoms, such as tender spots, hemianesthesia, and the like. In other cases there is epilepsy, paralysis agitans, or chorea.

Diagnosis.—This is based upon the retention of absolute integrity of sensation, of muscular strength, and of co-ordination of the legs, demonstrable in the recumbent position. From *hysterical paraplegia* it differs in that the power of motion is intact in the recumbent position. From *intermittent lameness* it is distinguished by the fact that in intermittent lameness the inability to walk comes on after the patient has been walking a while, and the power of locomotion is restored after rest. Abasia-astasia has been observed in tumor of the frontal lobe of the brain.

Prognosis.—This is regarded as favorable, though relapses occur.

Treatment.—The evident hysterical nature of the affection, in the majority of cases, suggests the treatment for such cases. The rest-cure, massage, gymnastics, electricity, gradually increasing practice in walking, are measures which are likely to be useful. Th. Ziehen, to whose article in Eulenberg's "Real-Encyclopädie" I am indebted for much of the information in this section, recommends "suggestion without hypnosis," especially in the hypochondriacal and hysterical forms, as a reliable means of rapid cure; and in the cases in which fear or terror is conspicuous, small doses of opium.

FAMILY PERIODICAL PARALYSIS.

Definition.—A rare form of hereditary or family paralysis of the voluntary muscles, usually general, except the face, recurring at intervals of from one or two weeks to three months, and confined principally to children. It is attended with a loss of reflexes and electrical reaction, but no mental or sensory disturbance.

The disease is rare. It was first described by Cavaré in 1853 and by Romberg in 1857. Edward Wyllis Taylor* collected twenty-five cases, including two of his own, up to September, 1898, to which John K. Mitchell† added a twenty-sixth in 1899.

Etiology.—The disease is hereditary and is transmitted through the mother. As many as twelve members of a single family have been affected, though it does not usually affect all the children. Goldflam suggests that the paralysis is due to autointoxication, the poison acting upon the nerve endings in the muscles, while he also found that the urine secreted during the attacks was more toxic than at other times. The view of autointoxication is not accepted by all, and J. J. Putnam has advanced a theory of inhibition. The recent studies of John K. Mitchell on the case referred to, for some time under his observation, tend to confirm Goldflam's view, and also to show that there are two poisons, one of which predominates in one case and the other in another, and according as one or the other predominates the effect is greater on the peripheral nerves and muscles or the spinal center. It should not be omitted that some clinicians, including C. L. Dana, consider the majority of cases hysterical, though he says some may be cases of recurring poliomyelitis.

Symptoms.—The disease occurs in *youth* and in the *midst of health, even during sleep*. Beginning as a weakness or weariness in the arms and legs, it is *usually complete in twenty-four hours*. It is rarely confined to the legs, and may also involve the muscles of the neck, and even those of the tongue and pharynx, while those of the head and face remain intact.

Sensation for the most part is *unaffected*, as are also the special senses. The deep reflexes are diminished, sometimes abolished, while the superficial reflexes are feeble. Faradic sensibility of nerves and muscles is greatly lessened, sometimes absent. There is no fever, and sometimes the temperature is below normal, while the pulse is slow. Nothing abnormal has been found in the blood or urine, though the breath is heavy, the tongue is coated, and the urine is relatively diminished during the attack and increased after its termination, as happens in migraine.

The attack recurs at intervals of from one to two or more weeks, in some instances daily. It *begins to abate usually in a few hours or after a day or two*, and ultimately disappears completely, and the patient remains well until another attack sets in.

Treatment.—None is of any service, though some of the earlier cases seem to have yielded to quinin, though it is more than likely that these were in some way complicated with malaria.

* "Journal of Nervous and Mental Diseases," vol. xxv., 1898, p. 637. Dr. Taylor alludes to fifty-three cases, but does not include cases inadequately reported: as, for example, cases merely mentioned by writers, but not reported in detail.

† "Amer. Jour. of the Med. Sci.," December, 1899.

VASOMOTOR AND TROPHIC DERANGEMENTS.

ACUTE ANGIONEUROTIC EDEMA.

SYNONYM.—*Giant Urticaria*.

Definition.—Edematous swelling occurring suddenly in various parts of the body, disappearing in a few hours, perhaps to recur again.

Historical.—Its history has been studied by Quincke and Strübing.

Etiology.—Heredity is sometimes observed, but any other cause is unknown.

Pathology.—The condition is regarded by Quincke as a vasomotor neurosis producing sudden dilatation and increased permeability of the vessels. It is, however, one of the derangements which may be said to be of mixed vasomotor and trophic origin.

Symptoms.—The *face*, especially the eyelids and nose, is the most usual site, but the swelling may affect any part of *the body*, as the hands, face, or genitalia. Even the *mucous membranes* may be invaded, especially the lips, mouth, and pharynx, while a fatal edema of the larynx has occurred. The *onset* is *sudden* and the patient's previous health may have been excellent. *Gastro-intestinal disturbances* are, however, sometimes associated, manifesting by vomiting, colic, diarrhea, and gastralgia. There are also at times *heat, redness, and itching*.

Treatment.—Remedies calculated to increase muscular and nervous tone, such as strychnin, quinin, and iron, are indicated. In other respects the treatment is symptomatic, and directed to whatever symptoms demand attention.

RAYNAUD'S DISEASE.

SYNONYMS.—*Local Asphyxia; Symmetrical Gangrene of the Extremities*.

Definition.—A vasocontractile disease characterized by three stages, more or less complete—viz.:

1. Local syncope.
2. Local asphyxia.
3. Local gangrene.

Historical.—The disease was first described by Maurice Raynaud in 1862. Raynaud's thesis, translated by Barlow, with additional cases and bibliography, is published in volume cxxi., 1888, New Sydenham Society's publications.

Symptoms.—The disease is more frequent in women—Raynaud's cases including twenty women and five men. It is also a disease of early life; the majority of Raynaud's patients were between the ages of eighteen and thirty, while five were between three and nine. The first phenomenon noticed is an unusual *pallor or anemia of the part*, resulting in marble-like whiteness and loss of sensation. This is the *local syncope*. Affecting, as it often does, the fingers and toes, these have been called dead fingers and toes. It follows exposure to cold, and to comparatively slight degrees of cold in those predisposed. The condition may disappear under warmth, and then only does pain manifest itself—when the parts are being thawed out, as the saying is. *Local asphyxia* follows, consisting in *engorgement*,

the parts previously pale becoming purple and livid. The change is not simultaneous in all the fingers, some being still white while the others are livid.

The local asphyxia may succeed the local syncope, or it may come on independently of it. The tip of the nose and helices of the ears are the parts prone to cyanosis, but in addition to the fingers and toes the hands, feet, and arms and legs may be involved. A peculiar and striking mottling is the result on these large surfaces, produced by an alternation of various shades of purple with intervening lighter-hued spaces. In the darkest areas the capillary circulation is quite stagnant. There are also *swelling*, resulting *stiffness*, and *pain*, the latter often extreme and associated with an intense itching. But in Raynaud's disease there is perhaps more frequently *anesthesia* than pain. These are the phenomena, too, of chilblains, with which so many suffer in this climate with the approach of cold weather. In Raynaud's disease, as in chilblains, these symptoms may pass away in time under the influence of warmth; in fact, for a long time they occur only during the colder weather. A reaction takes place, and the parts assume a bright, red color in which the circulation is very active, and the anemia produced by pressure is rapidly replaced by an active hyperemia. The attacks may keep recurring for years without further effect, though in extreme cases there may be slight *loss of substance* in the ear-tips and fingers' ends, which in time may become indurated, uneven, and scarred from this cause.

The third stage of *local* or symmetrical *gangrene* is reached in a few cases only. In these the parts affected remain asphyxiated, and the phenomena of dry gangrene make their appearance. The fingers or toes, one or more, become black, dry, and cold, while gangrenous blebs appear in the parts adjacent to the sound tissue, a line of demarcation occurs, and the dead part sloughs away less extensively than at first seemed likely to be the case. Rarely, and only in cases of young children, does a fatal termination occur.

The symptoms that have been described may be said to be essential, but others also may be added of great clinical interest. One of these is *hemoglobinuria*, which is, of course, associated with a corresponding albuminuria. There are, at times, a few blood discs in the urine. Hemoglobinuria, when present, generally occurs at the same time with the cyanosis, and the attack has frequently been preceded by a chill. Other associate symptoms, less common, are scleroderma and edema, probably angioneurotic.

At other times *cerebral symptoms*, including torpor and partial loss of consciousness, are present; at others, epilepsy, mania, delusions, and even temporary hemiplegia. Dimness of vision is a symptom easily explained if we suppose there is a spasm of blood-vessels producing local retinal syncope. Other associated symptoms are peripheral neuritis with tingling and formication—neuritis being regarded as one of the causes of the disease; arthritic swelling; urticaria; erythema; also colicky pains, nausea, vomiting, and diarrhea.

Pathology.—Three chief theories have been brought forward to explain Raynaud's disease:

1. That it is due to endarteritis obliterans.
2. That it is caused by peripheral neuritis.
3. That it is the result of vascular spasm.

The intermittent nature of the disease is quite incompatible with its causation by endarteritis, which is progressively increasing in its effects. It is true that some of the results of peripheral neuritis are similar to those of Raynaud's disease, but the frequency of the former affection as contrasted with the rarity of the latter militates, also, against this view.

The theory of arteriole spasm, suggested by Raynaud himself, best explains the symptoms. Its frequency among women and children, whose vasomotor system is so impressible; its occurrence under the influence of cold, which is one of the most powerful excitors of vasomotor spasm; the frequent dimness of vision, which has been shown by ophthalmoscopic examination to be associated with contraction of the central artery of the retina; the occasional precedence of a chill; and the phenomena of hemoglobinuria, all go to show the probability of vasomotor spasm. Since the hemoglobinuria is apt to be associated with hemoglobinemia,—which probably arises from the solution of hemoglobin liberated in the asphyxiated parts,—such an origin for the hemoglobinuria must be admitted. It will be noticed that the conditions in Raynaud's disease are in some respects similar to those of intermittently hemoglobinuria, and such similarity affords a basis which may ultimately help to explain more satisfactorily the phenomena of both. The relation of Raynaud's disease to chilblains also affords an interesting field of investigation—in fact, has already been studied by Legroux.

Prognosis.—This is not altogether unfavorable. Only delicate and feeble children, as a rule, perish, while it is quite possible, under favorable circumstances, to outgrow the tendency.

Treatment.—Persons subject to local syncope and local asphyxia should be protected from cold, and when the attack comes on, they should be kept warm, if necessary in bed, the parts being wrapped in wool and subjected to artificial heat. Friction may with advantage be associated. Galvanism and faradism are recommended.

B. B. Cates, of Knoxville, Tenn., has reported the successful treatment of Raynaud's disease by nitroglycerin in doses of 1-100 grain (0.00065 gm.) increased to 1-50 grain (0.0013 gm.) three times a day, and Harvey Cushing has recently reported a case with recovery by the application of the tourniquet or rubber bandage to the affected limbs for a few minutes daily.

PROGRESSIVE FACIAL HEMIATROPHY.

SYNONYM.—*Unilateral Progressive Facial Atrophy.*

Definition.—A gradual progressive wasting of the bony, muscular, integumental, and adipose tissues of half the face.

Etiology.—That it is a trophic neurosis can scarcely be doubted. In one case—that of Mendel's—which came to autopsy there was the terminal stage of a neuritis in all the branches of the trifacial. In Homen's case, an acute one, and perhaps not strictly to be regarded as an instance of true facial hemiatrophy, a tumor was found pressing on the Gasserian ganglion and trigeminal nerve. It has been observed in syringomyelia.

The disease usually begins in youth, but in a few cases it did not make its appearance until middle age. It is rather more common in the female sex. Sachs has collected ninety-seven cases.

Symptoms.—The atrophy is much more frequent on the left side

than on the right. It may begin as a circumscribed spot on the cheek or chin, or diffusely, involving first the subcutaneous tissues, the muscles, chiefly those of mastication, and finally the bones, especially of the upper jaw. In the cases which begin in early youth the muscles remain intact. The tissues of the orbit take part in the atrophy, and the eye appears sunken. The corresponding halves of the tongue and of the soft palate are sometimes involved. The hair on the same side may fall out and appears thin. The line of demarcation is sharp in the median line. In a few rare

Fig. 133.—Left Facial Hemiatrophy—(Strümpell).

instances the disease is bilateral, and in a few cases also the atrophy involves the corresponding shoulder and arm. Sensibility is intact.

Diagnosis.—The disease, though very rare, can scarcely be confounded with anything else. The facial asymmetry associated with *congenital wry-neck* alone resembles it. Strümpell mentions a case of facial *hemihypertrophy* in a boy of ten under his observation. Hypertrophy of one side or of one limb is also a rare condition.

Treatment.—A suitable treatment is the application of electricity to the atrophic side, alternated with massage.

ACROMEGALY.

Definition.—A disease characterized by enlargement of the bones, especially the bones of the hands, feet, and face.

Historical.—It was first described by Marie, of Paris, in "Revue de Médecine," 1886. It had, however, been previously described under other names, as "hyperostosis of the entire skeleton" by Friedreich, as general hypertrophy, or "makrosomie," by Lombroso, as "giant growth," by Fritsche and Klebs. Since then numerous cases have been reported, and the disease was exhaustively described by Arnold, of Heidelberg, in Ziegler's "Beiträge," in 1891.

Etiology.—It is a disease of early adult life, usually occurring under thirty, and is, perhaps, slightly more frequent in women. Heredity, syphilis,

and the specific fevers have preceded the disease, but no necessary relation has been shown.

Morbid Anatomy and Pathology.—This consists in a true hypertrophic enlargement of the bones, except the superior maxillary, which contributes to the enlargement of the face by a dilatation of the antrum, while the lower jaw is simply enlarged. As stated, the enlargement is uniform and symmetrical instead of involving only the shaft as in osteitis deformans, or the ends as in arthritis deformans, and is quite independent of rheumatism. Hyperplasia of the pituitary body has been a striking feature in most cases which have come to necropsy, in every one of thirty-four collected by Furnival. Marie early sought to make these changes responsible, as disease of the thyroid is for myxedema. Persistence and enlargement of the thymus gland have been found, and atrophy as well as enlargement of the thyroid.

A further study of acromegaly in connection with "giantism," "dwarfism," and "cretinism," go to show that it is at least not improbable that all of these are the result of some deranged function of the pituitary gland. It is well known that giantism may degenerate into acromegaly, while a comparison between the skeletons of a dwarf and a macrocephalus suggests that they are opposite extremes of one and the same process. Of further interest in this connection is the embryonic relation between the pharyngeal tonsil—adenoids in the vault of the pharynx, and the extraordinary influence they have on nutrition—and the pituitary body, which are at one period of development in connection and subsequently separated by ossifications at the base of the skull; while not infrequently in early life they remain connected by a fibrous cord running through the body at the sphenoid.

Symptoms.—The most striking features are the *enlarged bones*, especially those of the hands and feet, the appearance of the former being well characterized as spade-like, while the fingers and nails are broad. The *legs* and *arms*, on the other hand, are not elongated early, but late in the disease the forearms and legs may increase in circumference; while the *ends* of long bones, like the femurs, are often prominent. The scapulæ, clavicles, sternum, and the ends of the ribs are also sometimes involved. The proper use of the hands is not interfered with. The *head* and face are *enlarged*, the latter is elongated, while the neck appears short, and the inferior maxilla may project beyond the upper, and the lower lip protrude in consequence. The *ears* are unduly prominent, while the *cartilages* of the nose, eyelids, and larynx are enlarged and thickened, as is also sometimes the tongue. The *spinal column* may be involved, and there may be kyphosis. The *muscles*, on the other hand, are sometimes atrophied, and the genitalia are unusually developed. The skin, though coarse and exhibiting a tendency to perspire, is not thickened as in myxedema.

Among other symptoms are *mental dullness*, a sense of fatigue, and quite severe pain in the head and extremities; *alteration of voice* due to changes in the tongue and larynx, and possibly to paresis of the vocal cords; impairment of special *senses* of taste, smell, and hearing; blindness due to optic atrophy; thirst, shortness of breath, *asthmatic* attacks, *palpitation*, and even *hypertrophy of the heart*. In a number of cases bitemporal hemianopsia has been observed and was due to pressure on the chiasm by the enlarged pituitary body. There are *menstrual derangement* and early cessation of the menses in women. The alterations in the *thyroid* have been

alluded to, and an area of dullness over the manubrium is ascribed by Erb to persistence of the *thymus*.

Diagnosis.—This is easy. The difference between acromegaly and *osteitis deformans* and *arthritis deformans* has been mentioned. In *osteitis deformans*, too, as pointed out by Marie, the face is triangular, with the base upward, while in acromegaly it is ovoid, with the large end downward. Acromegaly has been mistaken for congenital progressive hypertrophy or "giant growth," but in the latter only one limb is usually involved and the shaft of the bone is affected.

Prognosis.—The duration of the disease is long and usually ultimately fatal, although it is sometimes arrested. The fatal cases are probably those with tumor of the pituitary body.

Treatment.—None has been found to be of any value. Naturally, one thinks of the possible utility of extract of the pituitary gland, though if the condition be the result of excessive pituitary secretion, but little can be expected from such use. In fact, such has been the result in the few cases in which it has been tried.

SCLERODERMA.

SYNONYMS.—*Cutis tensa chronica*; *Sclerema*; *Dermatosclerosis*; *Glossy Skin*.

Definition.—A chronic, somewhat diffuse, indurated, hide-bound, and pigmented condition of the skin, trophoneurotic in origin.

Historical.—The disease was first described by Alibert, in 1817. A recent publication on the subject is "Die Sklerodermie," by Lewin and Heller, 1895, in which 508 cases were collected.

Etiology.—This is obscure. It is more common in women than in men, and is most frequent in early adult and middle age. In one case under my observation, that of a hack-driver, long exposure to wet and cold seemed a likely cause, and others report similar experience. Rheumatism, especially of the joints, and strong impressions on the nervous system have been regarded as causes.

Pathology.—The identity of scleroderma and morphea is claimed by some. I follow Louis A. Duhring in separating them, because both are capable of assuming a variety of forms which present entirely different clinical features at various stages. Scleroderma is much rarer than morphea. In the matured forms, while the epidermis is unaltered, there is increase of pigment in the lower layers of the rete, with a distinct overgrowth of connective tissue in the corium and subcutaneous connective tissue. Contrary to what would be expected, the sweat and sebaceous glands appear to be normal.

Symptoms.—The disease appears first in the neck, shoulders, back, chest, arms, and face. It begins usually as a stiffening of the *skin* which passes over into a *hard, tense, unyielding tissue*, resisting motion, and causing fixation and flexion. The patient is literally "*hide-bound*." The hand, with its smooth, glossy surface, utterly without wrinkles, is striking and distinctive. The change may involve the greater part of the body and even the whole of it. When less general, it is symmetrical. The condition passes insensibly into that of the surrounding healthy tissue. *Pigmentation* is usually a later symptom, but may be an early one.

There is generally *no constitutional disturbance* or other local symptoms, such as pain, burning, and tingling, but more rarely these are present. The evolution of the condition is generally slow, requiring weeks and months, and when completed, it is apt to remain unchanged for months or years, or slowly passes away, leaving the skin normal. Rarely, however, an atrophic state may succeed, producing such a shrinking or contraction that the integument is apparently bound to the bones, while over the joints the skin may become so fixed and immobile that ulcers and excoriations are easily produced.

Diagnosis.—The diagnosis rarely furnishes difficulty. In some stages it resembles morphea, from which it will be distinguished when that subject is considered.

Prognosis.—This should always be guarded, as the disease is often intractable, though recovery sometimes occurs.

Treatment.—Treatment of a curative kind is unknown. The patient should be thoroughly protected against cold, as he is exceedingly sensitive. Friction with oil is a rational means for softening the skin, and may give comfort, but do not check the spread of the disease. Cod-liver oil, iron, and arsenic are indicated. The constant electrical current has been recommended in the local forms.

MORPHEA.

SYNONYM.—*Keloid of Addison.*

Definition.—A trophic, asymmetrical neurosis of the skin, characterized by patches of skin firm in texture, white, pale pink, light yellow, or waxy hued, sometimes elevated, at other times depressed.

Etiology.—More common than scleroderma, it is also found more often in women, and at all ages. Its etiology is unknown, but its tropho-neurotic origin is more than likely.

Symptoms.—The *patches* occur more frequently about the breasts and neck and sometimes in the course of nerves, such as the intercostal or lumbar, or on the face along the branches of the fifth pair. They range from 2-5 inch (1 centimeter) to four inches (10 centimeters) in diameter. There may be a *preliminary hyperemia* with itching of the skin and increased pigment deposit, or a milk-white *leukodermia from the beginning*. *The spots are dry*, without perspiration, sometimes scaly. Ultimately there may be *anesthesia*, in pinkish or purplish hyperemic spots or in small linear cicatricial-like areas, which grow rapidly. In fact, the *rapidity of spread* of the spots is one of the most interesting clinical features. In the later stages there are often distinct *atrophy* and *cicatrization* with *pigmentation*. The spots may persist for months or disappear in a few weeks, and though more frequently persistent for a long time, they ultimately disappear spontaneously. The spots seem to be the *direct result of a cutting off of the circulation by a narrowing of the blood-vessels*. This may be by compression by an inflammatory exudate, but is more likely to be a vasomotor constriction, probably due to irritation of the vasoconstrictor nerves.

Histologically there is a condensation of the connective tissue of the corium with a shrinkage of the papillary layer.

Diagnosis.—Morphea differs from scleroderma in that its lesions are more circumscribed, and in an absence of sclerodermic hardness. Pigmenta-

tion and cicatrization usually appear only in the later stages of morphea, while they are seen in the early stages of scleroderma before there is change in structure. Scleroderma is symmetrical in distribution; morphea is not. The atrophic striæ seen in one form of morphea closely resemble the lineæ albicantes of pregnancy or other cause of distention.

Treatment.—That recommended in scleroderma may be expected to be useful in morphea, especially arsenic, which is recommended by Louis A. Duhring. Here, too, the constant galvanic current is held to be of service, an extended trial being, however, necessary.

AINHUM.

SYNONYMS.—*Ainham*; *Qungila*; *Suhka Pakla*, or *Dry Suppuration*; *Pityriasis æthiopiæ*; *Scleroderma annulare*.

Definition.—A trophic disease, resulting ultimately in the amputation of one or more toes, especially the little toe, confined almost exclusively to male negroes.

Historical.—It was first described in 1866 by da Silva Lima, of Brazil, to which country it was at first thought to be limited, but since then cases have been reported from almost every quarter of the tropical and semitropical globe, including the extreme southern United States.

Etiology.—It would seem that a moist, sandy soil and warm climate must have some influence in its etiology, but nothing definite is known. Its practical limitation to the colored race has been referred to. The operation of a pathogenic organism has been suggested, and the disease as an amputating leprosy. Traumatism has undoubtedly been associated with it.

Symptoms.—Ainhum begins as a furrow or crack at the digitopltantar fold, seen first on the inner side. In a few days the toe will swell and become the seat of a burning, shooting pain, which may extend into the foot and leg, though pain is not constant. The furrow increases laterally and in depth until finally the toe is constricted and the distal end becomes ovoid. The swelling subsiding, spontaneous amputation ultimately takes place, a dry scab forms at the furrow, and the case ends. It is not always confined to one toe, though it is as a rule. Sensation is not usually destroyed, though it may be, and the nail remains unchanged. There are no constitutional symptoms.

The histology of the process has been studied by C. H. Eyles, who concludes that there is an ingrowth of epithelium with corresponding depression of surface, due to a hyperplasia that strangles the papillæ and cuts off the nourishment of the epithelium and causes it to undergo horny change. The bone changes are those of a rarefying osteitis, proceeding from the periosteum inward. According to Collas, it is an amputating leprosy.

The **diagnosis** is easy. There is no disease which resembles it.

The **prognosis** is favorable as to any danger to life. The duration of the disease is from two to four years.

Treatment is unnecessary.

SYPHILIS OF THE NERVOUS SYSTEM.

SYNONYM.—*Syphilis of the Brain and Spinal Cord.*

Definition.—A term applied to the condition and symptoms resulting from invasion of the nervous system by syphilitic disease.

Etiology.—Any one of the various lesions which arise in the tertiary stage of acquired syphilis or are the result of inherited syphilis may invade the nervous system. More frequently they are the result of acquired syphilis, but a gummy tumor may develop in the brain of the fetus *in utero*. The phenomena of syphilis of the nervous system present themselves usually a year or more after the primary infection. Exceptionally only do they present themselves before the end of the first year, but may appear a few months after the infection. Occasionally from ten to thirty years may elapse after the infection before symptoms of syphilis of the nervous system appear.

Age and sex have a bearing only as they influence the distribution of the disease. The same conditions which predispose to the development of other brain affections predispose also to the implantation of the syphilitic poison. Such is the inherited nervous disposition, or vulnerability acquired in any way, say through traumatic or septic agencies. Such predisposition favors the earlier operation of the syphilitic poison as well as of other causes of nervous disease. For evident reasons also nervous syphilis is more frequent in the male than in the female sex.

Morbid Anatomy.—As stated, any of the tertiary syphilitic lesions may be the cause of nervous syphilis. While the fundamental process in each instance is the same, it may be quite definitely subdivided into two—

1. Extravascular syphilitic new formations.
 2. Syphilitic disease of the blood-vessels.
- I. Extravascular syphilitic new formations include—
- (a) Specialized new formations, the syphiloma or gumma.
 - (b) Simple inflammatory products.

(a) The *syphilitic gumma*, or syphiloma, is a circumscribed yellow or grayish-yellow mass often caseated in the center. It may occur as a single focus or in multiple foci. Its most frequent seat is in the dura mater or the subarachnoid space, whence it invades the brain substance and adjacent vessels and nerves. More rarely it starts *ab initio* in the substance of the brain, when it sometimes closely resembles the tyroma or solitary tubercle. The tendency to degeneration, which results in the caseation referred to, is the characteristic feature of the gummy tumor, but it is associated with another property of extreme importance, a fibroid change at the periphery, which produces the appearance of a capsule about the tumor, although no distinct capsule exists. Such fibroid change may also interpenetrate the tumor itself.

(b) Of even greater clinical importance is the *simple inflammatory luetic neoplasm*, which starts in the meninges,—*meningitis gummatosa*,—most frequently at the base of the brain, especially in the neighborhood of the optic chiasm, but also in the fissure of Sylvius and on the convexity. In these more diffuse areas one often finds, alongside of each other, the different stages of young granulation tissue, cheesy foci, and contracting con-

nective or scar tissue. Either of the two membranes, the dura mater or pia mater, may be involved.

2. *Syphilitic disease of the blood-vessels* includes *intravascular syphilitic growth*.

Starting from the endothelial cells of the intima, it produces a firm connective tissue which differs from atheroma in being thicker and more translucent, but which, after internal administration of iodid of potassium, becomes thinner and more opaque, in fact, more like the simple atheroma, for which it is, then, often mistaken. Thickening of the adventitia is also sometimes superadded. It is to be remembered that this intravascular and perivascular formation presents no distinctive histological features, any more than does syphilitic meningitis. The vessels affected are those of the base of the brain, especially the middle cerebral artery and its branches.

The possible results of such intravascular growth are *occlusion*, with resulting necrotic softening or induration of the cortex, especially in children; or *intracranial aneurysms* of the larger arteries. Of these, Gowers says: "We know two other causes of such intracranial aneurysms: one, very rare, is traumatic arteritis. The other is embolism 'imperfectly occluding the vessels,' probably the cause of two-thirds of such aneurysms before the degenerative period of life. In the remainder, in which there is no history of injury and no evidence of embolism, there is a history of syphilis in so many cases as to justify the opinion that most of them are due to this influence. Often the history is imperfect, because the aneurysm has been unsuspected until the final rupture, and syphilis has not been inquired for. When we consider how great is the amount of new growth in the walls of a diseased artery, and how prone are the new elements to change into extensible fibroid tissue, the wonder is that aneurysm is not a more frequent occurrence. Probably the explanation is to be found in the common persistence of the elastic layer, which affords the chief safeguard against permanent dilatation."

A third effect of syphilitic vascular disease is *hemorrhage* within the substance of the brain, and small hemorrhages are not uncommon within the brain and spinal cord.

In the *spinal cord* syphilis frequently produces chronic inflammation of the dura mater—spinal pachymeningitis. Its effect is mainly seen on the spinal and bulbar nerve-roots, although the cord also may be invaded by sclerotic fibrous tissue. The pia mater may be invaded in association with the dura mater, especially in diffuse inflammation, and sometimes is more involved than the dura mater. The most common syphilitic manifestation in the spinal cord, however, is meningo-myelitis. Gummata visible to the naked eye are seldom found in the spinal cord.

The *cranial nerves* may suffer from compression by tumor or chronic meningeal inflammation, or may be invaded by an inflammation involving the sheath and interstitial tissue.

Symptoms.—Of fundamental importance in studying the symptomatology of nervous syphilis is the fact that the symptoms due to syphilitic disease are in no way distinctive. They are essentially the same as those of tumor or meningitis or occlusion of blood-vessels from other cause. This being admitted, it might seem scarcely necessary to make a separate subject of syphilis of the nervous system. It, however, affords opportunity for a somewhat more systematic classification of the lesions and a review of the symptoms caused by them.

These symptoms vary with the seat of the lesion, of which sometimes

quite a close diagnosis can be made. The specific nature of the lesion may be inferred to a degree from the symptoms, but most largely from the history. From the grouping of the symptoms may be inferred the most important of the local processes, as originally suggested by Huebner. They are:

1. *Basal Brain Syphilis or Basal Gummy Meningitis.*—The symptoms are to a certain extent those of a tumor in this section—viz., *general cerebral and focal symptoms*, due to the local effect of the growth.

General symptoms are intense headache, often worse at night, apathy, loss of memory, somnolence, and tendency to stupor, all of which characterize more or less the typical tumor of the brain. Maniacal excitement, ultimate imbecility, and physical weakness may supervene. The *compression or focal symptoms* due to basal syphilis are also the same as those due to tumor. The nerves concerned are especially the optic and oculomotor (third), and to a less degree the trochlear (fourth) and abducent (sixth) of the eyeball. The symptoms include narrowing of the field, hemianopsia, and even total blindness, alterations in the pupil and defects in the movement of the ball and eyelids. In syphilis these effects are irregular and seldom bilateral. There may also be optic neuritis and even choked disc, but the latter is less frequent than in other varieties of brain tumor. Syphilomata always cause a rapid and severe form of optic neuritis, so that chronicity in a neuritis is presumptive evidence against its syphilitic origin. Especially characteristic of syphilis is variation in the severity of the symptoms, due to variation in intracranial pressure the result of contraction of the new formation; and especially characteristic is amelioration, the result of properly timed specific treatment. Other nerves which suffer are the auditory, facial, olfactory, and trigeminal. Gummata on the nerve-trunks furnish no symptoms distinct from those of inflammation.

The course of syphilitic lesions is subacute or subchronic, never acute or chronic. Marked improvement, arrest, and even cure may result from proper treatment. On the other hand, involvement of the blood-vessels by syphilitic disease may lead to hemiplegia, epilepsy, and bulbar symptoms, of which there can only be one termination, and that a fatal one.

2. *Gummy Meningitis and Syphiloma of the Convexity and Neighborhood of the Fissure of Sylvius.*—In this more rare seat of localization the same prodromata may precede the severer symptoms, sometimes for a considerable time. The latter include, first, *general or local epileptiform convulsions*, which are sudden and succeed one another at longer or shorter intervals. They are of great diagnostic value, it being true of them, as originally said by Fournier, that, occurring in subjects over thirty, if not due to uremia or alcoholism, in nine out of ten cases they are caused by syphilis. They are rarely preceded by an aura. Other cortical symptoms are hemiplegic or monoplegic paresis, cortical derangements of speech, such as motor aphasia and the like, and imbecility. These cases are often fatal. The convulsions continue, consciousness becomes deranged, coma supervenes, and death ensues. Even here, however, a judicious treatment is often of great service.

Syphilitic meningitis is more common at the base of the brain than at the convexity, though gummy tumors are more common in the latter situation. In either place the symptoms of the local meningitis are such as indicate a surface lesion, at the base by implication of the cranial nerves, at the

convexity by causing motor phenomena. The signs always point to a superficiality of situations and become thus of value in a topical diagnosis, but they do not indicate that lesions more deeply situated are absent.

3. *Syphilitic Disease of the Walls of the Arteries.*—The characteristic symptoms are those of a sudden focal lesion, and are due to the sudden closure of a vessel by *thrombosis*. The most frequent symptom is hemiplegia. *Convulsions* are exceedingly rare. *Hemianopsia* may sometimes be present, indicating disease in the *posterior cerebral artery*, while lesions may occur in parts of the brain in which there can be no focal symptoms. Disease of the basilar and vertebral arteries, sufficient to cause definite symptoms, is seldom survived. In nineteen cases out of twenty, according to Gowers, the Sylvian artery and its branches are the vessels invaded.

Cerebral embolism causes the same symptoms, but it seldom occurs before forty-five, or the age of tendency to degeneration, unless there is valvular heart disease or endocarditis. In the absence of these, therefore, we can infer syphilis with considerable certainty. Except embolism and injury, sudden hemiplegia occurring between twenty-five and forty-five is very seldom due to any other cause than syphilis. The course of the disease and extent of the paralysis vary as greatly as when caused by embolism. It may be slight and transient, or severe and lasting. All of the symptoms may not occur instantaneously, some hours or days being required to develop them. On the other hand, the phenomena of embolism are more apt to be suddenly complete. In thrombosis one stroke may succeed another at short intervals, and this is rather characteristic of syphilis. So is the fact that *consciousness is seldom totally lost*. Giddiness and vomiting sometimes precede it, more often does severe headache—in fact, in more than half the cases. The headache may be general or chiefly on the side of subsequent lesion. It may precede the threatened lesion by only a few days, or a week, often for several weeks, rarely for two or three months. There may be tingling in the side about to be paralyzed. In severe cases death takes place promptly, ordinarily with high temperature.

4. *Cases of Combined Cerebral and Spinal Syphilis.*—Under these are included cases illustrating any one of the three forms considered, associated with symptoms of a more widespread syphilitic disease. Thus there may be a combination of the cerebral symptoms described, with spinal symptoms, the latter especially often as the result of *meningitis of the cervical cord* producing paraplegia, hemiplegia, or arm paresis alone, and pain in the course of the spinal nerves, or the cerebral symptoms may be associated with those of *tabes dorsalis* or progressive paralysis, and if so, there is scarcely a limit to the complex of nervous symptoms which may thus arise.

Diagnosis.—A gumma of the cortex and glioma in the same region may produce identical symptoms. So, too, the symptoms due to occlusion of an artery by syphilitic disease may be identical with those due to embolism—in fact there are no symptoms or combinations of symptoms that are not produced by other causes. How, then, shall we know the syphilitic origin? Having first made the topical diagnosis, we notice any modification of the usual symptoms of meningitis or brain tumor or arterial occlusion, or such additional symptoms as may be due to syphilis. What are these? We have seen that the very sudden onset of symptoms is not usual in syphilis except from occlusion of a blood-vessel. At least a week is usually necessary for their development. On the other hand, they are very seldom chronic. We

have seen that there is great variation in the severity of the symptoms. We have seen that convulsions occurring after thirty not due to uremia or alcohol are in nine cases out of ten due to syphilis; that localized spasms, unilateral or more limited, ocular palsies, morbid somnolence, point to syphilis; that hemiplegia in persons under forty-five years and not due to cardiac embolism is likely to be due to syphilis. Persistent headache, worse at night, either alone or associated or preceding the palsy, is characteristic of syphilis. Of value in diagnosis is the therapeutic test,—the effect of treatment,—but it must be remembered that lesions not syphilitic—glioma, for example—may be improved by antisymphilitic treatment. The symptoms are usually relieved by specific treatment. Above all, though not conclusive, is the knowledge of the presence of syphilis learned from the anamnesis, from ocular discovery of lesions, from miscarriages in women, and the presence of syphilids. Multiple sarcomatosis of the brain and spinal cord may cause symptoms almost exactly like those of syphilis, but fortunately the former is a very rare condition.

Prognosis.—Much benefit may be obtained by a timely and appropriate treatment of syphilis of the nervous system, though some cases do not respond to treatment. It is to be remembered, when there is actual destruction of nervous tissue, as in old cases of syphilis of the nervous system or in forms of degenerative disease due to syphilis, no medicines can be of much benefit. It is only the syphilitic lesion itself which is amenable to treatment, and with its removal comes relief to the pressure and irritation which cause so many of the symptoms of nervous syphilis.

Treatment.—It is evident from what has been said that treatment, to be efficient, must be prompt and early; whence the importance of an early diagnosis. Mercury and the iodid of potassium are almost the sole drugs needed, and at first they should be united. The most effectual way to bring about the mercurial effect is by inunction, although some prefer the hypodermic use of bichlorid of mercury. The method of inunction, using from thirty to ninety grains (2 to 6 gm.) daily, and beginning with the axilla, has been described on page 208. Simultaneously the iodid of potassium should be administered, beginning with ten grains (0.66 gm.) three times a day, rapidly increasing until some effect is produced. As soon as this effect is noticed the dose may be held at a sufficient amount, usually a dram (4 gm.) a day. It is well known that very large doses of iodid of potassium are borne in syphilis without producing iodism.

The mercurial inunction should be kept up for a couple of weeks after the symptoms have commenced to yield, or it may be substituted by the bichlorid of mercury in 1-12 grain (0.0055 gm.) doses three times a day, which may be further reduced and finally omitted. The iodid of potassium should, however, be kept up for an indefinite time in such doses as are well borne. Such remedies should be given as are indicated to relieve special symptoms, as phenacetin, antipyrin, and opium to relieve pain. A prompt bleeding is undoubtedly of service at times in apoplectic cases, and is harmless in any case. It should, therefore, be used tentatively in all cases in which it is not contra-indicated by debility, the quantity of blood drawn being regulated by the effect on the symptoms and on the pulse.

Should it happen that the symptoms are totally relieved by treatment, what should be our course thereafter? Certainly not to allow the patient to believe he is permanently cured. For almost inevitably the symptoms will return if such a course is pursued. Doubtless the advice given by

Gowers in his admirable Lettsomian lecture is good, that every syphilitic subject, for at least five years after the date of his last symptoms, should have a three weeks' course of treatment twice every year, taking for the time twenty to thirty grains of iodid of potassium a day. But it is questionable whether the period should be limited to five years. Better is it to continue the intermittent treatment for the remainder of his days. Especially likely are the symptoms to return in the second half century, when the natural tendency to tissue degeneration sets in.

SECTION X.

DISEASES OF THE MUSCULAR SYSTEM.

MYOSITIS.

RHEUMATIC MYOSITIS, ACUTE AND CHRONIC.

These have been treated in connection with the subject of rheumatism.

INFECTIOUS MYOSITIS.

Definition.—A rare form of acute or subacute inflammation of striated muscle, due to unknown infectious agencies.

Morbid Anatomy.—Several cases have come to necropsy. The conditions found have been firmness, fragility, and fatty degeneration of the muscle substance, with serous infiltration and hyperplasia of the interfascicular connective tissues. In another case there was hyaline degeneration in varying degree without involvement of the intermuscular tissue.

Symptoms.—The parts usually involved are the extremities, but the disease may also invade the trunk-muscles and heart. There is swelling with slight edema, hardness, and stiffness, making motion painful and difficult. Instead of pain there is rarely paresthesia. The symptoms resemble those of trichiniasis, insomuch that it has been called pseudo-trichiniasis. In addition to the symptoms named an erythematous rash, irregularly scattered over the trunk and extremities, is regarded by Löwenfeld as characteristic. It is sometimes followed by slight pigmentation. There sometimes succeeds an atrophy of groups of affected muscles, and Wagner suggested that some of the cases may be examples of acute progressive muscular atrophy. Such cases are hardly fair examples of infectious myositis. The duration of the disease is from three months to three years.

Another form of infectious myositis is acute purulent myositis, sometimes associated with pyemia.

PROGRESSIVE OSSIFYING MYOSITIS.

This is a rare form of myositis, in which the muscles undergo progressive calcification, localized or extending over widespread areas. The disease is more common in males, and usually begins about puberty. It occupies many years in development, and consists in a preliminary inflammatory process, followed by more or less extensive deposits of bony plates throughout the muscular system, and at times in ossification of entire muscles, with fixation of joints and vertebræ.

Treatment.—No treatment has availed in any of these forms of acute inflammation.

IDIOPATHIC MUSCULAR ATROPHIES—PRIMARY MYOPATHIC FORMS OF MUSCULAR ATROPHY.

In addition to the spinal or myelopathic forms of muscular atrophy described under nervous diseases, there are several varieties of muscular wasting which apparently reside in the muscles themselves, and which are therefore strictly idiopathic. These forms occur in the young, and follow decidedly upon hereditary disposition. They are all probably the result of a congenital tendency to defective development.

There are several clinical types of primary muscular atrophy, of which the principal are:

1. Pseudo-hypertrophy.
2. Erb's form, or the juvenile, or the scapulo-humeral form.
3. The facio-scapulo-humeral type of Landouzy and Dejerine.

These are all forms of one disease, called by Erb progressive muscular dystrophy.

I. PSEUDOHYPERTROPHY OF MUSCLES.

SYNONYMS.—*Pseudohypertrophic Muscular Paralysis*; *Lipomatosis luxurians muscularis* (Heller); *Atrophia musculorum lipomatosa* (Seidel).

Definition.—A state of muscular paresis associated with an atrophy of the muscles involved—an atrophy obscured by interstitial fatty overgrowth.

Etiology.—This is especially an affection of childhood, and heredity is an important causal factor, many members of the same family being sometimes affected through several generations. Boys are more frequent subjects than girls, though the disease is more apt to be transmitted through the mother, even though she may not herself be a subject. Heredity is not invariable. The disease usually begins before puberty, though sometimes as late as the twentieth or twenty-fifth year or later. Hysteria, epilepsy, feeble-mindedness, with an occasional anomaly of the skull, have been observed in the same families.

Morbid Anatomy.—The nervous system is not involved except in rare cases. Minutely examined, the muscles exhibit marked differences in the size of the muscular fasciculi, some being wider, many narrower than normal, while there is considerable increase in the adipose and connective tissue between the fasciculi. The fibrillæ themselves are not fatty.

Symptoms.—The disease begins gradually with paretic symptoms, without the hypertrophic appearances which are later so pronounced. A child previously healthy exhibits clumsiness in its movements and insecurity on its legs, being especially awkward in jumping and running upstairs. Then close examination discovers that certain muscles or groups of muscles are enlarged, the calves of the legs being especially conspicuous. The extensors of the leg, the glutei, the lumbar muscles, the deltoid, triceps, and infraspinales next become enlarged, while the hands, arms, and neck are rarely involved, in strong contrast to the spinal atrophies. *Walking* becomes more and more *difficult*, until finally a diagnosis may be made from the gait alone, which becomes waddling, while the shoulders are thrown back, the belly is thrown forward, the vertebral column being also arched

forward in the lumbar region. The buttocks stand out, and the legs are far apart. In walking the legs are raised slowly, the toes dropping from paresis of the dorsal flexors. Especially characteristic is the child's method of rising from the floor. He first gets on all-fours, and raises his trunk by moving the arms along the floor. The arms are then drawn toward the legs until the knees can be reached, when, with one hand on the knee, he pushes himself up, then grasps the other knee, and completes the act of raising himself to the erect position. Late in the disease the same paretic condition may extend to the upper extremities, making it impossible to rise.

The enlargement of the muscles is due to an interstitial deposit of fat, and as a consequence they are soft and flabby instead of hard and firm, as in true hypertrophy. Thus the hypertrophy is truly a pseudo-hypertrophy, the condition being really one of atrophy of muscular substance. Along with this may be associated a genuine atrophy of other muscles, with loss of substance unassociated with fatty infiltration, especially in the upper extremities. Very rarely there is a true hypertrophy, except of individual muscle-fibers.

Fibrillar twitchings are rarely present. *Electrical excitability* is diminished in proportion to the destruction of muscular tissue, but there is never a reaction of degeneration. *Sensibility* remains normal, and the sphincters are intact. The patellar reflex is sometimes absent. The skin, especially of the legs, sometimes presents a peculiar bluish mottling. As a rule, the *intelligence* of the child is *preserved*, though sometimes there is mental and moral obliquity.

2. ERB'S FORM, OR THE JUVENILE TYPE OF PROGRESSIVE MUSCULAR DYSTROPHY.

This type is also commonly found before the age of twenty, usually between fifteen and twenty, but its subjects are not so young, as a rule, as those of the pseudo-hypertrophic form. It is, like all the forms of muscular dystrophy, hereditary in families of which female members are affected, while the boys may have pseudo-hypertrophic paralysis. It starts rather more frequently in the upper extremities, the upper arms and shoulders, but may begin also in the back and legs. The following are the *muscles involved*, according to Erb: In the upper extremities the pectoralis major, latissimus dorsi, and later the triceps; while there remain normal, at least for some time, the sternomastoid, the levator anguli scapulæ, the coracobrachialis, the teres major and teres minor, the deltoid, the supraspinatus and infraspinatus, and the small muscles of the *hand*, which, it will be remembered, are remarkably wasted in myelopathic atrophy. The muscles of the forearm, except the supinator longus, remain exempt for a long time, if not altogether. In the lower extremities the glutei, the quadriceps, the peronei, and the tibialis anticus are affected, while the sartorius and calf muscles are spared for a long time.

Very characteristic is the marked projection of the scapula, due to paralysis of the serratus. The gait in this form becomes waddling and walking is ultimately impossible, although, like its congeners, the progress of the disease is slow, twenty-three to thirty-eight years being the range of duration of cases described by Erb. Bulbar symptoms are rare, but the diaphragm may atrophy and death be due to respiratory deficiency.

The muscular changes are essentially atrophic, though in the beginning a few of the muscular fibers may be hypertrophied. The interstitial con-

nective tissue is increased, its nuclei proliferated, and there is no interstitial fat. The number of muscle nuclei is also increased, and vacuoles may be seen in the individual fasciculi.

3. THE FACIO-SCAPULO-HUMERAL TYPE OF JUVENILE PALSY.

This is also a family form. Duchenne called attention to the fact that in certain children's palsies the muscles of the face are involved in the atrophy, but the fact was overlooked until Landouzy and Dejerine opened the subject anew, and showed that this event is not infrequent—indeed, may be the first symptom. This atrophy may begin later in life—say the twentieth to thirtieth year. In these cases the eyes can no longer be completely closed, and whistling, laughing, and talking become difficult. An appearance characteristic, even diagnostic, known as the *facies myopathique*, results, to which the half-closed eyes, the sunken cheeks, and the tapir mouth contribute. The muscles of mastication, the internal ocular, and those of the forearm and hand remain normal. Fibrillary contractions are absent, and there is no reaction of degeneration. In other respects it resembles the juvenile form of Erb's palsy, with which it is closely allied. From what has been said it is evident that the three forms just described are modifications of one variety, a view strengthened by the fact that two or more of the types may be present in the same family.

4. THE PERONEAL TYPE OF PROGRESSIVE ATROPHY.

SYNONYM.—*Progressive Neural Muscular Atrophy.*

This form, described by Charcot and Marie, and independently by Tooth, is met in the second half of childhood, seldom after twenty. It occurs also in families, more frequently in males. It begins in the peroneal muscles, involving also the intrinsic muscles of the foot, and may lead to club-foot, of the variety *pes equinus* or *pes equinovarus*. The upper extremities may be affected after many years, and rarely it begins in the hands. It differs from the other forms of juvenile atrophy in the presence of fibrillary contraction and the occasional presence of the reaction of degeneration, while vasomotor and sensory disturbances may also be present.

Degeneration of the peripheral nerves has been found with ascending degeneration of the posterior columns. Both the symptomatology and morbid anatomy of this, so far as known from a limited number of autopsies, go to show that it is really a result of neuritis.

Prognosis and Treatment.—These are also essentially identical with those of progressive muscular atrophy.

MYOTONIA CONGENITA.

SYNONYM.—*Thomsen's Disease.*

Definition.—A hereditary affection, characterized by overdevelopment of muscles and by tonic cramp on attempt at voluntary motion.

Historical.—The disease was described in 1876 by Thomsen, a Schleswig physician, in whose family it had been present for five generations. Since then numerous cases have been described in Scandinavia, Germany, France and Italy. It is rare in this country and in England. In 1889 Hale White made a thorough study of the subject and published his results in "Guy's Hospital Reports" for that year.

Etiology.—The disease is always congenital, the symptoms making their appearance in early childhood and in family groups, more frequently in men. Cases of acquired myotonia have been observed, but these are regarded as somewhat different from Thomsen's disease. A few isolated cases presenting the same symptoms have been described. It is to be regarded as a congenital anomaly of the muscular system.

Morbid Anatomy.—The muscles are characterized, especially in the extremities, by voluminous development in strong contrast to their power. In addition to an obvious macroscopic enlargement there is also found histologically an evident increase in the volume of the muscular fasciculi, recognized by Erb and confirmed by Hale White, together with intermuscular proliferation of the muscle nuclei and moderate increase of the connective tissue itself. The heart is exempt, but the diaphragm may be involved. There is no lesion of the spinal cord. The only necropsy in a case of Thomsen's disease ever observed was reported by Dejerine and Sottas. The muscles were altered, but the nervous system was normal.

Symptoms.—The disease manifests itself at first in childhood by a *stiffness* or "mild tetanus," in which the relaxation which necessarily precedes each muscular act is delayed. Voluntary contraction takes place slowly and with difficulty. The arm and leg muscles are involved, and thus the child's play is interfered with. There is, however, *no paralysis*, and after motion is started, it proceeds with facility. Prompt, rapid, and precise muscular movements are, however, difficult, and military service, for example, becomes impossible. *The condition is aggravated by cold and emotion.*

Sensation and the reflexes are normal. Rarely there is mental weakness. A peculiar reaction of muscle and nerve to *both* currents is developed, called the *myotonic reaction* of Erb. The motor *nerves* show quantitatively a normal faradic and galvanic excitability, and all briefly acting stimuli give short contractions; but with continuous irritation by both currents the contractions attain their maximum slowly and relax slowly, while vermicular wave-like contractions pass from the cathode to the anode. The *muscles* are also faradically easily excited, responding to a fairly strong current always with the above-described prolonged contraction. To galvanic irritation of muscle there is a slight increase of excitability, and to somewhat strong currents the contractions are sluggish, tonic, and continued. They occur only with current closure and not with current opening. The mechanical irritability of the muscles to strokes from the percussion hammer is also increased.

Diagnosis.—If more is needed than the peculiarity of the muscular phenomena, the electrical and mechanical muscular reactions described are characteristic.

Prognosis.—The disease is incurable, but patients become accustomed to the defect and conceal it as much as possible.

Treatment.—Nothing specific is known. Friction and massage, with muscular gymnastics, are rational measures to be recommended.

SECTION XI.

THE INTOXICATIONS.

ALCOHOLISM.

Definition.—The effect on the human economy of the intemperate use of alcohol in some one of the forms in which it is used as a beverage. Such effect is either acute or chronic.

ACUTE ALCOHOLISM.

Definition.—This is the condition known as inebriety or drunkenness. Varying amounts of alcohol are required to produce it, very small quantities sufficing to intoxicate those unaccustomed to its use, while the habitual drinker may consume large quantities without effect.

Symptoms.—The order of symptoms is not always the same. More frequently the primary effect is one of excitement, associated with flushed face, bright eye, and loose tongue. To this succeeds the well-known staggering gait of drunkenness, which increases until its subject is unable to walk and finally falls to the ground. The ready speech, at first coherent, now wanders at random, and finally ceases altogether. The stage of narcosis is reached, and the drunken man breathes stertorously in his sleep, his face being congested and his breath alcoholic. He may, perhaps, be aroused, and may respond vaguely and incoherently to a question, but soon drops off to sleep again.

In another subject the first stage is much more violent, and he may cry out boisterously, and either spontaneously or upon the slightest provocation inflict injury or even commit murder. In other subjects, again, there is no stage of excitement, and they are morose, or pass gradually and directly into stupor. The stage of inco-ordination and ultimate stupor is, however, invariable if the quantity of alcohol drunk is enough to bring it about. The effect is upon the cortical nerve-cells of the brain.

Other less conspicuous features are a lowered temperature,—96° F. (35.6° C.) to 90° F. (32.2° C.), or even lower,—involuntary evacuations of the bowels and bladder, dilated pupils, and muscular twitchings.

Diagnosis.—The diagnosis of drunkenness is usually easy, yet mistakes are not infrequent; it has been mistaken for *apoplexy* or *apoplexy with fracture of the skull*. In the latter case stupor is usually deeper, and the patient cannot be aroused, while the breathing is more stertorous. The subject should always have the benefit of the doubt, and resident physicians in hospitals will often save themselves and the institution they serve much opprobrium if they will remember this. *Uremic coma* developing with convulsions also simulates drunkenness, and, when the existence of Bright's disease is unsuspected, may cause error. In such the odor of alcohol in the breath is wanting, while that of urine is sometimes present, although, of course, a person with nephritis might have an attack of uremic coma after he had been drinking alcohol. In acute alcoholism the pupil is

commonly dilated. In uremia it is variable, being sometimes dilated and sometimes contracted. In all doubtful cases the urine should be drawn by the catheter and tested for albumin. In *opium poisoning*, which may also be confounded with alcoholism, the pupil is contracted.

CHRONIC ALCOHOLISM.

Definition.—This is a condition which supervenes sooner or later in individuals who habitually use alcohol intemperately. *Dipsomania* is a term applied to a condition in which there is an inherited immoderate desire for alcohol at times, followed by periods in which there is no such inclination. Intemperance does not always imply the consumption of the same amount of alcohol, smaller quantities producing harmful effects in some persons while larger amounts are apparently harmless in others. The predisposition in some persons to be easily affected organically by alcohol is due to some as yet uncomprehended constitutional weakness. There is reason to believe that the children of alcoholics are not only more susceptible to the degenerative effects of alcohol, but also to other diseases, such as gout, rheumatism, syphilis, and diseases of the nervous system. Among the latter may be mentioned, especially epilepsy, melancholia, dementia, and insanity.

Morbid Anatomy.—If we include under this the numerous morbid states which are directly or indirectly ascribed to the long-continued use of alcohol, such as cirrhosis of the liver, gastritis, low grades of meningitis, and the arterial changes so frequently ascribed to it, a large amount of space would be consumed. Fortunately, these conditions have already been described as separate entities, and their relation to alcohol as a cause has been discussed.

A few words may, however, be devoted to the consideration of the effect of alcohol on elementary parts, since it is through such effect that its consequences are produced. Some time ago Lionel S. Beale called attention to the destructive effect of alcohol on protoplasm. More recently, in 1894, Obersohn, working in the laboratory of Gaule, in Zürich, demonstrated not only that alcohol, ether, and chloroform destroy cellular protoplasm, but also that the cells which are the most complicated, so far as function is concerned, such as nerve-cells, are the most vulnerable. These conclusions were confirmed by other experimenters, among them Wilkins, in this country, in 1895, and the whole tendency of experiment and observation at the present day is to show the degenerative effect of alcohol on elementary histological units.

Chronic alcoholism, like acute, predisposes to other diseases. Its direct effect, is, as already stated, mainly on the protoplasm of cells, modifying or impairing their normal metabolism, at times destroying cells and substituting them by fibroid material, at others inciting to inflammatory action; at others still simply delaying oxidation, as in the case of the adipose vesicle, whose fat remains unoxidized because its congener, alcohol, is more easily oxidized. In some instances, as in the case of the liver-cells, fat is deposited in new situations because it cannot be sufficiently burnt up. Different kinds of alcoholic beverages also seem to act differently, some, as gin, producing destruction of liver-cells and cirrhosis, while others, as malt liquors, produce fatty livers. It is also true that persons addicted to intermittent debauch are less liable to inflammatory lesions than constant consumers.

As a consequence of irritation of the intima by the alcohol, arise endarteritis, sclerosis, and thickening followed by atheroma and fragility. Irritation of nervous tissues results in different forms of meningitis and cerebritis with degeneration.

Thirty years ago Lancereaux announced that alcoholic excesses are one of the principal causes of tuberculosis, affecting by preference the back of the right lung, while disease of the left in front is the result of insufficient aëration or alimentation; also that such disease is characterized by improvement and general arrest if the patient leaves off his habit, and by recurrence if he relapses. As recently as 1895* this clinician retracted this view, while the observations of Lagneau developed the remarkable fact that tuberculosis only became prevalent in France after the phylloxera had ruined the vines and curtailed the supply of wine. Then tuberculosis, previously only one-half as common in men as women, reversed its election, twice as many men being affected as women.

Kidney Changes.—The effect of alcoholism on the kidney is also two-fold in the direction of contraction and enlargement, the former due to gradual destruction of renal cells and tubules with substitution of interstitial tissue, the latter to fatty infiltration and hypertrophy. I have often expressed the belief that alcohol is a less frequent factor in the production of interstitial nephritis than was formerly supposed, because of the facilities for its elimination in its long journey from the stomach through the liver and lungs before it reaches the kidney. In this I am sustained by W. Howship Dickinson and the enormous experience of the late Henry F. Formad as Coroner's physician in Philadelphia.† The enlarged kidney of alcoholics was also studied by Formad, who called it the "pig-back" kidney, and found it a true hypertrophy rather than a degenerative change.

Symptoms.—These may be classified according to the systems they invade. Thus we have the effects of alcohol on the—

Nervous System.—The most constant of these is the well-known unsteadiness—especially of the hands in the performance of muscular actions. It is also apparent in an attempt to protrude the tongue. Gradual mental deterioration is an inevitable consequence, sooner or later, of chronic alcoholism. It is manifested in sluggishness of intellect, in weakness of resolution, a loss of moral character, in irritability, restlessness, and occasional dementia and insanity. Yet it is surprising how some enormous consumers of alcohol maintain their mental acumen and ability to manage large financial interests, while their vascular and digestive apparatus is evidently the seat of advanced degeneration. When dementia and insanity are present, they are probably due to vascular degeneration and consequent secondary changes in the brain structure. The tendency of such insanity is toward delusions, including suspicion, distrust, fear of impending evil, and, more rarely, delusions of grandeur, as in general paralysis of the insane.

Multiple and simple neuritis is a well-recognized and almost characteristic symptom of chronic alcoholism, and has already been considered.

Pachymeningitis hæmorrhagica is sometimes met. More frequent are slight thickening and turbidity of the pia arachnoid membrane. But this is not peculiar to alcoholism, being the same as that found in the neuroses of insanity.

* "Effets comparés des boissons alcooliques chez les hommes et leur influence prédisposante sur la tuberculose," *France Méd.*, 1895, xliii, *et al.*

† "Heart and Kidney in Bright's Disease," *Trans. of the Assoc. of Amer. Physicians*, vol. iv., 1889. Dr. Formad's experience covered as many as 1172 autopsies in a single year.

Digestive Apparatus.—This is a favorite point of attack in alcoholism. Chronic gastric catarrh is one of its most frequent consequences, producing loss of appetite, nausea, constipation, coated tongue, and foul breath, symptoms which are always worse in the morning, and are temporarily relieved by the dram which the habitual drinker is apt to seek at this time of day. Autopsy in such cases may be negative as to the stomach, or reveal the changes described under chronic gastric catarrh.

Symptoms due to Liver Changes.—From these arise the symptoms due to cirrhosis and contraction, fatty infiltration, and enlargement. The interstitial overgrowth so characteristic of cirrhosis is probably secondary to a primary poisonous and destructive effect of the alcohol on the cells, as confirmed by the experiments of Weigert, and more recently by those of Obersohn and Wilkins, previously referred to. The compression of the cirrhotic liver on the portal vessels produces secondary effects, viz., hyperemia of the stomach, causing gastric catarrh; of the rectum, producing hemorrhoids; and of the esophagus, pharynx, and nasal mucous membrane, resulting in hemorrhage in any one of the localities; in dilatation of the venulæ of the face and nose, and eruptions on the latter, constituting the acne rosacea or “blossom,” by which the toper is so often marked. In many cases, on the other hand, the livers of hard drinkers have been found normal.

From vascular changes result cardiac and renal diseases, and their symptoms, unequal distribution of the blood in the brain, and consequent symptoms, viz., dizziness, thrombosis, apoplexy, softening.

DÉLIRIUM TREMENS, OR MANIA A POTU.

Definition and Symptoms.—This is a special manifestation of chronic alcoholism, ascribed to the long-continued action of alcohol on the brain, though its occurrence coincides rather with the sudden withdrawal of the alcohol. On the other hand, a debauch, however prolonged, by a person previously temperate, is never followed by mania a potu, so that the relation of the illness to the withdrawal of alcohol may be more apparent than real. Purely accidental circumstances may determine the cessation from drinking. It is very frequently an attack of acute illness, especially pneumonia, to which drunkards are especially predisposed. The first symptom is usually sleeplessness associated with intense depression, or there may be intense restlessness, during which the patient, unless restrained, will go out of the house on some imaginary business. To this succeed hallucinations of vision, as the result of which he imagines he is pursued by monsters, serpents, rats, mice, and other vermin. The intense shivering terror of the victim under these circumstances is pitiable, and the “horrors”—a term applied to the disease—is but a feeble expression of the terrors of the patient. Frequently, in his attempts to escape these objects, he is unmanageable, and must be confined. Suicide is not infrequent with such patients. At other times the eager though misguided intelligence displayed in watching the imaginary objects is amusing. Auditory hallucinations may be present, and unusual noises be complained of. At the same time, even though the patient is violent, the pulse will be found frequent, feeble, and often irregular. There is great muscular weakness, as evidenced by the tremor which accompanies all muscular acts. There is slight fever, 102° to 103° F. (38.9° to 39.4° C.), which is increased if there is intercurrent inflammatory disease.

Diagnosis.—This is never difficult. The symptoms certainly resemble those of *meningitis*, and meningitis is also sometimes present, but with the history of the case and the general appearance of the patient a mistake is not likely to be made. It is most important, however, to examine each case thoroughly, as pneumonia is so frequently associated with delirium tremens and constitutes its most serious danger. Again it is said a *pneumonia of the apex* is sometimes accompanied by delirium similar to that of delirium tremens.

Prognosis.—If there is pneumonia, recovery is a rare event, but if delirium is uncomplicated, recovery generally takes place, certainly from the first attack, and generally even after one or more attacks and a duration of from three or four days to a week. If recovery does not take place, the adynamia increases, the pulse grows increasingly feeble, the tongue dry, the delirium becomes muttering, and the patient dies with the usual symptoms of the typhoid state. This event is, of course, more common in hospital practice.

Treatment of Alcoholism.

Acute alcoholism rarely requires any treatment except restraint from the further use of alcohol and opportunity to sleep off the debauch. A full dose of chloral—from fifteen to thirty grains (1 to 2 gm.)—may be necessary when there is extreme excitement. Morphin is indicated, but as alcoholics sometimes have contracted kidney, caution should be exercised in its use. In cases where the subject is not too drunk to swallow, from half a dram to a dram (1.85 to 3.7 c.c.) of aromatic spirit of ammonia often acts happily; and when there is reason to believe that alcohol or undigested food is in the stomach, an emetic of warm water and mustard—a heaped dessertspoonful of mustard to half a pint of water (250 c.c.)—may be given and the stomach washed out. Should it be deemed desirable that an emetic be given to one unconscious, apomorphin hypodermically administered is the best—from 1-15 to 1-10 grain (0.0044 to 0.0066 gm.).

The first step in the treatment of *chronic alcoholism* is the withdrawal of the poison. Except when mania a potu is present, this may be total. Nothing is to be gained by gradual withdrawal, while it only prolongs the struggle. No drugs like morphin or chloral or cocain should be used in the treatment of chronic alcoholism, as to do so is simply to substitute one evil for another, and to weaken the resolution of the victim. The bromids may, however, be availed of, and trional, chloralamid, and sulphonal may be employed to procure sleep. Not less than fifteen grains (1 gm.) of any of these drugs should be administered for an adult, while twice the dose may be necessary. Hydrobromate of hyoscin is often an admirable remedy to quiet excitement. It may be given in doses of 1-96 grain (0.0007 gm.). Attempts at reformation are rarely successful, but success is not impossible. Some means of restraint is usually indispensable, and as a rule can only be secured in an institution. Unfortunately, relaxation of this is apt to be followed by a relapse. The difficulties increase in the presence of hereditary tendency. An abundance of nutritious food should be insisted upon, as it is found to be the best substitute for alcohol, while tea and coffee may be allowed freely, having the advantage of being stimulating without intoxicating. Tonics, such as strychnin 1-30 grain (0.0022 gm.) three or four times a day, or quinin, should be administered.

As to the remainder of treatment, it must be mainly symptomatic, di-

rected to the symptoms as they arise. Neuritis, one of the most important of these, has been elsewhere considered.

Still another drawback is the intense depression which succeeds the exciting effect of alcohol and often impels to a return to its use. To cure this longing, which he ascribes to gastritis and a peculiar irritation of the gastric nervous supply, Zedekauer recommends:

℞ Chlorated water,	2	drams (8 gm.)
Decoction of althea,	5¼	ounces (165 gm.)
Cane-sugar,	2	drams (8 gm.)

M. Sig.—A tablespoonful every two or three hours.

This, he says, relieves the unpleasant sensation and longing for drink and restores the appetite.

Various means have been at different times resorted to with the object of disgusting the victim with alcohol. C. Carter strongly commends atropin, because of its physiological antagonism to alcohol. He says that if small doses—less than 1-100 grain (0.00066 gm.)—of atropin be administered hypodermically three or four times a day to a victim of the alcoholic habit, it will produce a great distaste for alcoholic liquor in from one to five days. Whisky will become repellent both to sight and smell, and will have a most intolerable taste, resembling that of turpentine or benzine. If, under these circumstances, drinking is still attempted, nausea and vomiting follow without the addition of apomorphin or other emetic to the liquor.

Treatment of Mania a Potu.

The first indication after withdrawal of the alcohol is to secure sleep. For this purpose the soporifics previously named scarcely suffice, though they may be tried in the full doses specified. Especially may we hope to obtain some result from the hyoscin in doses of 1-96 grain (0.0007 gm.) given hypodermically. In many cases of delirium tremens it is scarcely possible to do without morphin, which may be given hypodermically in 1-4 grain (0.0165 gm.) doses, caution being observed not to repeat too often. Chloralose may be given in from five- to ten-grain (0.33 to 0.66 gm.) doses, dissolved in warm water; it has the advantage of small doses, equal in effect to the largest of chloral, while it also diminishes tremor and has no harmful secondary effects. R. Bellamy gives twenty grains (1.32 gm.) of trional, mixed in water, with ten minims (0.62 c. c.) of tincture of capsicum, after a calomel purge. A very hot bath is given, of which the temperature is gradually lessened. If in thirty minutes the delirium shows no signs of abatement, ten grains of trional (0.65 gm.) are again given. In all cases forced feeding in small quantities often repeated is practiced, the diet consisting of milk, eggs, and soups. Paralydehyd in fluid dram (3.7 c. c.) doses is a remedy which may be expected to be of service. The fluid extract of ipecac has recently been recommended by W. F. Waugh, of Chicago, to produce sleep, in from twenty- to thirty-minim (1.23 to 1.85 c. c.) doses in water, followed by dorsal decubitus for at least five minutes to avert nausea. A cold bath sometimes has a tranquilizing effect, especially if there is fever, or sponging the body may suffice. Many things must be done to keep the patient occupied, because, after all, the treatment amounts for the most part to a conflict between the patient and faithful attendants and the irrepressible and, at times, almost maniacal desire of the patient to get away. In preventing this it may sometimes be necessary to confine him to bed, but all

gentleness should be exercised in carrying out this measure. It is much better to use a folded sheet than the unsightly straps which are sometimes used in hospitals.

I have said that alcohol may be withdrawn at once. Some object to this because of fear of resulting adynamia, and it may happen that there is great weakness, as indicated by frequent and feeble pulse demanding alcohol. As a rule it is much better to stimulate with the aromatic spirit of ammonium, digitalis, and strychnin, 1-2 dram (2 gm.) doses of the first, ten minims (0.62 c. c.) of the second, and 1-30 grain (0.0022 gm.) of strychnin being given every three hours to overcome such weakness. Even larger doses may be demanded by emergencies. Nourishing food in easily assimilable shape, repeated at short intervals, should be insisted upon as the best substitute for alcohol. With the first sound sleep comes, usually, relief, and the patient awakes convalescent, unless, as already said, the mania is accompanied by acute disease, like pneumonia, when death is apt to be the termination, whatever our efforts.

THE MORPHIN HABIT.

SYNONYM.—*Morphinism*.

Definition.—An irresistible craving for morphin, which is commonly used in gradually increasing daily doses to meet the demand. Periodic attacks, or “morphin sprees,” comparable to alcohol sprees, during which large quantities are used for the time being, also occur.

Etiology.—The morphin habit is most frequently acquired as the result of long-continued administration of morphin, by a physician's order or otherwise, to relieve some suffering caused by a painful or incurable malady or for insomnia. The influence of heredity in favoring the formation of the habit is acknowledged. Neurotic persons are more apt to become its victims. The victim of alcohol often becomes a morphin fiend, being deluded by early experience with the drug to believe that he can thus overcome the previous more disgusting, if not more terrible, habit. The same is true of cocain.

The quantities consumed are often enormous, as much as 400 grains (25.92 gm.) as a daily dose being reported.

Symptoms.—The chief symptom is, of course, the *craving for morphin*, but it brings with it others which are more or less temporarily relieved by a dose of the drug. Among these are *irresolution* and *loss of self-control*, and a *moral obliquity* similar to that induced by alcohol, especially in women, who are the most frequent subjects. *Untruthfulness*, especially with regard to the drug and the quantities used, is habitual. *Epigastric pain* or *nausea*, or both, are frequently complained of toward the time when another dose is due, though whether this is actual or feigned is not always easily determined. *Mental depression* is a more constant and characteristic symptom, associated with *intense anxiety*, *restlessness*, and a *sense of impending evil*, both relieved for a time by the dose. All of these symptoms are increased by a more prolonged withdrawal of the drug, when the mental depression becomes intense, sometimes impelling to suicide. So far from the usual constipating effect of morphin being produced by the drug thus used, diarrhea is not infrequent.

As the habit is prolonged *tremor*, *paresis*, and more rarely *ataxia* are superadded, while diffuse and neuralgic *pain* is complained of. *Sleep* is irregular, digestion is bad, and appetite and nutrition fail, the pulse becomes feeble and rapid, vasomotor derangements appear, as shown by a tendency to sweating and by dilatation of the pupils. Except when under the direct influence of the drug the patient grows weak and becomes a ready victim to acute disease.

On the other hand the opium eater sometimes attains old age, presenting a wizened, sallow appearance quite characteristic. The pleasurable effect so often ascribed to opium is rarely realized, though it is not unlikely that a certain amplification and distortion of actual facts which may arise in the dreamy state may form the basis of such weird and beautiful fancies as are pictured by DeQuincey.

Diagnosis and Prognosis.—The diagnosis is easy, but the prognosis is exceedingly uncertain because of the difficulty in carrying out treatment.

Treatment.—Successful treatment is scarcely possible outside of an institution, and even within one serious difficulties beset the way, the chief of which is the deception practiced by the patient. Patients should be divested of their own clothing and put to bed in hospital garb, because in this way alone can we be sure that morphin is not concealed about the person. In the case of women, whenever possible, a special nurse should be assigned to each case. The latest testimony favors complete and sudden withdrawal of the drug as furnishing a short struggle, though a severe one. Such treatment is usually followed by diarrhea, vomiting, and insomnia. Some counsel even that no adjuncts should be employed, but certainly there can be no harm in the employment of general tonic treatment and remedies directed to the irritability of the stomach and torpor of the liver. A calomel purge is useful at the start. It is a well-established fact that, as in alcoholism, the patient should be well nourished, given such food as milk, cream, beef-juice, or beef peptonoids, rich broths, and beef-tea. When there is great asthenia, aromatic spirit of ammonium, strychnin, and digitalis may be given as directed under alcoholism. If possible, an occupation of an absorbing kind should be furnished. In most cases it is impossible to secure the consent of the patient to sudden and complete withdrawal, when the gradual plan must be adopted. The success of either plan depends on securing effectual control of the patient, and if this cannot be obtained, all efforts fail.

To promote sleep, one of the numerous hypnotics in which the present day is rich should be given. Chloralamid is probably the best of these. It is not easy of administration, because of its pungent taste and difficult solubility. Twenty grains (1.32 gm.) or thirty grains (1.98 gm.) are a moderate dose, and are easily soluble in a fluid dram (3.7 c. c.) of a mixture of two parts alcohol and one part glycerin. Of such solution two teaspoonfuls should be given in a glass of sherry wine or four tablespoonfuls of milk at the ordinary temperature. Trional and sulphonal or somnal may be given in from fifteen to twenty-grain (0.99 to 1.32 gm.) doses dissolved in hot water. Hyoscin in doses of 1-96 grain (0.0007 gm.) may also be tried. Chloral itself may be used in doses of from ten to thirty grains (0.66 to 1.98 gm.). If there is cardiac weakness, the dose should not exceed ten grains (0.66 gm.). Chloralose may be given in from five to ten-grain (0.33 to 0.66 gm.) doses in wafers or in hot milk

Too much carelessness is practiced by physicians in placing morphin in the hands of patients to be used at their pleasure. The hypodermic syringe has wrought untold mischief, and should never be placed in the hands of patients. On the other hand, when morphin is judiciously ordered for patients suffering extreme pain only, it is very rarely the case that a habit is established.

CHLORALISM.

Definition.—The chloral habit or the habitual use of chloral.

This habit is sometimes acquired when the drug is used to obtain sleep or prescribed by the physician for any purpose.

Symptoms.—For symptoms and treatment of *acute chloral poisoning* see page 1185.

The presence of the *chloral* habit is characterized by nervousness, mental weakness, and depression of spirits, even to a degree of melancholia. There may also be general weakness, characterized by muscular tremor and cardiac palpitation. Lowered temperature is characteristic. These symptoms are aggravated by sudden withdrawal of the drug. There is sometimes dyspnea, aggravated at meals or after exertion. Mania and dementia are reported.

Various skin eruptions or a tendency toward them are a symptom. Though there may be no eruption, the slightest exertion or a glass of wine will produce an intense erythematous redness on the face and elsewhere on the body. This erythema, which may also extend to the mucous membranes is ascribed to vasomotor weakness. There may be diarrhea from the same cause.

Treatment.—Treatment requires the gradual withdrawal of the drug and cardiac stimulation by ammonia and digitalis, the use of nutritious food, tonics, massage, and electricity. For insomnia, if needed, sulphonal or trional, administered as previously directed, are more suitable than chloralimid. In extreme cases morphin may be used. It is not usually difficult to master the habit.

COCAINISM.

Cocainism has become a comparatively frequent modern habit. It is especially common among physicians, some of whom acquire the habit in tentative local applications to their own mucous membranes in the treatment of patients. I have known three successive chiefs of clinic in throat and nose dispensary service to acquire the habit. Cocain is also taken as a substitute for some other drug, and its subjects are very apt to be those with neuropathic tendencies.

Symptoms.—The effect is a total demoralization of the individual, who loses all moral responsibility, delaying and neglecting appointments in the most remarkable manner. There is volubility of tongue, suggesting alcoholism, and the presence of hallucinations, which also resemble those of the alcoholic effect. The eyes are bright, and the pupils are dilated. The subject becomes suspicious, charging his wife with infidelity, and his best friend with persecuting him. Hallucinations of hearing, sight, and smell are sometimes present, including tinnitus aurium. Mild epileptoid seizures, with

partial loss of consciousness, may occur, limited to muscle groups, as about the eyes. Nystagmus is also a symptom. The pulse becomes weak and feeble. The symptoms are often associated with those of alcoholism and opium.

A symptom to which a certain amount of diagnostic value has been attached is a sensation of foreign bodies under the skin. In one case observed by Rybakoff of Moscow, was a sensation as of worms beneath the skin. The recognition of the symptom is ascribed to M. Magnan of Paris.

Treatment.—If uncomplicated, treatment is promising. It mainly requires withdrawal of the drug, which should be total. The assistance of a trusty nurse or friend may be needed, but it is not often necessary to remove the patient to a sanitarium—I am speaking of uncomplicated cases. Cases complicated with alcoholism or the opium habit are more difficult to handle, and incarceration in an institution becomes necessary.

Tonics of the usual kind—strychnin, in full doses, and quinin—should be ordered. Non-intoxicating stimulants, like ammonia and coffee, should be given to counteract the depressing effect, while good, nourishing, easily assimilable food is necessary.

THE TOBACCO HABIT.

To CURE: Apomorphin, 1-30 grain (0.0022 gm.), fresh and pure, every two hours, increasing the dose until slight nausea is felt.

BISULPHID OF CARBON POISONING

should be mentioned. Considerable has been written on it in the German literature lately. It occurs in the vulcanization of rubber. A characteristic symptom of the chronic form is neuritis with resulting paralysis like that of lead poisoning.

LEAD POISONING.

SYNONYMS.—*Colica pictonum*; *Plumbism*; *Saturnism*; *Devonshire Colic*.

Definition.—A disease of manifold symptoms resulting from the toxic effect of lead on the system, having its subjects mainly among workers in lead-works, and among painters, glaziers, and plumbers.

Etiology.—The lead enters the system by inhalation, through the digestive tract, or by the skin. Almost without exception the cases I have had in hospital were from the lead-works in the neighborhood of Philadelphia. The Philadelphia Hospital is almost never without one or more such cases. Even animals in the neighborhood of lead-works are said to have had the disease; also birds which have been fed on berries grown in the vicinity of such works. Water which has been kept in lead tanks, or even painted tanks, or water passed through lead pipes, has produced the disease. It must, however, be very pure water, such as rain water, and it is the very impurities of our drinking-waters which protect us. Almost all drinking-waters contain sulphate of lime, the sulphuric acid of which combines with the superficial layer of lead and forms an insoluble coating of sulphate of lead which prevents further solution.

Accidental contamination has been caused by the use of cosmetics and hair dyes. To the use of chrome yellow as a substitute for eggs for coloring were traced a number of cases occurring in Philadelphia in a very interesting study by Dr. D. D. Stewart.* Even the use of vegetables canned in tin vessels is held to have produced lead poisoning.

All grades of what is known as tin, which is really iron coated with a layer of tin, contain a small quantity of lead; and the more inferior the tin, the larger the quantity of lead. Certain conditions favor the solution of this lead. Thus, if any of the vegetable acids, as acetic, tartar, or citric, be present, they may dissolve the lead and form soluble salts, which are readily absorbed. Of course, such solution is favored by prolonged action of the acids; hence old canned vegetables are more dangerous than those recently canned, and it would be a wise measure to insist that canned foods should be stamped with the date of the canning. The solder used in closing the cans may also be a cause of poisoning. When it is considered how enormous is the consumption of canned foods, and how few the cases of lead poisoning traceable to it, it is evident that even moderate precautions may suffice to remove the danger altogether.

Among the more rare cases of lead poisoning may be named materials used in making rag carpets,† cooking in badly glazed crockery-ware, beer drawn through lead pipes, or beer, cider, and wine from bottles which have been washed with shot of which some have been left behind, the use of snuff packed in spurious tin-foil containing lead, and from sleeping on mattresses the hair in which was dyed black by some lead-containing substance; and one, a most incredible case, mentioned by Naunyn, is that of a proof-reader who was poisoned after many years' reading of printed proof. Notwithstanding the solubility of the acetate of lead so much used in medicine, it is very rare that poisoning has resulted from its administration, and there need be no fear of using it for the purposes in which it is indicated until at least two drams (7.4 c. c.) have been given.

It has always been an interesting question how lead in the system operates to produce its peculiar effects. That the lead itself lodges in the tissues is easy of demonstration, and analysts have gone so far as to determine the exact quantity in the different tissues of animals poisoned by lead; which, by the way, is surprisingly small, the largest amount found being 1-4 of one per cent. in the bones, while that in the muscles was but 2-1000 to 3-1000 of one per cent. On the other hand, it would seem that lead is contained in the tissues of many persons who are healthy—according to J. J. Putnam, in 25 per cent. It was formerly customary to ascribe the symptoms of lead poisoning in part to the direct action of lead in the tissues; the cramps and the palsy to the presence of lead in the muscular substance; the colic to the lead in the unstriped muscular fiber-cells, and the nervous symptoms to the lead in the nerve-centers. In part, too, these phenomena were ascribed to anemia of the tissues, due to the contraction of the arterioles, stimulated by the presence of lead in the muscular coat of the vessel. More recently, however, the soundness of these views has been shaken by some experiments of Huebel. Lead causes degeneration of nerve-cells and nerve-fibers. The changes thus induced in the cell bodies of the neurons have been studied by Lugaro, by Nissl's method. In accordance with these views the

* "Philadelphia Med. News," June 18 and December 27, 1887.

† A very interesting case thus caused is reported by Drs. J. Milton Miller and G. Oram Ring in the "Amer. Jour. of the Med. Sciences" for February, 1896, p. 193.

symptoms have been ascribed to altered function in the nerve centers thus affected. The phenomena of lead poisoning have been compared to those of chronic alcoholism, which are ascribed to effects upon the nerve-centers, of circulating blood charged with alcohol.

Some recent studies by Strauss and Phillipson on metabolic changes in lead-poisoning found certain toxic products of decomposition in the intestines which it is reasonable to suppose might produce the symptoms in lead cases. Whether the lead or the atony of the bowel produced these toxins could not be proven.

Most cases occur among adults, usually between the ages of thirty and forty, but in children occasionally. Women are said to be more predisposed than men, as four to one, and to be more readily brought under its influence.

The period of exposure necessary to produce lead poisoning varies greatly, from a month to many years.

Morbid Anatomy.—This is not striking. Tissue may contain a considerable amount of lead without exhibiting changes. Fatty degeneration and fibrosis are, however, characteristic. Thus, the muscles become fatty and fibroid. The kidneys gradually lose their parenchymal cells and become fibroid, while nerves exhibit fatty degeneration. In the spinal cord are found in chronic lead poisoning the changes characteristic of anterior poliomyelitis—*i. e.*, sclerosis of the anterior cornua, with atrophy of the cells and nerve-fibers, but the remainder of the cord and nerve-roots are not altered. Demonstrable changes in the central nervous system, even when there are symptoms of lead encephalopathy, are not numerous. In 32 out of 71 cases Tanquerel found none. Von Monkalow discovered a high degree of atrophy, especially marked over the frontal region at the vertex, and in the crura cerebri. Small hemorrhages in various parts of the brain and atheroma of the arteries have been noticed; also overgrowth of connective tissue. Severe enterocolitis has been found in acute cases.

Symptoms.—While the symptoms which make known the presence of lead poisoning are at times rapid in their development and at others slow to appear, there seems on this account scarcely sufficient reason for dividing them into two classes of acute and chronic.

The most striking of the symptoms, and often the first to which attention is called, is *colic*. Indeed, it, with constipation, next to be considered, is often the sole manifestation of the disease, and from these two alone a diagnosis may be made, after exposure to lead absorption. The term *lead colic* has long been a recognized term in medical terminology. It is most frequent in the region of the umbilicus, and is often relieved by pressure. It varies greatly in degree, being sometimes a simple grumbling pain, at others of extreme severity, the patient writhing in the paroxysm. This, as a rule, does not last long, but is soon followed by another. On the other hand, the pain may continue for hours or until relief is afforded by treatment. It is probably due to powerful contractions of the muscular wall of the intestine, by which the nerve filaments distributed through it are compressed. As contrasted with flatulent colic, the abdomen is not distended, but flat, and may even be contracted, sometimes so much so that it is said that the vertebræ may be discerned through the abdominal walls. Yet distention of the abdomen is occasionally present. The pulse during the attacks of colic is often strikingly slowed, having been noticed as infrequent as 30 beats in a minute.

Groups of muscles anywhere, and especially the flexor muscles, as of

the arms and legs, become involved in cramp, the latter more frequently. There may also be cramps in the fingers and toes. In addition to these painful cramps, which, like the colic, are intermittent, there is pain in the neighborhood of the joints. The sum of these painful joints and muscles has received the name *arthralgia saturnina*. They are quite frequent, occurring, according to statistics of Tanquerel, in 755 out of 2151 cases.

Constipation is very common, even more commonly present than the colic, and yet it is not invariable, and may even be substituted by diarrhea.

A *blue line* on the patient's gums is a very characteristic symptom, and appears at the border of contact of the gums with the teeth, or just above it. As a rule, it is easily recognized when present. It is caused by the presence of sulphuret of lead, produced by the action of sulphureted hydrogen upon the lead in the tissue of the gums. Hence the line is more common and distinct on the gums of those who take no care of the mouth, and in whom sulphureted hydrogen is generated in the decomposition of the food. This line often remains after all other symptoms have subsided, and although it is not invariably present, its disappearance may be considered as quite a certain sign that the lead has been practically eradicated.

Anemia is a very constant symptom in lead poisoning, and its higher degrees are attended by a sallowness which early gave rise to the term *icterus saturninus*, but which is in no way due to a deposit of bile pigment. In more serious cases, too, the impaired nutrition results in an *emaciation* which is sometimes extreme. Along with the anemia there is often *loss of appetite*, and frequently a *sweetish* taste and *fetid breath*.

Comparatively recent studies have found associated with lead poisoning in common with other toxic conditions a granular degeneration of the erythrocytes. The granular change which responds to the basophilic stains was first investigated by Geelmyden, Hausemann, Von Noorden and others, but Grawitz was the first (1889) to lay particular stress on the condition as evidence of a special form of degeneration. It would appear from the recent studies of Stengel, White, and Pepper* that no poison thus far studied is as regular in its production of degeneration or as prompt in its action as lead.

Another symptom of great importance is *muscular paralysis*. This, in contrast with muscular cramp, is more likely to involve extensor muscles than flexors, and especially those of the wrist, giving rise to the very characteristic symptom known as "wrist-drop," which, in Tanquerel's experience, occurred in 107 out of 2151 cases. Usually it is not until the colic and arthralgia present themselves that the wrist-drop appears. On the other hand, it has been the first symptom observed. It may last but a few days, or it may resist all treatment. It may affect a single muscle or groups of muscles. It is further characterized by the fact that the muscles affected are subject to rapid and extreme *atrophy*, so that they seem almost to disappear. Dislocations of the more movable joints, as the shoulders and phalanges, may occur in consequence. While sensibility is but slightly impaired, *electromuscular contractility* rapidly *disappears*. The muscles cease to respond to the faradic current, while the reaction to galvanism is unchanged or slightly increased at first. *Tremor* of the paralyzed muscles is often observed.

Another set of symptoms of lead poisoning not uncommon are those due to *involvement of the central nervous system*. Occurring usually only

* "Further Studies of Granular Degeneration of Erythrocytes," "American Journal of the Medical Sciences," May, 1902.

in those who are peculiarly exposed, they come on in from eight days to fifty years, the majority showing themselves, according to Tanquerel, within the first nine months. The most frequent mode of manifestation is in *eclampsia* independent of Bright's disease. True epilepsy may follow these convulsions. But there may be headache or amaurosis, optic neuritis, apathy, stupor, or the opposite condition of maniacal excitement or melancholia and hallucinations. In a few cases of lead poisoning the symptoms are limited to the central nervous system—in 72 out of 1390 cases observed by Tanquerel. *Tremor* is a frequent nervous symptom of lead poisoning.

A frequent complication of lead poisoning, more especially when it has been present for some time, is *interstitial nephritis*, and its resulting morbid product, the contracted kidney, as shown by the presence of a small degree of albuminuria and hyaline tube-casts; and as this is the form of kidney disease in which uremic convulsions are most frequent, it is evident that these must be distinguished from the convulsions just referred to as part of saturnine encephalopathy. Hence an examination of the urine in every case of lead poisoning should be early made in the study of the case.

Arteriosclerosis is often a direct result of lead poisoning, hypertrophy of the heart, and interstitial nephritis.

Gout is a well-recognized symptom of lead poisoning, but the relation between the two was sufficiently considered in treating of that disease. True, uratic deposits may occur in the big toe joint and in the tissues, their precipitation being favored by the lead, which may act by diminishing the alkalinity of the blood, as suggested by Rolfe. I may repeat, also, that in this country the association is an uncommon one.

Prognosis.—As to prognosis, it depends largely upon the degree of saturation of the system with lead. Ordinary lead colic is commonly followed by recovery. As a rule, therefore, persons who respond most quickly to the action of the poison are those who most promptly recover, provided, of course, they are removed from the influence of the lead, for such persons, too, being most susceptible, are in great danger from prolonged exposure. We are enabled to infer something of the prognosis from the symptoms which are present. If the attack be ushered in by a colic, and there be no other symptoms except constipation, we may confidently expect our patient to recover completely. If there be arthralgia and palsy, the prospect is less certain, still less so if there be atrophy, and least of all if there be encephalopathy, though even here recovery may take place. Contracted kidney due to lead poisoning is also usually incurable. No favorable prognosis should be given when the patient is unable to remove himself from the cause. It must be remembered, too, that relapses occur, often at long intervals, even when the patient is removed from exposure, and that the primary disease has been known to make its appearance a long time after exposure.

Treatment.—Much may be done to guard against the occurrence of lead poisoning by *proper precautions* on the part of those exposed to it, and those employed in lead-works may do much to protect themselves, or rather their employers may do it for them. Such persons should keep themselves scrupulously *clean* by frequent *hot baths* and frequent changes of clothing, which should never be allowed to become saturated with lead. Mehu recommends that *hypochlorite of sodium* be added to the hot baths. It is made by mixing in 2 1-2 gallons (10 liters) of water 13 ounces (400 gm.) of chlorinated lime with 11 drams (43 gm.) of sodium carbonate. *Sulphur baths* were recommended by Todd, it being thought that sulphur has the

power of neutralizing lead by forming insoluble compounds with it. From two to four ounces (62.5 to 124.5 gm.) of sulphuret of potassium are mixed in from twenty to thirty gallons of water (75.5 to 113.4 liters). Above all, the employees in lead-works should *not* be allowed to *eat meals* in the lead-factory, as the metal is often introduced with food. Finally, the *ventilation* of the factory should be of the best. Experience has shown that much may be done to arrest the dangers of lead-works by such precautions. The same remarks as to cleanliness, bathing, and change of clothing apply to painters, and indeed to all who have to do with lead in any shape or degree. It is evident that leadlined and painted cisterns should never be used in houses, that cosmetics and hair-dyes are dangerous, and that care should be taken in the selection of canned foods not to use those which have been too long canned.

The curative measures may be divided into those for the immediate relief of urgent symptoms and the removal of the lead from the system. It is scarcely necessary to say that the patient should be promptly removed from the influence of the lead. The extreme pain of lead colic requires to be relieved by the hot bath or poultice, and an opiate, of which the best mode of administration is by the hypodermic syringe, 1-4 or 1-3 grain (0.016 or 0.02 gm.) of sulphate of morphin being required for the purpose. Identical treatment is required for the arthralgia. The accompanying constipation is best relieved by sulphate of magnesium, the sulphuric acid of which, on theoretical grounds, at least, aids in rendering inoperative the lead which has entered the system by forming an insoluble sulphate.

These more urgent symptoms being relieved, measures directed to the *elimination of the lead* should be taken. The hot baths already referred to may be used for this purpose, as well as for prophylaxis, while *purgatives* and *diuretics* may aid the elimination. The *iodid of potassium* is the remedy most relied upon to eliminate lead. It is believed that after its absorption the lead becomes intimately united with the albumin of the tissues, forming an insoluble compound; that the iodid of potassium, after its absorption, combines with the lead and forms a soluble iodid of lead, which is dissolved out, re-enters the circulation, and is passed out with the urine and feces. It is evident that elimination by these channels will be encouraged by purgatives and diuretics. It is even suggested that acute lead poisoning may be produced by the liberation of the soluble lead salt into the blood in this way. Hence caution is suggested in the use of the iodid. Practically, I can scarcely conceive this to occur with such doses as are ordinarily given, ten grains (0.66 gm.) three times daily, after a time reduced to five (0.33 gm.), but this dose should be kept up indefinitely. Iodid of potassium is more efficient when given fasting and freely diluted.

For the paralyzed muscles *faradic electricity* is indicated and should be daily applied, both to resist the tendency to atrophy and to overcome it.

That *restorative* and *blood-making* remedies, in the shape of nutritious, easily assimilable food, together with iron, should also be given to antagonize the cachexia which is always a part of plumbism is evident. In view of the nervous and muscular symptoms which enter so largely into the disease *strychnin* may be expected to be a useful adjunct to our treatment, and it is generally so considered. It should be given in full doses, 1-30 grain (0.0022 gm.) three times a day, and increased to 1-20 grain (0.0033 gm.), which should be kept up. *Ergot* is said to have been useful in restoring the power of muscles involved in the palsy.

ARSENICAL POISONING.

ACUTE ARSENICAL POISONING.—Acute arsenical poisoning is usually the result of accidental or intentional ingestion of Paris green or “Rough on Rats,” prepared and sold for the destruction of rats, mice, vermin, and insects. Occasionally it is taken also with suicidal intent.

Symptoms.—These are intense *abdominal pain*, at first gastric, with *vomiting*; later intestinal, with *diarrhea* and *tenesmus*, which may be followed by collapse and death. The symptoms are not unlike those of cholera, including rice-water stools, cardiac weakness, and cyanosis. Sometimes a *skin eruption* makes its appearance, and sometimes *blood* and *albumin* appear in the *urine*. Fatal cases terminate in one or two days.

Recovery from these acute effects may be followed by paralysis.

Treatment.—The ingestion of a poisonous dose of arsenic is apt to be followed by free vomiting. But even in the event of emesis, mustard or sulphate of zinc, from ten to thirty grains (0.068 to 0.1944 gm.), should be administered, and the stomach well washed out with draughts of warm water. With the emetic or before it the antidote should be administered. The best antidote is freshly precipitated sesquioxid of iron, which forms, with arsenic, an insoluble compound. It must be freshly prepared, taking any of the sesqui solutions of iron, preferably the chlorid, and neutralizing it with sodium carbonate or magnesia. The precipitate, being hastily washed by emptying on muslin or a filter, pouring water on it and allowing it to drain, should be freely administered. Dialyzed iron may be used, but it is best also precipitated with ammonia or other alkali before using. In extreme cases the tincture of the chlorid of iron, Monsel's solution, or any of the sesqui preparations may be substituted for the precipitated sesquioxid.

After the emetic has acted, and while the antidote is being given, castor oil should be administered to carry off the poison from the bowels.

CHRONIC ARSENICAL POISONING.—This is ascribed to wall-papers covering occupied apartments, sometimes to arsenic long administered as a medicine, to artificial flowers, and clothing fabrics. The glazed green and red papers are those especially dangerous. Occasionally, arsenic medicinally administered may produce the symptoms of slow arsenical poisoning.

Symptoms.—Chronic arsenical poisoning may be suspected in the presence of unexplained *anemia* and *debility*, irritation of the conjunctiva, mouth, pharynx, and lower digestive tract, *numbness*, *tingling*, and *gastroalgia*; also nervous symptoms and altered nutrition in special parts. All these symptoms may, however, be produced by other causes. *Paralysis* may also ensue, resembling that of lead palsy, but affecting rather the lower extremities, especially the extensors and peroneal group, whence may arise the characteristic *steppage gait* of peripheral neuritis. *Deranged electrical reaction* may be present before any loss of power, but on differential examination a weakened power of wrist extension and feeble power to spread the fingers may be detected.

Treatment.—The patient should be removed from the exposure and the symptoms be treated as they arise. The iodid of potassium may be used.

PTOMAIN AND LEUKOMAIN POISONING.

Ptomain, from the Greek $\pi\tau\omega\mu\alpha$, a cadaver, is a word suggested by the Italian toxicologist, F. Selini, for substances generated in the decomposition of organic matter, which more recent studies have shown to be the result of bacterial action. Ptomains are basic, uniting with acids to form salts. Leukomains are similar basic substances formed in the living body. Ptomains differ greatly in their character and properties, certain ones being intensely poisonous, others harmless. For the former L. Brieger suggested the name toxins, retaining that of ptomains for the non-poisonous basic products; but, as Victor C. Vaughan suggests, there are difficulties in the way of such classification, because a ptomain may be poisonous under certain conditions and harmless under others.

Leukomains are more usually harmless, although they may also produce disease under certain conditions.

Among ptomain poisons are the agencies which are responsible for various forms of meat poisoning, poisoning by milk products, by shell-fish and fish.

MEAT POISONING.—This succeeds the eating of various forms of meat which has been the seat of a decomposition in the whole or some one of the constituents of the mass.

Sausage poisoning, also called botulismus and allantiasis, follows the eating of infected sausage. Numerous outbreaks have occurred in Germany, more particularly in Wurtemberg and adjacent Baden. In 1820 Kerner had collected reports of 76 cases, of which 37 were fatal, and in 1822 he had increased the number to 155, with 84 fatal. The poisonous qualities are referred to defective methods of preparation which permit decomposition.

Ham poisoning not due to trichina has occurred in England, Germany, and Switzerland, while poisoning has also been traced to beef, mutton, veal, turkey, and goose-grease, and in America to canned meats. Some of these must be ascribed to muriate of zinc and tin, but others are doubtless due to the meats. Poultry, especially if kept too long, and game birds also prove poisonous at times.

Symptoms.—The symptoms of various epidemics vary somewhat, but the following are more constant, after a period of incubation of from one to forty-eight hours: *nausea, vomiting, cramps, and diarrhea*—in a word, acute gastro-intestinal irritation. To these may be added *dryness of the mouth, constriction of the throat, difficulty in swallowing, vertigo, indistinctness of vision, dilatation of pupils*, while sometimes *constipation* substitutes diarrhea. *Thirst, headache, and muscular weakness* may also be present.

The symptoms may begin at once without incubation in a feeling of languor and general malaise, loss of appetite, nausea, and griping pain in the belly.

In fatal cases the symptoms of cholera are simulated, such as cramps in the legs or arms, or both, muscular twitchings, stiffness of the joints, drowsiness, coldness of surface, pinched features, blueness of fingers and toes and around the sunken eyes—in a word, the symptoms of collapse. On the other hand, the temperature sometimes rises to 101° to 103° F. (38.3° to 39.4° C.), with a pulse of from 100 to 128.

POISONING BY MILK AND ITS PRODUCTS.—The causes of poisoning by cheese claimed attention as far back as 1827, when analyses of poisonous

cheeses were made by Hunnefeld. The older view that the poisons are fatty acids has been refuted, and Vaughan isolated a ptomain in 1884 which he has called tyrotoxinon (τυρός, cheese, and τοξικόν, poison). Tyrotoxinon was not, however, always found by Vaughan in cheeses of acknowledged poisonous properties. In 1885 he found tyrotoxinon in milk which had stood in well-stoppered bottles for about six months, and in 1886 Newton and Wallace obtained it from milk which had poisoned a number of persons in a hotel at Long Branch, N. J. Since then tyrotoxinon has been isolated many times from poisonous milk. Finally, in 1886, Vaughan obtained tyrotoxinon from ice-cream which had proved poisonous, and since then it has been frequently found in such cream. A number of cases of poisoning after eating "cream puffs" have been reported in Philadelphia and elsewhere, in which doubtless the same ptomain is responsible. A family under my observation was poisoned by *blanc mange*, of which all had eaten freely, and which had been made for several days.

Symptoms.—The symptoms of milk and cheese poisoning are those of gastro-intestinal irritation, comparable in various degrees to those described as due to meat poisoning, etc

POISONING BY SHELL-FISH AND FISH (*Ichthysmus*).—The mussel furnishes the most frequent source of poisoning from this cause, instances of which were reported as early as 1827 by Combe. A ptomain was isolated by L. Brieger in 1885, from poisonous mussels, at Wilhelms-haven, where numerous instances occur. Brieger has called it mytilotoxin, from *mytilis*, a mussel. It is found chiefly in the liver of the mussel, but whether in a special poisonous mussel or a mussel which becomes poisonous under certain circumstances is not settled, though the latter would seem to be true, since Schmidtman found that non-poisonous mussels placed in the waters of Wilhemshaven Bay became poisonous, and poisonous mussels from the latter became harmless after being placed in the open sea.

Symptoms.—Both cooked and raw mussels may produce the poisonous symptoms. Three sets are described:

First, those of gastro-intestinal irritation, similar to those described as due to meat poisoning and which may terminate fatally within two days, the autopsy revealing inflamed stomach and intestines.

In a second set of symptoms the nervous system seems to bear the brunt of the poison, and these cases are said to be the most frequent. The symptoms include a sense of heat and itching, usually beginning in the eyelids, but soon extending over the whole face and sometimes over a large portion of the body. An eruption, vesicular and papular, makes its appearance and intensifies the itching. The eruption is often followed by asthmatic breathing. Sometimes the dyspnea precedes the eruption, the face becomes livid, the patient unconscious, and there are convulsive movements of the extremities. In other cases there are delirium, convulsions, coma, and death within three days. In other nervous cases there are numbness and coldness, frequent pulse but no fever, the pupils are dilated, and death takes place in a couple of hours with symptoms of collapse.

In a third set of cases a symptom like intoxication by alcohol is present, followed by paralysis, coma, and death.

Treatment of Ptomain Poisoning.

This is mainly symptomatic—the *purgative* and *emetic* effect of the

poison generally promptly gets rid of any residue which may be in the stomach or intestinal canal. But if there is any reason to believe that these are not emptied, purgatives should be administered, and of these calomel is probably the best because it is less apt to be rejected.

In addition counterirritation by mustard, hypodermic injection of 1-4 grain (0.0165 gm.) *morphin*, repeated if necessary, to relieve pain, digitalis from ten to thirty minims (0.66 to 2 gm.), and strychnin 1-30 grain (0.0022 gm.) administered in the same manner to counteract collapse may be given. *Stimulants* by the mouth should be given if retained, and to this end champagne becomes very suitable, or milk mixed with carbonated water may be given in small quantities.

GRAIN POISONING.

For a century or more districts have been subject to ailments which have been traced to the use of certain grains as food, some of which have been found to be spoiled or the seat of disease. People in some parts of France, Germany, Switzerland, Italy, Spain, and India have been thus affected.

I. **ERGOTISM.**—Ergotism is one of these ailments. It is a disease found to succeed upon the use of meal contaminated with the *sclerotium*, an intermediate stage of development of the *claviceps purpurea*, a fungus which infests the rye grain. An ergot is this sclerotium, which appears at the base of the grain as a hard, dark-hued "spur," which, as it grows, lifts up the diseased and withered mass of the original grain. Wheat, barley, and rice may also become spurred. The growth of the fungus is favored by wet seasons. The disease prevailed in France, Switzerland, and Germany much more commonly from the tenth to the eighteenth century than at present. The cause of ergotism was discovered in 1830 by Thuillier.

Two forms of chronic ergotism are recognized, one convulsive or spasmodic, the other gangrenous.

Spasmodic Ergotism.—In this form there is a prodromal period of from ten to fourteen days, during which there are a peculiar sense of weariness and anxiety, a tingling and sense of formication in the skin, especially of the fingers and toes, gastro-intestinal irritation manifested by vomiting, purging, and colicky pains, accompanied sometimes with slight fever. Then *spasmodic symptoms set in*. These consist at first in involuntary twitchings, which soon pass into painful continuous contractions, the arms being flexed and the legs and toes extended. The cramp lasts for an hour or more, followed by a period of exhaustion, which may be succeeded by another painful convulsion. There may be delirium, melancholia, or dementia. The urine may be suppressed or violent dysuria may be present from spasm of the bladder. Pustules, boils, whitlows, and other evidence of deranged nutrition may appear. Cardiac contractions are slow and feeble, the arteries are constricted and contain little blood. Death may occur from cardiac paralysis, and is often preceded by convulsions or paralytic symptoms. The duration of the illness is from four to eight weeks or longer.

Sclerosis of the posterior columns of the cord was found in some of the cases which came to necropsy. Thus, Tuzcek and Siemens found it four times in nine autopsies, which represented, also, the deaths in a group of twenty-nine cases.

Gangrenous Ergotism.—This form is ushered in by the same prodrome as that described for the spasmodic. On this succeeds, from the third day to the fourth week, an erysipelatous redness in some peripheral locality, as in the toes and fingers, ears, and nose. This is followed usually by dry gangrene, but the moist form, which may be confined to a finger or toe or may involve the whole hand or foot, may also appear. The disease may not go beyond the erysipelatous redness.

For acute ergot poisoning see concluding section.

2. PELLAGRA.—This is a disease thought to be due to a fungus which infests moldy maize or Indian corn. Lombroso and others have isolated a ptomain from the meal made of such corn. The disease occurs in Lombardy, the South of France, and in Spain, especially among the poorer classes in the country districts, where the meal of maize is largely used. It begins almost invariably in an erythema in the spring of the year, which is followed by a scaly and wrinkled condition of the skin, especially in the parts exposed to the air. Occasionally crusts form, and beneath these pus is found. Along with these skin diseases there are digestive derangements, salivation, dyspepsia, and even dysentery. The disease lasts a few months, when improvement sets in. In the more severe and chronic forms there may be headache and backache, the strength and mental faculties are affected, sensation is obtunded, and cramps with convulsions supervene, such as in ergotism.

The morbid anatomy is vague. There may be fatty degeneration and a pigmentation of the viscera.

3. LATHYRISM, or LUPINOSIS.—This is a condition resulting from the use of meal made from the chick-pea, or grain of a variety of vetches, more particularly the *lathyrus salicis* and *lathyrus cicera*. It is used in admixture with barley and wheat in India, Italy, and Algiers. According to James Irvine, the symptoms supervene in India when the proportion exceeds 1-12.

The symptoms are, first, gastro-intestinal irritation, then a condition of spastic paralysis, which may pass on to complete paraplegia. The arms are rarely, if ever, affected.

No associated morbid change has been discovered.

Treatment of Grain Poisoning.

This consists, primarily, in the removal of the cause and the substitution of wholesome food; in removal, also from the district, if possible, and suitable treatment of symptoms.

SECTION XII.

EFFECTS OF EXPOSURE TO HIGH THOUGH BEARABLE TEMPERATURE.

Such effects are easily separable into two groups, covered by the terms heat exhaustion and thermic fever.

HEAT EXHAUSTION.

Definition.—A condition of syncopal exhaustion with vasomotor paralysis and lowering of body-temperature, caused by exertion under high temperature. Such condition may arise quite independently of the direct rays of the sun. The heat may be that of confined rooms and may be artificial heat.

Symptoms.—The sense of *great weakness*, often experienced in hot weather after some unusual exertion, exhibits the mildest degree of this condition. In the more severe forms a sense of faintness, associated with *pallor*, *dizziness*, at times *blindness*, and the starting of cold *perspiration* are the first symptoms. Sometimes the victim can get to a place where he may sit or lie down; at other time he faints away before assistance can reach him. Then follows a condition of *unconsciousness* or semi-consciousness, whence, under favorable circumstances, he may respond to gentle stimulus by ammonia or wine and then fall into a sleep, from which he will awake in an hour revived.

In more severe cases the *collapse* is more permanent, the *pulse* is extremely feeble and frequent, the *skin* continues leaky, while there may be *great restlessness* and *muttering delirium*. It is characteristic of this form of heat affection that there is extreme *adynamia* with *lowered body-temperature*. H. C. Wood, whose name is inseparably associated with the subjects of heat exhaustion and thermic fever, reports a case with a temperature as low as 95° F. (35° C.), with complete collapse.

Diagnosis.—Heat exhaustion is characterized by *lowered temperature* and feeble pulse, as contrasted with the opposite in *thermic fever*. It is important that the two conditions should not be confounded, because of the widely different treatment required. The syncopal attack from *cardiac failure* or from *concealed hemorrhage* much more closely resembles heat exhaustion, being associated also with feeble pulse and lowered temperature, but as the treatment is identical, the distinction is less important. The fall in temperature is, however, less decided in *syncope*.

Treatment.—The patient should be put to bed at once with his head horizontal or slightly raised. When possible, stimulants should be administered moderately by the mouth—brandy, whisky, or ammonia with digitalis. If this is not possible, digitalis and strychnin should be given hypodermically, from ten to thirty minims (0.66 to 2 gm.) of the former and 1-30 grain (0.0022 gm.) of the latter. Friction should be applied, and dry heat by hot-water bags or cans.

THERMIC FEVER.

SYNONYMS.—*Heat Fever; Sunstroke; Coup de soleil.*

Definition.—A state of high fever induced by exposure to heat, natural or artificial.

Etiology and Pathology.—In this country the majority of cases occur in the summer season in those exposed to the direct rays of the sun, though they occur also among those exposed to high temperature within doors, as in sugar refineries, fire-rooms of ocean steamers, laundries, and the like. A heated atmosphere charged with moisture, impeding, therefore, evaporation, produces fever much more rapidly than a dry heat, which is in fact slow to produce it. The habitual use of alcohol is found to be a potent predisposing cause—at least alcoholics succumb very much sooner to the influence of overheat than temperate persons.

The pathology of the two conditions of heat exhaustion and thermic fever is thus explained by H. C. Wood: "There is in the pons or higher portion of the nervous system a center whose function it is to inhibit the production of animal heat, and in the medulla oblongata a center (probably the vasomotor center) which regulates the dissipation of bodily heat. Fever is due to a disturbance of these centers, so that more heat is produced than normal and proportionately less thrown off. Let it be supposed that a man is placed in such an atmosphere, that he is unable to get rid of the heat which he is forming. The temperature of the body will slowly rise, and he may suffer from a general thermic fever. If early or late in this condition the inhibitory heat center becomes exhausted by the effort which it is making to control the formation of heat, or becomes paralyzed by the direct action of the excessive temperature already reached, then suddenly all tissues will begin to form heat with the utmost rapidity, the bodily temperature rises with a bound, and the man drops over with one of the forms of *coup de soleil*.

"Heat exhaustion," on the other hand, "with lowered temperature, represents a vasomotor palsy—*i. e.*, a condition in which the existence of the heat paralyzes the center in the medulla oblongata, and the heat is dissipated more rapidly than it is produced." It must be admitted that the explanation of heat exhaustion is less satisfactory than that of thermic fever.

Morbid Anatomy.—The high temperature characteristic of heat fever remains a long time after death. Hence putrefaction sets in early. Rigor mortis also occurs promptly. The blood remains liquid. There is general venous engorgement, especially of the lungs and cerebrum. In early autopsies the left ventricle is found contracted, the right dilated.

Symptoms.—A sense of uncomfortable *burning heat* and feeling of *oppression* may precede the "stroke" which fells its victim, who quickly becomes *unconscious* and comatose, perishing sometimes instantly, at other times in a few hours. In other cases there are intense *headache, dizziness, oppression, nausea, and vomiting*, occasionally *diarrhea*. *Chromatopsia*, or colored vision, may be present. Sooner or later unconsciousness sets in, and may be associated with *muttering delirium* and intense *restlessness*. In this condition the patient is commonly admitted to hospital with face flushed, eye suffused, skin hot and dry, temperature from 107° to 112° F. (41.6° to 44.4° C.), the *breathing* labored, sometimes *stertorous*, the *pulse* frequent

and full. The pupils at this stage are usually contracted, though at first dilated. The urine is scanty, sometimes albuminous. Usually there is relaxation of the muscles, but at times there is a *convulsive tendency*, shown

Fig. 134.—Temperature Chart from a Case of Sunstroke, Treated by Ice water Baths and Frictions. Recovery.

In fatal cases the stupor deepens, the pulse becomes more frequent and loses even its seeming strength, then is irregular, the inspiration is labored and irregular, and toward the last shallow, or assumes the Cheyne-Stokes type previous to death. Death does not usually take place for several hours. In favorable cases improvement is indicated by a falling temperature and a return to consciousness.

Recovery may be complete, but more rarely a permanent condition results in which there may be more or less constant *mental weakness*, as evidenced by incapacity for sustained mental effort, while exposure to moderate degrees of temperature produces great excitement or headache or pain in the upper cervical region. *Epileptic* convulsions sometimes occur. In these cases there is probably a certain degree of meningitis.

Attention has lately been called by C. F. Close* to cardiac dilatation as a symptom of thermic fever.

Mention has already been made, when treating of fevers, of the form of continued fever occurring in the south of the United States, where it is known as "Florida fever" and "country fever," and in India and the West Indies as *fièvre inflammatoire*, for which John Guitéras proposes the name *continued thermic fever*, but which more recently he is inclined to ascribe to a septic origin.

Diagnosis.—The diagnosis of heat fever presents no difficulties. The distinction between it and *heat exhaustion* has been alluded to.

Prognosis.—The prognosis depends partly upon the severity of the case and the promptness and thoroughness of treatment. A few cases are almost instantaneously fatal. If the cooling treatment can be applied properly, a decided majority—fully 60 per cent.—recover. A temperature of 110° F. (43.3° C.), though indicating gravity, should not discourage.

Treatment.—The success of treatment of thermic fever depends altogether upon our ability to lower the temperature. To this end the patient should be placed in a *bath of water* to which ice is freely added to keep the temperature down as low as it can be, which in summer is not likely to be below 60° F. (15.54° C.). The surface of the body is further vigorously *rubbed with ice*. In the absence of bathing facilities the patient should be placed on a mattress covered with a mackintosh and be rubbed with pieces of ice. The refrigerating effect may be further increased by *ice-water enemas*. This treatment should be regulated by the thermometer in the rectum, and abated as the temperature approaches the normal, and renewed as it again rises.

After this, or in addition to this, *treatment* should be *symptomatic*. For convulsions, chloral or chloroform; for heart failure, digitalis and strychnin hypodermically; for asphyxia, bleeding. Mild cases or recurrent fever may be treated with the antipyretics represented by antifebrin, phenacetin, and antipyrin.

The sequelæ referred to should be treated symptomatically.

* "Journal of the Am. Med. Assoc.," March 9, 1901.

SECTION XIII.

ANIMAL PARASITES AND THE CONDITIONS CAUSED BY THEM.

While the number and variety of parasites which infest man are extremely large, the number of these which are directly harmful is very much smaller. Representatives of sufficient importance to deserve consideration are found among the—

- I. Protozoa, simple cellular organisms representing the lowest classes of the animal kingdom without nervous or circulatory systems.
- II. Platyhelminthes, or flat worms.
- III. Nematodes, or thread worms.
- IV. Acanthocephali, or thorn-headed worms.
- V. Arthropoda, or jointed animals.

I. PROTOZOA.

1. *Psorospermiasis*.—The protozoa are represented by the psorosperms or sporozoa, and these by the *coccidia*. The latter are spherical or oval, nucleated organisms, composed of granular protoplasm. They vary in size, the smallest being from 0.012 to 0.015 mm. (0.0005 to 0.0006 inch) long, and from 0.007 to 0.01 mm. (0.003 to 0.004 inch) wide, and the largest from 0.04 to 0.049 mm. (0.0016 to 0.0019 inch) long, and from 0.022 to 0.28 mm. (0.0008 to 0.0011 inch) wide.

They lodge within the epithelial cells of man and the lower animals, one or more within a single cell, whence they are also called *cytozoa*. They are closely allied to the hematozoa or blood parasites which occupy the corpuscles of fish and amphibia. Other varieties are found outside of cells in the submucous tissues, and in the villi of the intestinal wall of dogs, cats, rabbits, man, and other animals, or in organs adjacent, such as the liver and kidney. Wherever they lodge they immediately become encysted, forming whitish, oval nodules, especially easily studied in the liver of the rabbit. These nodules vary in size from that of a pin's head to that of a split pea, and resemble the tubercles of tuberculosis. In most of the cases *in man* the *liver* is found to be the seat of invasion, and the resulting tumors may be felt during life. They have thus been mistaken for echinococci. The spleen, kidneys, omentum, peritoneum, and pericardium may also be invaded. Other symptoms are abdominal muscular pain, tenderness, sometimes diarrhea, nausea, dry tongue, hematuria, and peritonitis. The effect appears to be one of intense irritation, like that of general miliary tuberculosis or trichiniasis, causing death in variable periods, from fourteen days to several years. Cases of internal psorospermiasis, as previously described, have been reported in France, Germany, Austria, and England, but not in America. Two cases of external or cutaneous psorospermiasis, affecting the skin only, were reported by Rixford and Gilchrist in the "Johns Hopkins Hospital Reports," vol. I. The affection attacked the skin of the face, trunk, and

extremities, producing tubercular nodules. Subsequently, internal organs, including the lymphatic glands and lungs, were invaded, producing symptoms and lesions like those of tuberculosis, but enormous numbers of sporozoa were found in the caseous masses.

2. *Parasitic Infusoria*.—The protozoa are also represented by the infusoria, and of these especially the subclass *flagellata*. These include the (a) *plagiomonas urinaria*, found once only by Künster in the fresh urine of a man who had suffered from chronic suppuration; (b) the *trichomonas vaginalis*, an irregular spindle-shaped organism from 0.015 to 0.025 mm. (0.0006 to 0.0009 inch) long and from 0.016 to 0.018 mm. (0.0006 to 0.0007 inch) wide, found in the acid vaginal mucus; (c) the *trichomonas* or *cercomonas hominis*, a pear-shaped organism from 0.004 to 0.007 or 0.015 mm. (0.0002 to 0.0006 inch) long and from 0.003 to 0.004 mm. (0.0001 to 0.0002 inch) wide, terminating behind in a pointed projection and in front in four cilia, found in intestines and stools; also (d) the *lamblia intestinalis*, a similar shaped organism found in the intestinal canal. Flagellates have also been found in the lungs in gangrene, bronchiectasis, and pleurisy. Of the ciliated infusoria, *balantidium* or *paramcium coli*, an oval body from 0.07 to 0.1 mm. (0.0027 to 0.393 inch) long and from 0.05 to 0.07 mm. (0.0019 to 0.0027 inch) wide, has been found in the large intestine in dysentery.

II. PLATYHELMINTHES, OR FLAT WORMS.

The flat worms include the—

- A. Trematodes, or flukes.
- B. Cestodes, or tape-worms.

A. TREMATODES, OR FLUKES.

These are divided into liver flukes, blood flukes, and bronchial flukes.

(a) Liver Flukes.

These include—

1. The *distomum hepaticum*, or *fasciola hepatica*, from 25 to 32 mm. (0.9842 to 1.2598 inches) long and from 8 to 13 mm. (0.3149 to 0.5118 inch) wide, found in the liver, blood-vessels, and in abscesses in man.

2. The *distomum buskii*, large, from 4 to 8.5 cm. (1.5748 to 3.3464 inches) long and from 1.4 to 2 cm. (0.5511 to 0.8 inch) wide, found in the liver and feces.

3. The *distomum lanceolatum*, from 8 to 10 mm. (0.3149 to 0.3937 inch) long and from 1.5 to 2.5 mm. (0.059 to 0.0984 inch) wide, found in the intestine, whence it has been passed per anum and even by the mouth.

4. The *distomum sinense*, from 10 to 13 to 18 mm. (0.3937 to 0.5118 to 0.7086 inch) long and 2 to 3 mm. (0.0787 to 0.1181 inch) broad. This is a distoma especially prevalent in Japan, where it was described as *distomum endemicum* and *distomum perniciosum*. It occurs in 20 per cent. of the inhabitants of certain provinces, according to Baelz.

5. The *distomum conjunctum*, 10 mm. (0.3937 inch) long and 2.5 mm. (0.0984 inch) broad, found in the liver.

6. The *distomum felineum*, from 8 to 18 mm. (0.3149 to 0.7086 inch) long and 1.5 to 2.5 mm. (0.059 to 0.0984 inch) wide, found in man and cats.

All of these are known as liver flukes, being found in the bile-passages and upper part of the small intestine. When numerous, they give rise to very serious disturbance, including cholangitis with resulting jaundice, enlargement of the liver, emaciation, diarrhea, and often ascites.

(b) *Blood Flukes.*

SYNONYMS.—*Bilharzia hæmatobia*; *Schistosoma hæmatobium*; *Distomum hæmatobium*; *Distomum capense*.

This distoma was first described by Bilharz in 1852. The male is thread-like, from 4 to 15 mm. (0.1574 to 0.5905 inch) long and 0.6 mm. (0.0236 inch) wide in the widest portion; the female is much longer than the male,—from 15 to 20 mm. (0.5905 to 0.7874 inch),—but much narrower, so that it may enter the *canalis gynecophorus* of the male.

It inhabits the venous system, especially the portal vein and the veins of the spleen, kidney, the venous plexuses of the bladder and rectum in boys of the lower classes, more rarely men and women in Egypt and Africa, 50 per cent. of the former being infested, according to Bilharz. It is geographically much more widely distributed in Africa, throughout the east coast as far as Capeland, in numerous districts in the interior, and from the gold coast to Algiers.

Symptoms.—The symptoms of the bilharzia disease begin usually with hematuria and burning pain in the urethra, the latter increased during micturition and due to the irritation of the worm. In addition to blood the urine contains pus, shreds of mucus, and the eggs of the bilharzia, which are easily recognized with a low power of the microscope. They are ovoid and terminate in a thorn-like end. The larva may be seen in the interior of the egg. The ova may become the nucleus of stone in the bladder, a fact which is held responsible for the large number of cases of stone in the bladder in Egypt. Hypertrophy of the prostate may ensue. The large bowel may be invaded, causing dysentery. The hemorrhage may lead to anemia, debility, and exhaustion, terminating fatally, though most cases recover. Attacking, especially, children, the disease commonly disappears at puberty.

(c) *Bronchial Flukes.*

SYNONYMS.—*Distomum Westermanni*; *Distomum pulmonalis*.

This is an ovoid fluke from 8 to 10 mm. (0.3149 to 0.3937 inch) long and from 4 to 6 mm. (0.1574 to 0.2362 inch) broad, of a reddish-brown color. It is met in various parts of China, Japan, and Formosa, where it infests the bronchial tubes, causing cough and hemoptysis.

B. CESTODES, OR TAPE-WORMS.

(a) *Intestinal Cestodes.*

Historical.—When mature, these occupy the intestine of man. The larger forms, at least, of tape-worm were known to the ancients as animal parasites infesting the alimentary canal. The correct notion of the origin and development of the tape-worm is, however, comparatively recent, and for a long time the young worm

was supposed to start from the links or proglottides of the adult worm. The cysticerci or larval forms have also been long known, but they were regarded as simple cystic tumors until almost simultaneously Redi in Italy, and Hartmann and Weper in Germany, inferred their animal nature, after which they were regarded as worms, and made by Zeder, in 1800, a separate class of bladder worms.

In 1683 Edward Tyson discovered the head with its double row of hooklets in a large tape-worm in a dog; in 1684 Redi recognized the head and the suckers of several tæniæ; in 1700 Andry recognized the head of the *tænia saginata*, and in 1777 Bonnet and in 1779 Gleichen-Russworm that of the *bothriocephalus*. From that time it was believed by most authors that the tape-worm was an animal which nourished itself by fastening its head into the intestinal wall. About the middle of the last century Küchenmeister, by his celebrated feeding experiments, proved that the cysticerci or bladder worms represented a larval stage in the development of the tape-worm, the latter having for its habitat the intestine of man, and the former, the muscles and solid organs of certain lower animals and rarely of man.

Varieties of Tape-worm Infesting Man.—Of the several varieties of tape-worm which infest man, five only deserve special consideration—viz., the *tænia saginata* or *mediocanellata*, the *tænia solium*, the *bothriocephalus latus*, the *tænia flavopunctata*, and *tænia confusa*.

The *tænia medicanellata* or *tænia saginata* is known as the beef tape-worm, because its embryos or cysticerci are found, as a rule, in cattle, producing the so-called "measled" veal and beef; also as the "unarmed" tape-worm, because the head is unprovided with hooklets. It has been found in the flesh of the giraffe. The *tænia solium* is known as the pork tape-worm, because met in the larval state in the flesh of swine, producing "measled" pork; and as the "armed" tape-worm, because of the hooklets named. The beef tape-worm, or *tænia medicanellata*, is the most common form of tape-worm occurring in the United States, and I believe also at this time on the Continent of Europe, especially in Western Europe. In the middle of Germany it is less unusual to eat uncooked pork, and although the laws of inspection there are very stringent, the *tænia solium* has been, at least until recently, the most common variety of tape-worm there. But in Holstein Heller has met the *tænia saginata* four times as often as the *tænia solium*. The late Professor Leidy, to whom large numbers of worms were constantly being sent for opinion, informed me that all specimens sent to him for examination during a period of fifteen years were *tænia medicanellata*.

The *tænia medicanellata*, or unarmed worm, has a head quadrate in shape, from 1.5 to 2 mm. (0.06 to 0.0787 inch) in diameter, provided with four suckers, placed one toward each angle of the head, and a small central rudimentary sucker without rostellum or circlet of hooks. To this head succeeds a slender neck, then the links. The *tænia solium* has a smaller head, spherical in shape, from 0.6 to 1 mm. (0.0236 to 0.0393 inch) in diameter, provided, in addition to the four suckers, with a proboscis or snout called a rostellum, on which are two rows of hooklets, the inner row being the longer. There are from 12 to 14 in each row, making in all 24 or 28. The heads of both worms are at times more or less pigmented. There is also a difference in the segments. The ripe segments of the *tænia saginata* average from 16 to 20 mm. (0.63 to 0.8 inch) in length and from four to seven mm. (0.1574 to 0.275 inch) in width. The ripe segments of the *tænia solium* average from 10 to 12 mm. (0.4 to 0.47 inch) long and from 5 to 6 mm. (0.2 to 0.2362 inch) broad.

Tape-worms are hermaphroditic, both sets of reproductive organs being contained in one segment. Further peculiarities of these organs will be considered in speaking of diagnosis. As to the length of the entire worm, the

tænia mediocanellata is put down at from 4.8 to 7.2 meters (16 to 24 feet), but I have known more than ten meters (40 feet) to be passed. The *tænia solium* is usually much shorter—from 1.8 to 3.6 meters (6 to 12 feet), but may be longer. The number of links or proglottides in the *tænia solium* is from 800 to 900, in the *tænia saginata* 1000.

How do these tape-worms obtain access to the intestine of man? As already stated, the larva or cysticercus of the *mediocanellata* is found in "measly" beef. The egg containing the larval or embryo worm is in some way ingested by cattle. The envelope with which it is surrounded is digested, and the embryo released. The latter is provided with hooklets arranged in three pairs, one central and two lateral. The central pair are simply stilettos for boring, the lateral for tearing and propulsion. By these means it bores its way through the intestinal wall and invades the muscular tissue, where it becomes encysted, forming the *cysticercus bovis*. It is a singular fact, however that the "measles" of *tænia saginata* very rarely come under observation. When found, the cysticercus of this worm is an oval cyst, scarcely as large as a pea, and is probably often overlooked. Notwithstanding its apparent rarity it is responsible for the majority of tape-worms in man.

In the case of the *tænia solium*, the links of the worm thrown off by man in the feces are eaten by the pig; during digestion the shell of the egg is dissolved, and the embryo liberated. The embryo of the *tænia solium* is not provided with the double row of hooklets possessed by the mature worm, but, with six hooklets only, arranged in pairs like the hooklets of the *tænia saginata*. It invades the muscular tissue, like the *tænia saginata*, becomes encysted, and thus the *cysticercus cellulosa telæ* is formed, and the pork becomes "measled." The "measle" of pork is larger than that of beef. In the former it sometimes reaches a length of nine-tenths of an inch (22.86 mm.), while in the latter it is, as a rule, not more than one-fourth of an inch (6.3 mm.) in length.

The "measles" of beef and pork are rendered inert by cooking, but it constantly happens that imperfectly cooked beef or pork is eaten, when the capsules of the embryo are dissolved off in the stomach, the embryo passes into the small intestine, attaches itself, and grows. From twelve to sixteen weeks after the attachment of the larva fragments of the worm may be discovered passing per anum.

The laws demanding the inspection of pork and beef are causing the tape-worm to become less common, but it is still quite often met. At the present day we are much less in the habit of eating uncooked pork than underdone and raw beef. This is also the case in England. It is on this account that the pork tape-worm is less common in America and England than the beef tape-worm.

The third variety of tape-worm, the *bothriocephalus latus*, is distinguished by the greater width of its segments and their shortness in an anteroposterior direction. These statements refer to the average, for the links taken from different parts of the same worm vary much in their dimensions. The number of links of the *bothriocephalus* is from 3000 to 4000. Still more widely does the head of the *bothriocephalus latus* differ from that of either of the two which I have described. It has neither rostellum nor hooklets, is club-shaped, 1.5 mm. (0.06 inch) long and one mm. (0.04 inch) wide, and is marked by two lateral depressions. The head, therefore, is less formidable than that of either of the two other worms.

This worm is not often met in this country. It is more common in Switzerland and Russia, but is also found in Ireland, Sweden, and Germany, especially in Eastern Prussia, and recently in the neighborhood of the Starnberger See and Munich. It is called the Irish tape-worm as well as the Russian and Swiss tape-worm. It is believed that the cysticercus of this variety of tape-worm is found in certain fish of the salmon and trout family, and that man acquires the worm by eating these fish uncooked. The length of the bothriocephalus is put by Heller at from 4.5 to 7.5 meters (15 to 25 feet), but if it be the longest of the tape-worms, as is generally stated, it must at times far exceed this.

There is still another form of tape-worm which, there is reason to believe, is more common than is supposed. This is the *tania flavopunctata*. It is a small tape-worm, not exceeding from 30 to 37.5 cm. (12 to 15 inches) in length. In the "American Journal of the Medical Sciences" for July, 1884, the late Dr. Leidy described the segments of one of these worms from specimens sent to him. They were passed by a child three years of age after the administration of santonin. In fact, all the specimens of this worm as yet described seem to have come from children from fifteen months to three years of age. The joints are proportionately short in all cases, the breadth exceeding the length several times. They are transversely linear, slightly wider back of the middle, with the posterior angles rounded and the posterior margin slightly, but irregularly crenate. The anterior immature joints exhibit no distinct traces of sexual organs, while succeeding ones have a more coarsely granular appearance, due to the presence of immature eggs. The pair of longitudinal vessels common to all tape-worms are conspicuously visible in the segments. At the posterior part of the body the joints in a ripe condition are of a pale-brown color, due to the contained eggs. The ripe joints are interrupted here and there by a variable number—one or more—of sterile joints. The ripe joints are longer, broader, and thicker. The eggs distend the joints and are diffused throughout a simple cavity, bounded by thin parietes, and are not inclosed in ramified or dendritic uterine pouches, as is the case with most tape-worms. In Dr. Leidy's specimens the mass of eggs so concealed everything in these joints that the generative apparatus could not be determined. But in the joints devoid of eggs there was to be seen a narrow, clavate organ, which Dr. Leidy suspected to be the seminal receptacle, together with four or five oval bodies, probably testiculæ. In these joints only, as a rule, could the genital aperture be recognized at the lateral margin of the joints, immediately behind the middle.

The joints of this tape-worm range in length from 0.2 mm. (0.008 inch) in the neck to 0.5 mm. (0.02 inch), an inch (2.5 cm.) from the posterior extremity; and in width from 0.63 mm. (0.025 inch) in the neck to 2.5 mm. (0.1 inch), an inch from the posterior extremity. The mature eggs are raw-sienna colored, mostly spherical, and 0.07 mm. (0.003 inch) in diameter. The specimens sent to Dr. Leidy were parts of three worms, so it would seem that more than a single worm may infest the host, which is the case with other cestoid worms.

Another instance of this worm has been described by Dr. Weinland, of Cambridge, Mass., and a third by E. Parona, in Italy. It was named by Weinland *tania flavopunctata* in consequence of yellow spots lying near the middle line in each successive joint, and representing, according to Dr. Weinland, a testicle. This spot had disappeared in Dr. Leidy's specimen

as it had also in Dr. Weinland's when it reached Professor Leuckhart some years afterward. The inclosed embryos are oval and are provided with six hooks arranged in three pairs. The intermediate or larval condition of this worm is unknown. I have taken some pains to describe the *tania flavo-punctata*, because, as I have already said, it may be more common than is usually supposed, and it is desirable that it should become so familiar that it may be recognized when met. The larvæ are developed in lepidoptera and beetles.

Tania confusa is the name given by Henry B. Ward to a new tape-worm described by him in 1896. Its length is about 5 cm. (2.0 inches); the terminal proglottides are 25 to 35 mm. (1 to 1.3 inch), long and 3.5 to 5 mm. (0.14 to 0.20 inch) wide, somewhat larger than the ripe links of *tania saginata* and *tania solium*. Its scolex has a diameter of 3 mm. (0.066 inch) quite small, provided with four suckers and a retracted rostellum with six or seven rows of small hooks,* the largest hooks being in the external row.

Symptoms of Tape-worm.—Given a tape-worm in the human intestine, what symptoms does it produce? It has often happened that the parasite has been present without giving rise to any symptoms, having been accidentally discovered by the expulsion of segments.

The signs occasioned by its presence may be put down in general terms as those of irritation. They may be either direct or reflex. Among the direct consequences are vague abdominal pains, nausea, and meteorism. Nausea is very common, and both it and the pain are easily accounted for by the irritation of so large a mass of living matter in the intestine. The reflex phenomena include a great variety of nervous symptoms, among which may be named headache, vertigo, dizziness, epileptiform convulsions, reflex paralysis, and even insanity; loss of appetite, and other disorders of digestion, faintness, derangement of vision and of hearing, including noises in the head. Itching and dryness of the nose and anus and vague pains throughout the body are sometimes noticed. Sensations of weariness and vague discomfort may alone be present. The only distinctive symptom is, however, the passage of links of the worm. Notwithstanding the presence of these symptoms, we are often compelled, in the absence of positive demonstration,—*i. e.*, the passage of pieces of the worm,—to administer a purge, in the action of which segments will be passed if a worm is present.

Diagnosis.—It is a matter of no small importance that physicians should be able to distinguish the different varieties of tape-worm, for the difficulties of treatment vary considerably with the different worms, the *tania saginata* being much more easily dislodged than the *tania solium*; and the *bothriocephalus latus*, perhaps, easiest of all. In the first place the frequent spontaneous expulsion of segments of worm may be taken as presumptive evidence that they belong to the *tania saginata*, as those of the *tania solium* rarely drop off. Again, the segments of *bothriocephalus latus*, while occasionally expelled, are seldom expelled singly, being discharged in pairs or several joined.

The segments of the *tania saginata* are stronger, thicker, and less transparent, and when expelled spontaneously, contain very few eggs. The uterus which contains the eggs, and which may generally be demonstrated by allowing a segment to dry on a piece of glass, or, better, slightly compressed between two glass slides, is composed of a central canal with lateral

* "A New Human Tape-worm," Henry B. Ward, "Western Med. Rev." vol. i., 1896.

branches which are more distinct and less numerous in the *tenia solium*—being from 9 to 12—than in the *tenia saginata*, which has from 15 to 20. The genital pores are lateral in the case of the *tenia solium* and *tenia saginata*, but central in the *bothrioccephalus*, which has also a brown, rosette-shaped uterus very easily distinguished from that of the other two more common forms of teniæ.

The *tenia confusa* has a most distinctive head, is very slender compared with the three other worms infesting man.

Prognosis.—This is favorable, as a rule, in all forms of tape-worm, but the *tenia saginata* and *bothrioccephalus latus* are much more easily dislodged than the *tenia solium*, the head of which often resists removal for a long time, the segments continuing to reproduce themselves until the head is dislodged. From eight to twelve weeks are usually necessary for the worm to redevelop itself to a size at which segments are again discharged.

Treatment.—There is, perhaps, no morbid condition which has brought more opprobrium upon the regular profession and more “grist to the mill” for advertisers and those who use secret remedies than tape-worm, and to our humiliation it must be said that these persons do seem to have more success in getting rid of tape-worm promptly than we do. There are, I think, two reasons why this is so. In the first place, it is certain that they do not use different remedies from those commonly in use by the profession, but they give larger doses. In the second place, they see a large number of cases and develop a sort of specialty which, like all specialties, produces greater skill in treatment. In order that a tape-worm may be successfully removed it is necessary that it shall be of a certain size; so that, if a large part of the worm has been brought away by medicine, it is useless to give anything more until the remaining part increases sufficiently in size.

There are half a dozen remedies for tape-worm, and they are all good. I think that the two best are probably the ethereal extract of male fern and kousso flowers. Some prefer the first of these, while others prefer the second. In my hands kousso has been decidedly the most efficient—that is, having failed with everything else and having succeeded with *kousso*, it has naturally become the remedy with which I usually begin the treatment. It is the dried flowers and immature fruit of the *brayera anthelmintica*, a tree native to Abyssinia.

Patients require some preparation before any remedy is employed. In all cases they should be kept absolutely quiet during treatment. They should eat nothing from breakfast time of one day until the next morning, during which the bowels should be moved by a saline cathartic, when one ounce (30 gm.) of kousso and eight ounces (240 c. c.) of water are to be taken. A more pleasant way is to give seventy-five grains (5 gm.) in a glass of white wine every half hour until four doses are taken. If at the end of six hours no movement of the bowels has taken place, a promptly acting aperient, as a dose of oil, compound jalap powder, or elaterium, is taken, but generally kousso requires no purgative after it. The worm is usually discharged entire. Of course, one is never certain that this is the case unless the head is found. At the same time, it does not follow because the head cannot be found that it has not been passed, for it is very small, and may be lost in the discharges. In the *tenia solium* the head is about the size of a small pin's head; in the *mediocanellata* it is a little larger, and in the *bothrioccephalus* it is still larger. If the head has not been removed, it is certain that in from ten to sixteen weeks the worm will grow out again and begin to

discharge links. Koussou is said to have induced miscarriage; it should not, therefore, be given to pregnant women. Instead of koussou, the resin which it contains, called *koussin*, may be given, but I have had no experience with it. The dose is from twenty to forty grains (1.33 to 2.66 gm.), inclosed in a wafer. The fluid extract is also efficient in dose of half a fluid ounce (15 c. c.).

The next remedy in efficiency is the ethereal extract of the rhizome of *aspidium filix mas*, or male fern, whose active principle—an oleoresin—is extracted by ether. The preparation of the patient is about the same as for koussou. The dose of the ethereal extract is from 2 to 2 1-2 drams (8 to 10 c. c.), followed in a couple of hours by a purgative. It is a dark, thick liquid, bitter, slightly acrid, and nauseous. Instead of the ethereal extract of male fern the oleoresin may be given in a gelatin capsule. The dose is from 1 1-2 to 2 fluid drams (3.88 to 7.4 gm.). Two hours later a dose of purgative medicine should be administered. An important point to be borne in mind is the varying quality of these drugs, and that they deteriorate with age.

The third remedy, in order of efficiency, is the bark of the root of the pomegranate. This has been given in the shape of a decoction, from two to four ounces (60 to 120 c. c.) to the pint (0.5 liter). Boil the bark half an hour, strain, and drink. The fluid extract is more convenient in the dose of from forty-five minims to two fluid drams (3 to 8 c. c.). Two hours later a purgative should be given. An alkaloid is obtained from pomegranate, named pelletierine, in honor of the chemist, Pelletier. This is sold in a single dose of from eight to twenty-five grains (0.5 to 1.6 gm.). When first introduced, it was vaunted as a "sure cure," but the experience of practitioners has not been uniform, and success has been by no means invariable. I have been successful with it.

Kamala, the hair of the *rottlera tinctoria*, is said to be very efficient in tape-worm, but I have had no experience with it. It is given in doses of from one to two drams (4 to 8 gm.) suspended in syrup, repeated in from eight to ten hours if it does not purge. The fluid extract is also given in doses of half a dram to a dram (2 to 4 c. c.). It is purgative, sometimes drastically so. It may also cause nausea and vomiting.

Another efficient remedy is the oil of turpentine. It is, however, apt to produce symptoms so unpleasant that it should be the last used. The dose is from an ounce to two ounces (30 to 60 c. c.), mixed with twice that amount of castor oil—a horrid dose, but if others fail, it may be tried.

Still another is pumpkin-seed. There are two ways in which it may be given. Three or four ounces (30 to 120 gm.) of the seeds may be crushed in a mortar with water, then strained, and the emulsion taken fasting, after a day's dieting. A few hours later a brisk purge should be taken. Second, the seeds may be made into an electuary which is almost as pleasant as sugar candy, and often is about as effectual. I should place these different remedies in the order of their efficiency as follows: koussou, male fern, pomegranate, kamala, turpentine, and, lastly, pumpkin-seed.

Combinations are sometimes very efficient. The following is recommended by Strümpell:

℞	Granati corticis radicis,	℥ iv-v (120 to 150 gm.)
	Aquæ,	Oij (1000 c.c.)
	Macerate for twenty-four hours and boil until it is reduced to five fluid ounces (150 c.c.)	
	Add:	
	Oleoresinæ filicis,	gr. lxxv (5 gm.).

The whole amount is to be taken in three or four doses as close together as possible.

Thymol, in doses of ten grains (0.66 gm.) three times a day in a wafer, has been recommended. Another method is to give five grains (0.33 gm.) every hour with or without preparation. Papain juice of *carica papaya* is given in doses of from one to ten grains (0.066 to 0.66 gm.).

It is sometimes useful to know the exact course pursued in a given successful case. Thus, in such a case the patient was fasted for twenty-nine hours. Twelve hours after fasting began he was given one ounce of castor oil. Twenty-four hours after fasting began he was given 1, 1-2 drams (5.55 c. c.) of oleoresin of male fern. In five hours more he was given another ounce of oil. The worm came away entire in a mass.

Prophylaxis is of the greatest importance. Great attention should be paid to the cooking of meats, especially of large joints, in order that they may be thoroughly "done." Rare meats should not be eaten.

(b) *Visceral Cestodes.*

1. *Cysticercus Cellulosæ*.—It is not only as tape-worm that the system is in danger from these parasites. Human flesh may also become "measled," or infested with *cysticercus cellulosæ*. Although the beef measles has thus far never been found in man, some sixty or seventy cases have been noticed in which the pork measles is said to have caused death. As I have explained, the embryos already contained in the links of the worm are developed into cattle in that of the *tania saginata*. When cysticerci infest human beings, the embryos may have been introduced with food or drink; but more frequently the links are regurgitated* into the stomach, and there dissolved by the gastric juice. The embryos, thus released, migrate into the tissues and become there encysted—*cysticercus cellulosæ* in human tissue. Situations in which cysticerci are found are the brain, spinal cord, and cavity of the eyeball. In the former a train of symptoms is developed which sometimes suggests a diagnosis. In other situations they seldom give rise to any symptoms. Even in the brain they may occupy the "silent region" without evincing symptoms. Seated in the subcutaneous tissue, they may give rise to stiffness and pain on motion.

2. *Echinococcus Disease*.—Another effect, in the human being, of tape-worm is the echinococcus or "hydatid cyst." This is the result of the ingestion of the embryo of a small tape-worm known as the *tania echinococcus*, or hydatid-forming tape-worm. This small tape-worm, which is not more than 1-5 inch (4 to 5 mm.) in length, is very common in dogs. It is composed of three or four segments, of which the terminal one alone is mature. This segment is about two mm. (0.08 inch) long and 0.6 mm. (0.025 inch) wide. It contains about 5000 eggs. The head of the worm is very much like that of the *tania solium*, provided with a rostellum, two rows of hooklets, and four suckers. The embryo also has six hooks, arranged in three pairs, by which it burrows through the intestinal wall and reaches the peritoneal cavity or muscles, or it may enter the portal vessels and be carried to the liver. By the systemic vessels it may reach the brain and other distant parts. Its most common seat is the liver. It may find entrance with food

* Portions of tape-worm thus regurgitated may even pass by the mouth.

and drinking-water, which may contain scores of these larvæ and yet appear pure; or the embryos may be inhaled with dust.

Geographical Distribution of Echinococcus.—Except in Iceland, where there are more dogs than persons, and Australia, where the intercourse between man and dogs is also very intimate, echinococcus disease is rare in human beings. In Iceland the ratio is put by various authorities as from 1 in 6, to 1 in 61 residents. In some parts of Germany it is not very rare. Thus, in Rostock, during a period of twenty-three years, there was one case of hydatid disease to 1414 residents; in Upper Mecklenburg, one in 129,000 persons, and in Greifswald, one out of seventy-five autopsies disclosed the disease. It usually affects persons between twenty and forty. In Manitoba, North America, where there are settlements by Icelanders, the disease is not very infrequent. Thus, A. H. Ferguson reports that between forty-five and fifty subjects have been treated in Winnipeg since 1874, when the Icelandic immigration occurred.

Of the organs and tissues invaded, the liver is the most frequent, fully half of all hydatids being found in this organ. After this the kidneys, bladder, and genitals in about 10 per cent.; intestinal canal, 9 per cent.; lungs or pleura, 8 per cent.; brain and spinal cord, 6 1-2 per cent.; bones, 3 1-2 per cent.; heart and blood-vessels, 3 1-2 per cent.; other organs, about 8 per cent. Of 85 cases collected by Wm. Osler in Canada and this country up to 1891, the liver was the seat in 59—considerably over 50 per cent.

The symptoms, diagnosis, and treatment of hydatids of the liver were given when treating diseases of the liver.

The symptoms of hydatids elsewhere are not distinctive. In the pleura and lungs the discharge of hooklets through a perforation in the chest-wall alone justifies a diagnosis of hydatids in the pleural cavity; the finding of hooklets in the urine, hydatid of the kidney or urinary passages. The symptoms of hydatids of the brain are those of brain tumor, the disease being more frequent on the right side. The presence of hydatid disease elsewhere is presumptive evidence that the brain symptoms are due to hydatid disease.

Treatment.—The treatment of hydatid disease, so far as any is possible, is given in connection with the diseases of the various organs in which it occurs.

III. NEMATODES, OR ROUND WORMS.

Of these, the ascarides, the trichinæ, the anchylostoma, and the filariæ are the most important.

A. THE ASCARIDES.

(a) *The Ascaris lumbricoides.*

Description.—This, the ordinary round worm, is the most common human parasite. It is found more frequently in children, but is not rare in adults. The worm is also found in cattle and in hogs. It is cylindrical, pointed at both ends, yellowish, striated, and longitudinally marked by four bands. The female is from 15 to 25 cm. (6 to 10 inches) long, the male from 10 to 20 cm. (4 to 8 inches). Its resemblance to the ordinary earth worm is so close that it is not easy to distinguish them. The ova, often very numerous in the feces, are brownish-red and have a thick shell. They are 0.075 mm. (0.0039 inch) long and 0.058 mm. (0.0023 inch) wide.

The worms are probably developed from eggs which are swallowed in food and drink. They inhabit the upper part of the small intestine, commonly one or two, but sometimes large numbers. From this situation they may emigrate downward and pass out of the anus or upward into the stomach and esophagus, whence they may be withdrawn through the mouth or nose, or they may be vomited. They may even enter the trachea and produce suffocation, or the Eustachian tube, passing out of the ear at the external meatus. They sometimes invade the common bile-duct and its branches in the liver.

Symptoms.—Often there are none, the worms being accidentally discovered. At other times there are colicky pain, meteorism, fretfulness in children, vertigo, headache, chorea, and even convulsions. Grinding of the teeth in sleep by children is regarded by the laity as a symptom of "worms." It is probably caused by gastro-intestinal irritation of any kind. No symptom is to be relied upon which is not supported by ocular demonstration. Obstruction of the bowel has resulted from the presence of large numbers forming knotted masses or balls. If a worm enters the bile-ducts, obstructive jaundice is almost sure to be caused by it.

Treatment.—The remedy which has been most satisfactory in my hands is santonin in combination with calomel. Powders containing santonin and calomel, of each one or two grains (0.066 to 0.132 gm.), may be prescribed rubbed up with sugar of milk. Of these, one is given night and morning until the bowels are freely moved. The santonin may color the urine and produce yellow vision, or xanthopsia, but I have never seen harmful results in a large experience, though poisoning, manifested by convulsion, is said to have been produced. For very young children the dose may be reduced to 1-4 to 1-2 grain (0.0165 to 0.033 gm.). The worm tablets extensively advertised usually contain santonin as their basis. There is an official troche, U. S. P., containing 1-2 grain (0.033 gm.) of santonin. Santonica, or Levant wormseed, whence santonin is derived, is no longer used. What is known as wormseed oil, the oil of chenopodium, another excellent remedy for round worm, is derived from the *chenopodium anthelminticum*, or American wormseed. The dose is ten minims (0.65 c. c.) to a child of five years. on a lump of sugar or in emulsion—before breakfast, dinner, and supper for two days, followed by a purge, of which none is more suitable for children than calomel, itself a vermicide.

(b) *Oxyuris vermicularis*.

SYNONYMS.—*Thread Worm*; *Pin Worm*.

Description.—The oxyuris is a minute white worm, well named thread worm, the male being from three to five mm. (0.1181 to 0.1968 inch) long, the female twenty mm. (0.7874 inch) long. Both sexes are rather blunt at one end and finely pointed at the other. It infests the rectum and colon of children and adults, more frequently the former. It migrates and may be found in the bed, and its ova are sometimes carried to the nose under the nails used in scratching. The primary infection is believed to be by uncooked fruit and vegetables containing the ova, which may, however, be transferred from person to person, from hand to hand, or otherwise by contact. It has been suggested that they may be transmitted through the excrement of flies. The worms are very easily detected in the feces, which contain also immense numbers of the ova. Their presence produces intense itching,

especially at night, when the worms migrate. This causes restlessness and sleeplessness, and may even cause convulsions in children and may weary and exhaust adults.

Treatment.—Some perseverance is sometimes necessary to get rid of the thread worm. I usually prescribe the same powder of santonin and calomel as for the round worm,—*i. e.*, from one to two grains (0.066 to 0.132 gm.) of each,—but at the same time order nightly injections into the rectum of vermicides, of which there are many—the infusion of quassia, of aloes, lime-water, vinegar, corrosive sublimate (1 to 500), salt and water. The injection should be retained for some time, and to this end the buttocks should be raised, or the child may be placed on its hands and knees. Only as much should be introduced—from two to four ounces (60 to 120 c. c.)—as can be conveniently retained. Too large a quantity is promptly rejected.

B. TRICHINIASIS.

Definition.—The name given to the invasion of the tissues of the body by the *embryos* of the *trichinia spiralis*. The mature, sexually developed worm has its habitat in the small intestine of man and other mammalia.

Historical.—The history of the development of our knowledge of the trichina is very interesting, and may be found admirably condensed in the little book by Max Braun, "Die thierischen Parasiten des Menschen," second edition, 1895. It was discovered in human muscle by Owen in 1835, but it was not until 1860 that Zenker showed that it was at times a cause of death in man. Since then three epidemics of trichiniasis have prevailed in Germany.

Description.—The *adult* male is from 1.4 to 1.6 mm. (0.055 to 0.063 inch) long, 0.04 mm. (0.0015 inch) thick, with a cloacum opening between two little projections in the hinder end. The female is from three to four mm. (0.1181 to 0.1574 inch) long, and 0.06 mm. (0.0023 inch) thick. The head is pointed and the tail is rounded. The larva or muscle trichina is from 0.6 to 1 mm. (0.0236 to 0.0393 inch) long, and lies coiled in an ovoid capsule which is at first translucent, but subsequently becomes opaque by calcification. Man, hogs, rats, guinea-pigs, and rabbits are easiest infected.

Man commonly acquires trichiniasis by eating infected ham insufficiently cooked. The capsules are digested and the trichinæ set free; they pass over into the small intestine and there develop into the sexually mature worm, attaining maturity about the third day. Each one discharges large numbers of embryos, of which the males die immediately after birth, while the females bore their way into the mucous membrane. A part perforate the intestinal wall and find their way into the mesentery and lymphatic glands of the mesentery. The young brood is carried away from the bowel in the lymph stream, and is distributed partly through the blood stream and partly by active migration. Before birth the young trichinæ are from 0.09 to 0.1 mm. (0.0035 to 0.0393 inch) long, growing slightly during migration, say from 0.12 to 0.16 mm. (0.0047 to 0.0063 inch). Their favorite seat of lodgment is the striated muscular tissue, within the striped muscular fasciculus itself, or between the muscular fasciculi and parallel to them. In nine or ten days after infection the first brood reaches its destination, to be followed by others, since the intestinal trichinæ continue to produce young throughout a life of seven weeks. A single worm, it is said, may bring forth from 8000 to 10,000.

The young trichinæ begin to be encysted in the muscle about the second or third week after infection, by which time the parasite has grown to 0.8

mm. (0.0314 inch) in length. Each one arranges itself in a spiral, of which the outline is oval, and becomes surrounded by a capsule of corresponding shape, the worm cyst lying with the long axis parallel to the direction of the muscular fibers. The cyst is transparent, 0.4 mm. (0.0157 inch) long, and 0.25 mm. (0.0098 inch) wide. After from five to eight months calcification may even involve the inclosed trichina itself. On the other hand, the capsule may undergo fatty degeneration, a pathological change which takes place at times early, at others only after the lapse of years. The encapsulated trichina remains living and capable of development for a long time—according to Damman in hogs eleven years, while in man they have remained living twenty-five, twenty-seven, thirty, and forty years after infection. It has been shown by Zenker that the encysting is not a necessary condition to the mature development of young trichinæ.

Human infection having been conclusively shown to be due to the eating of raw pork infested with trichinæ, it is not at once evident how swine become infected. It is well known that the rats which infest slaughter houses are infected in large numbers, but it is plain also that they may acquire trichinæ by eating pork. The two probably contribute mutually to the perpetuation of the disease.

As to the distribution of the trichiniasis: most epidemics have been in Germany. Even in America, where there have been two or three epidemics, it has been in German immigrant communities. Apparently it is rather the imperfect cooking of the pork which is responsible, for although a larger percentage of American pork appears to be infected than German, yet, as already stated, the disease is much more infrequent in America than in Germany. It is to be remembered that while thorough cooking effectually destroys the parasites, the requisite heat may fail to reach the interior of large joints containing viable larvæ.

Symptoms.—The immigration of numerous active parasites in muscular tissue is followed by intense irritation, manifested at first by fever and muscular pain. The latter is especially severe during motion. The acts of chewing, swallowing, and breathing are particularly difficult, because of the pain excited by these acts. In the early stage of the disease diarrhea is quite common, so that certain epidemics have been mistaken for typhoid fever and as often also for rheumatism. In the very beginning of the immigration into the muscles edema has sometimes been observed. The more general and thorough the invasion, the more intense the symptoms. Very high fever, delirium, infiltration of the lungs, and fatty degeneration of the liver have been observed. Death may take place either from exhaustion as the result of extreme irritation, or later in the disease from the same cause preceded by anemia and gradual loss of strength. Usually, however, improvement sets in about the fourth or fifth week, though convalescence in bad cases is slow, and many weeks elapse before recovery is complete.

Diagnosis.—It is usually the unexpectedness of the disease which leads to delay in diagnosis. The resemblance of the symptoms to those of *typhoid fever* and *muscular rheumatism* has been referred to, yet in the presence of a possible cause—as, for example, a German picnic or other feasting occasion where the favorite ham or sausage has formed part of the feast—such symptoms should immediately excite suspicion. The discovery by Dr. Thomas R. Brown in 1897* that eosinophilia is constantly associated with

* "Johns Hopkins Hospital Bulletin," April, 1897.

trichiniasis is important and when present is confirmatory of the existence of the disease. A differential blood count should therefore be made in suspected cases. When doubt exists, the harpoon, designed for obtaining samples of muscle for examination, should be unhesitatingly used, under ether or local anesthesia, and the part removed carefully examined under the microscope.

Treatment.—Here, as so often elsewhere, an “ounce of prevention is worth a pound of cure.” Such prevention consists in thorough official inspection of all pork brought to market, because cooking may fail of its purpose for the reasons already mentioned. For a similar reason swine should be grain-fed, rather than allowed to feed on offal. It is doubtful whether any direct measures can be used for arresting the disease after the muscles have once been invaded. It is a simple conflict of the mastery between the strength of the patient and the life of the trichinæ. In the majority of cases the former triumphs, though death is not infrequent from the causes named. If the disease is recognized early, the alimentary canal should be treated with vermicides and purgatives, with a view to getting rid of all the sexually mature worms which may happen to remain there, since it will be remembered that successive broods develop from the same mother-worm while in the intestinal tract. Glycerin, given in a tablespoonful (30 c. c.) dose hourly, is said to destroy the trichinæ. Benzine, in one- to two-dram (4 to 8 gm.) doses in capsules, and picric acid in dose of from five to eight grains (0.3 to 0.5 gm.), are also recommended, but are regarded as less reliable. To relieve the pains, hypodermic injections of morphin, 1-4 grain (0.0165 gm.), or warm baths may be used. Restoratives and stimulants should be given to keep up strength.

C. ANCHYLOSTOMIASIS—UNCINARIASIS.

Definition.—A term applied to the invasion of man by the *anchylostoma* or *sclerostoma duodenale*, also known as the *uncinaria duodenalis*, *dochmius anchylostomum*, *strongylus quadridentatus*, and *strongylus duodenalis*.

Description.—The male is from eight to ten mm. (0.3149 to 0.3937 inch) long, and has a prominent expansion or bursa at the tail end. The female is from 12 to 18 mm. (0.4724 to 0.7086 inch) long; both are provided with hook-like teeth, by which they attach themselves to the mucous membrane. The ova, which are abundant in the stools, are ovoid, 0.052 mm. (0.002 inch) long and 0.03 mm. (0.0012 inch) broad, provided with a thin, transparent shell and deposited in a state of segmentation. The habitat of the worm is the duodenum and the upper jejunum of man and certain anthropomorphous apes, it is said, throughout the inhabited globe; but beyond some apocryphal descriptions by physicians of the South American States, it is unknown here. Max Braun also says it is sporadic only in the colder countries, being more prevalent in southern latitudes, especially those of Italy and Poland; in fact, it has been largely spread by laborers from these countries throughout Germany and Austria-Hungary, the West Indies, and Brazil, the St. Gothard tunnel being one of the localities in which it was first studied. The larvæ are developed in damp earth and distributed by wind and water. Many of the victims are earth-eaters. Late years have shown a remarkable increase in anchylostomiasis in this country, for a dis-

semination of accurate knowledge of which we are indebted to Dr. Allen Smith of the University of Texas.

Symptoms.—The parasite fastens itself to the mucous membrane by the hooked teeth described, and feeds upon blood drawn therefrom. At first only causing gastro-intestinal irritation, there gradually results an anemia variously known as Egyptian chlorosis, brickmaker's anemia, tunnel anemia, and mountain anemia. The rate of development of the anemia varies, being sometimes very rapid. There occur also colicky pains, diarrhea, and small hemorrhages. A consequent symptom is extreme weakness and indisposition to effort mental or physical. Hypertrophy and dilatation of the heart have been found.

Diagnosis.—The diagnosis is rendered easy by the conditions surrounding the victims and confirmed by the discovery of eggs in the feces. At autopsy they may be found clinging to the mucous membrane in the duodenum and upper ileum. Anchylostomiasis, like trichiniasis and filariasis, is associated with eosinophilia. The latter condition is therefore helpful in diagnosis.

Treatment.—In treatment prophylaxis is most important. All water used by laborers should be disinfected. Thymol is said to be a specific, and should be given in thirty-grain (2 gm.) doses in wafers at 8 A. M. and 8 P. M., a purge of castor oil or magnesia being given after the second dose. Should the first effort fail, it may be repeated in a week. The diet should be liquid—milk and soups.

D. FILARIASIS.

Definition.—A condition constituted by the presence of several species of nematode worms, known as filariæ.

(a) *Filaria sanguinis hominis*.

A term applied to the several varieties of filaria which infest the blood of man. Of these, three species will be described:

1. *Filaria Bancrofti*.—The adult filaria thus named was first discovered by Bancroft in Queensland in 1876, and soon thereafter by T. R. Lewis in Calcutta. Before these discoveries the larva only was known, having been discovered by Demarquay in Paris in 1863 in the hydrocele fluid of a Havanese.

The adult male is 83 mm. (3.2677 inches) long and 0.4 mm. (0.0157 inch) in diameter, head rounded, tail pointed, and spirally rolled. The female is about 155 mm. (6.1023 inches) long and 0.7 mm. (0.0275 inch) thick. The worm is about as thick as a human hair. The egg is 0.038 mm. (0.0015 inch) long and 0.014 mm. (0.005 inch) wide. The normal habitat of the sexually mature worm is the lymphatic vessel of different parts of the body of man, though it has been found also in the left ventricle of the heart. The female is viviparous, exceptionally oviparous, producing an enormous number of young larvæ, which pass from the lymphatic stream into the blood and are thus distributed over the body. They are from 0.27 to 0.34 mm. (0.0106 to 0.0133 inch) long, 0.007 to 0.011 mm. (0.0003 to 0.0004 inch) broad, rounded anteriorly and pointed behind.

The larvæ are found in the peripheral circulation after sundown in a drop of blood taken for the purpose. The numbers increase until midnight,

when they again become less numerous. From midday to evening there are no filariæ to be found. The cause of this interesting fact cannot be ascribed to the periodic production of broods, since Mackenzie has shown that the order is reversed if the patient sleeps during the day and is awake during the night, under which circumstance the filariæ are found in the blood in the day. This is, however, not without exception. It would seem, as suggested by Linstow, that the event has something to do with sleep, and that during sleep the peripheral blood-vessels widen and again contract during awaking; that the filariæ cannot pass the contracted capillaries of the superficial skin, but rest in the larger blood-vessels in the deeper portion, to come out with the widening which accompanies sleep. Their number in the blood has been variously estimated at 140,000 by Carter, and by McKenzie at from 30,000 to 40,000.

The *filaria Bancrofti* is met in the blood in all tropical countries, especially India, China, Japan, and Brazil. It has also been found in the Southern United States in persons who have never been out of the country, first by Guiteras and later by others.

2. *Filaria Perstans*.—This second variety of *filaria sanguinis hominis* was also found by Manson in a larval state in the blood of a negro in West Africa. It is distinguished from the other filariæ of man by its small size,—0.2 mm. (0.0078 inch) long,—its active motility and contractility. Manson is inclined to ascribe to this the sleeping disease of negroes, and to it also the skin affection known among negroes as *kraw-kraw*, which is a papillopustular eruption, probably the same as Nielly's *dermatose parasitaire*, the parasite of which was called *rhabditis Nielly* (Blanchard, 1885). The posterior extremity is obtuse; the anterior has a retractile rostellum.

3. *Filaria diurna*, also described by Manson, is seen in the blood only in the larval state, agreeing in this respect with *filaria Bancrofti*, differing, however, from the latter in that it appears in the blood only in the day. It was discovered by Manson in the blood of negroes on the west coast of Africa. Manson considers that *filaria loa* represents the adult stage.

Etiology.—Patrick Manson discovered the young filaria, together with human blood, in the intestine of the mosquito, and thus secured the key to the problem of the transmission of the parasite from one person to another. He also noticed that the larvæ underwent a certain degree of development in the intestine of the mosquito, changing in form and size. On the sixth or seventh day they are 1.5 mm. (0.0599 inch) long and cylindrical, and at this time change their habitat to water through the death of the mosquito, which takes place after the deposit of eggs. Few mosquitos, however, live long enough to permit the development in their intestine of the filaria to the stage at which it is sufficiently mature to survive in water. Manson concludes, however, that man becomes infected by drinking water which holds the mature filariæ. Manson's studies have been confirmed by Lewis, and although his conclusions are not undisputed, they seem likely.

Symptoms.—The early presence of filariæ in the blood does not occasion subjective symptoms, and may last years without impairment of health. Sooner or later, however, as a rule, there appear anemia, enlargement of the spleen, and fever, with lymphatic tumors in different parts of the body. A differential blood count at this stage would be likely to discover eosinophilia. Later there develops, in consequence of lymphatic obstruction, possibly caused by the parent filaria, possibly by the ova, elephantiasis, especially of the scrotum (lymph scrotum) and lower extremities. To these

succeed enlargement of the lymphatic glands, chyluria, or hematochyluria already described, chylocele, more rarely nephritis, pyelitis, cystitis, and even peritonitis. Parasites are by no means always found in the blood in cases of elephantiasis or lymph scrotum. The mechanism of these phenomena is thus described by Manson himself:

“ A parent filaria is lodged in the left thoracic duct. In some way not yet understood it injures the walls of the vessel, causing ulceration or inflammatory thickening. In time this lesion leads to stenosis of the duct. *Pari passu* with the development of the stenosis the thoracic duct on the distal side of the stricture dilates, owing to the rising lymph. After a time the stricture becomes so narrow that the lymph and chyle no longer find their way past it to the left subclavian vein. They seek; however, to reach the blood by another route; a retrograde movement down the thoracic duct sets in, and so, by way of the pelvic lymphatics in the walls of the abdomen and the anastomosis between these and the lymphatics of the upper part of the body, the chyle from the intestines and the lymph from the lower extremities find their way into the circulation by the right thoracic duct. Possibly there are other routes, as by the lymphatics of the esophagus, diaphragm, and back. It is certain, however, that a frequent course pursued is that described, which is much the same as that pursued by the blood in the case of obstructed portal circulation. To accommodate this diverted chyle and lymph, the lymphatics by which they pass become enlarged and in many places varicose. The tendency to varicosity is very evident in such places as the scrotum, mucous membrane of the bladder, or wherever the lymphatics are abundant and feebly supported. In many instances these varices, when superficial, can be seen or felt and their nature readily recognized. If the inguino-femoral glands are involved, the varicose groin glands, so characteristic of filaria infection, are produced. Sometimes the varix is apparent on the surface of the abdomen even, as in a case related by Sir William Roberts and in another by Havelhing. That these varices are really part of an anastomosis conveying chyle from the abdominal viscera to the blood is proved by the nature of their contents, which are usually milky-white or slightly red-tinted chyle—not clear and limpid lymph, such as comes from the legs. As the lacteals are the only source of chyle, these chylous contents of the varicose lymphatics must have come from that source, and the route followed must have been the retrograde one described. Now if the lymphatics of the bladder happen to be involved in the compensatory anastomosis, and if they give way, as the lymphatics of the scrotum so frequently do in similar circumstances, the result is a leakage of chyle in the bladder, and chyluria. It is evident from this that the embryo filariæ, although they are generally present in the blood and the urine in chyluria, have nothing whatever to do with its production. This is further proved by the fact that in some few cases of genuine and persistent tropical chyluria no embryo filaria can be found either in blood or urine. Proper treatment of chyluria is in principle the same as the treatment of acquired varix in any accessible region. This should consist of rest, elevation, lowering of the tension in the lymphatic vessels by the use of saline purgatives, limited and appropriate food, and abstinence from fluids as much as possible. Certain drugs have been vaunted as specifics for chyluria. Temporary recovery from time to time is the rule, and the drug which was being used at the time the urine cleared spontaneously from the healing of the rupture in the varix of the bladder is often credited with the cure. I cannot understand how a drug introduced by the mouth can possibly cause the closure of a gaping varix in the bladder.”

Treatment.—No treatment appears to be of any value in exterminating the filariæ in the blood. The symptomatic treatment should consist in rest, lowering of the tension of the lymphatics by saline purgatives, by appropriate food, and limitation of fluids ingested. No drugs have any influence, though it is not unnatural that, being used at the time of the spontaneous intermission, they should secure a reputation for curative powers.

(b) *Filaria dracunculus*.

SYNONYMS.—*Dracontiasis*; *Guinea-worm Disease*.

Description.—*Dracontiasis* is a term given to the presence of the *filaria dracunculus* or *filaria medinensis*, or guinea-worm.

The female, until recently alone known, is from 50 to 80 cm. (20 to 32 inches) long or longer, and from 0.5 to 1.7 mm. (0.0196 to 0.0669 inch)

thick. Quite recently R. H. Charles found, along with two females removed from a dead body at Lahore, a much shorter worm, about four cm. (1.6 inches) long, attached by its hinder extremity to one of the females at a point about four cm. (1.6 inches) from its head, which he inferred to be the male attached to the vagina of the female, dying after impregnation, as is the case with some other parasites. Then, too, the vagina atrophies, as both it and the vulva are absent in the mature worm.

As to the development of the worm, the mature female contains enormous numbers of living embryos, which are discharged into the water of ponds. After a few days they probably enter the cyclops, a small crustacean, and there reach a certain stage of development, when they are imbibed with drinking-water by man and reach their ultimate destination, as described, in the subcutaneous and intermuscular connective tissue, especially in the lower extremities, about the foot-joint. To this it obtains entrance through the stomach, whence it penetrates the intestine and passes to the subcutaneous connective tissue, where it attains its full development, lying for a long time quiescent under the skin, and where it can be felt like a cord. Later it excites suppuration, and with the rupture of the abscess is discharged. It is also found elsewhere, as in the back, scrotum, perineum, the upper extremities, eyelids, and tongue. Usually one worm only is found, rarely several. It is wide-spread, occurring in all races, ages, and in both sexes. Van Harlingen described a case in a man who had always resided in Philadelphia. According to Braun, the fiery serpents described by Moses were guinea-worms. The term *Δρακοντιον* was applied by Agatharchides one hundred and forty years before Christ, and Galen called the disease *dracontiasis*.

Diagnosis.—The worms are easily recognized under the circumstances named.

Treatment.—As to treatment, the indication is to remove the worm intact after the abscess is opened, because of the irritation excited by the escape of the living embryos. The method of procedure directed is to roll the worm around a piece of smooth wood, each day a little, in order to prevent retraction, until the whole worm is withdrawn.

It is said that the leaves of the plant *amar pattee* are a specific cure, while *asafetida*, when given in full doses, is also said to be poisonous to the worm.

(e) *Other Filiaræ.*

Numerous other *filiaræ*, of less importance, have been found from time to time in man. Among them I select from Braun:

1. The *filaria immitis*, the common *filaria sanguinis* of the dog, found twice in man by Bowlby, in one instance associated with hematuria. He found, in the case of an Arab, numerous *filiaræ* in the portal vein, eggs in the thickened bladder-wall, kidney, ureter, and the lung; in another eggs were found in a tumor of the rectum in a seventeen-year-old youth.

2. The *filaria loa*, a delicate worm, from 30 to 40, rarely 70, mm. (1.11 to 1.57 to 2.75 inches) long, found between the conjunctiva and the eyeball in negroes on the West Coast of Africa; whence it has spread to South America and the West Indies.

3. The *filaria oculi humani vel lentis*, which in several instances was removed with lenses the seat of cataract, of which it seems to have been the cause.

4. The *filaria labialis*, found in a pustule in the lips of a child.

5. The *filaria hominis oris* (Leidy), obtained from the mouth of a child.
6. The *filaria lymphatica vel bronchialis*, found in lymphatic glands of the lungs and in the trachea and bronchi.

E. OTHER NEMATODE WORMS.

1. The *trichocephalus dispar*, an interesting worm of which the anterior portion, equal to three-fifths of the body, is very delicate and hair-like, while the hinder portion is much thicker. It is from four to five cm. (1.6 to 2 inches) in length, the male being somewhat shorter. The hinder end of the female is conical and pointed, while in the male it is more obtuse and rolled like a spring. The ova are oval, 0.05 mm. (0.0012 inch) long, and provided with a button-like projection like that on the end of a lemon.

Its habitat is usually the cæcum of man, rarely the appendix vermiformis, and exceptionally the small intestine. Usually they are few in number and give rise to few or no symptoms. In some instances large numbers are found, and serious brain symptoms have been ascribed to them, in other cases anemia. It is said to be one of the commonest parasites in man the world over, in either sex and at any age except infancy. Beriberi has been ascribed to it. The larvæ are probably developed from the eggs in water, and are possibly ingested in drinking-water. The ova are very resisting to the destructive agents to which they are ordinarily subjected. Large numbers are found in the feces.

2. The *eustrongylus gigas*, or *strongylus gigas*, is an enormous nematode, the male of which measures 240 cm. (2.1 feet), and the female 100 cm. (3 feet 4 inches) long and 12 mm. (0.5 inch) thick. It lives in the pelvis of the kidney, more rarely in the abdominal cavity of the seal, dog, wolf, horse, and other animals, and exceptionally in man.

3. The *strongyloides intestinalis*, or *anguillula intestinalis et stercoralis*, is a small nematode worm, first found in 1876 in the stools of French soldiers in Cochin China suffering with severe diarrhea. They are found in all parts of the intestine and in the biliary and pancreatic ducts, producing diarrhea only when present in large numbers.

IV. ACANTHOCEPHALI.

SYNONYM.—*Thorn-head Worms.*

Description.—These are nematode-like worms in the intestinal canal, which are provided at the anterior end with a retractile proboscis furnished with hooks, hence called thorn-headed.

Of these the *gigantorhynchus*, or *echinorhynchus gigas*, is a large worm, the male being from ten to fifteen cm. (4 to 6 inches), and the female from thirty to fifty cm. (12 to 20 inches) long, which attains its full development in the intestine of the hog, attaching itself to the mucous membrane by its thorn head. The intermediate host is the cockchafer grub in America and the June bug. As these insects may be accidentally swallowed by man, it is not impossible that the parasite may develop in his intestine.

V. ARTHROPODA.

Of these, both the arachnides and insecta contribute to human parasites.

A. ARACHNOIDEA.

(a) *Acarinae*.

1. *Sarcoptes* or *acarus scabiei*—the itch insect. This is the most frequently met of the arachnide parasites. Its oval, nearly circular little body, provided with horns and bristles, is barely visible to the naked eye under favorable circumstances, the male being from 0.2 to 0.3 mm. (0.0078 to 0.0118 inch) by 0.145 to 0.19 mm. (0.0057 to 0.0074 inch); the female, from 0.33 to 0.45 mm. (0.0129 to 0.0177 inch) by 0.25 to 0.35 mm. (0.0098 to 0.0137 inch).

The female lies at the end of a burrow in the epidermis, in situations where the skin is most delicate, as between the fingers, at the elbows, and under the knees, in the groin, and on the penis, very seldom in the face, but in any delicate part. In this burrow, some millimeters to a centimeter long, the female deposits her eggs. The male is seldom seen, dying after copulation, and the female after depositing her eggs. The eggs hatch in from four to eight days, and in about fourteen days the larvæ are sufficiently matured to make their own burrows. The disease is communicated by personal contact or by clothing.

Symptoms.—These are first an intense itching which incites to scratching, which, in turn, causes excoriations, papules, vesicles, and pustules.

Diagnosis.—The diagnostic feature is the shining little vesicle readily recognized by a moderate magnifier in the webs of the fingers, though it is often obscured and obliterated by the eruption and marks caused by scratching.

Treatment.—This is very simple. Sulphur ointment is a prompt specific. The body should be first bathed thoroughly with soft soap, and then as thoroughly anointed with the ointment, which should be allowed to remain until the next day, when there should be another bath, followed by another vigorous application of the ointment. Three or four days of this treatment should suffice. An ointment of naphthol, one dram to the ounce (4 gm. to 30 gm.), is recommended.

2. *Demodex folliculorum*, a minute parasite from 0.3 to 0.4 mm. (0.0118 to 0.0157 inch) long, which resides in the sebaceous follicles, with the grease of which it can sometimes be squeezed out. It is oftenest met on the face and nose. It is said to be present in about 50 per cent. of persons, but this is probably exaggerated. It usually gives rise to no symptoms, but is said sometimes to be the cause of obstruction of the follicles and produces thus the little worm-like accumulations of fat which may be squeezed out of the follicles, and which cause inflammation and acne.

Treatment.—Acne is well treated by a lotion of corrosive sublimate, 2 to 1000, and it may be by its effect on the demodex that it is useful.

3. *Lepus autumnalis*, or harvest bug, is a minute red parasite, from 0.3 to 0.5 mm. (0.0118 to 0.0196 inch) long, which has three pairs of legs, with rows of bristles upon its back and belly. It prevails in summer on

grasses and plants, attaches itself to the skin of man and animals by its hooklets, and gives rise to irritation.

Treatment.—It is successfully destroyed by sulphur ointment and corrosive sublimate, 2 to 1000.

4. *Ixodes ricinus* is a minute oval tick, the male being 1.2 to 2 mm. (0.0474 to 0.0787 inch) long, and brownish-red in color, the female four mm. (0.1574 inch) long, yellowish-red, when distended with blood bluish-gray, twelve mm. (0.4724 inch) long, six to seven mm. (0.2362 to 0.2755 inch) broad, which infests the skin of sheep, cattle, dogs, horses, and men, causing irritation and inflammation.

It may generally be removed by rubbing or greasing with any sort of oil or vaselin.

(b) *Linguatulidæ, or Pentastomes.*

The pentastomes include the *pentastomum tanioides*, or *linguatula rhinaria*, and the *pentastomum constrictum* or *porcephalus constrictus*.

1. The *pentastomum tanioides* is a lancet-shaped worm, already described in connection with parasites of the liver. The adult infests the frontal sinuses and nostrils of the dog, more rarely of the horse, and has been found in the nostrils of man.

2. The *pentastomum constrictum* has as yet been met only in the larval state. It is milk-white in color, with golden-yellow hooklets, 13 mm. (0.5118 inch) long and 2.2 mm. (0.0866 inch) wide, provided with twenty-three rings. It has been found by Pruner encysted in the liver of two negroes in Cairo, by Bilharz in two instances encysted in the liver and mucosa of the bowel, and by Aitken in the liver and lungs of an English soldier in the West Indies.

B. INSECTA.

Of these, the order *rhyncota* is represented by pediculi or lice and the cimex or bed-bug, the *diptera* by the pulex or flea.

(a) *Rhyncota.*

Pediculi (Phtheiriasis; Pediculosis).—Of these, three varieties infest human beings of filthy habits:

1. The *pediculus capitis*, or head-louse. The male is from 1 to 1.5 mm. (0.0393 to 0.059 inch) long, the female from 1.8 to 2 mm. (0.0708 to 0.0757 inch) long. The color varies somewhat with the races. In the white it is gray with a dark border, in the negro and Chinaman darker. Its eggs are 0.6 mm. (0.0236 inch) long, of which the female lays about fifty, which mature in about a week, and in eighteen days are ready to reproduce. The eggs are attached to the hairs, and are easily visible, being known as nits.

The head-louse is found the world over, upon the hairy heads of men and sometimes in other parts of the body where there are hairs. Even when they are quite numerous they may produce no symptoms. Generally, however, they cause itching and scratching, especially when the louse bores deep into the skin and produces pustular dermatitis, with resulting

crusts and scabs in which the hair becomes matted and tangled, forming the *plica polonica*, so called from its frequency in Poland.

2. The *pediculus vestimenti*, or body-louse, is considerably larger, being from two to five mm. (0.1574 to 0.1968 inch) long and whitish-gray in color, the back part of the body being wider than the thorax. Its eggs are from 0.7 to 0.9 mm. (0.275 to 0.0354 inch) long, and about seventy are laid by the female. It lives on the clothing in which it deposits its eggs, about the neck, back, and abdomen. The puncture incident to sucking is often covered by a hemorrhagic point. It, too, causes itching and scratching, with irritation and inflammation of the skin, and in old cases a roughness and pigmentation causing dark spots and a condition known as *morbus errorum* or vagabond's disease, which has been mistaken for Addison's disease.

3. The *pediculus pubis*, *phthirus inguinalis*, or crab-louse, is smaller than the head-louse, grayish-yellow or grayish-white, the male being from 0.8 to 1 mm. (0.0314 to 0.0393 inch) long, the female 1.12 mm. (0.0441 inch) long. The eggs are pear-shaped, from 0.8 to 0.9 mm. (0.0314 to 0.0354 inch) long, and from 0.4 to 0.5 mm. (0.0157 to 0.0196 inch) wide. They infest the parts of the body covered by shorter hairs, such as the pubis, axilla, and eyebrows. The *pediculus pubis* does not wander so much as the *pediculus capitis* or *vestimenti*, but adheres more closely to the skin and there removal is often with difficulty.

These lice rarely give rise to symptoms.

Treatment.—*Of Pediculosis.*—For the head-lice: The hair should be cut short and burned, the head thoroughly washed with soap and water, and then anointed with mercurial ointment or washed with tincture of cocculus indicus, or with coal-oil or turpentine, or carbolic acid, 1 to 50. Cocculus indicus is to be preferred because of its freedom from odor. The washing should be repeated for several days in succession.

The treatment for the crab-louse is the same, but, as mentioned, it adheres firmly to the skin, and it is generally necessary to pick off the individual louse.

To get rid of the body-louse the clothing, if not too valuable, should be burned, but may be boiled, or, when this is not admissible, treated by superheated steam.

The itching promptly disappears with its cause, but, if necessary, it may be allayed by a warm bath to which four or five ounces (120 to 150 gm.) of sodium bicarbonate are added.

Repeated bathing with soft soap should be done until it is absolutely certain that the parasite and its ova are removed.

4. The *cimex lectularius*, or common bed-bug. This familiar insect is reddish-brown, oval in shape, from four to five mm. (0.0574 to 0.1968 inch) long, and three mm. (0.1181 inch) wide. The female lays three or four times a year about fifty eggs, 1.12 mm. (0.0441 inch) long, which require about eleven months for their perfect development to the sexually ripe condition. They live in the crevices of beds, floors, and rafters, in furniture, behind wash-boards and wall-paper, in the habitations of man. During the day they lie concealed; at night they wander in search of the blood of the human being, which they draw by means of a long proboscis. The peculiar odor of the insect is due to a secretion of a special organ with which the bug is provided.

Human beings are variously susceptible to the bite of the bed-bug, some

being quite indifferent to it, others being, as it were, special favorites of the little creature.

Treatment.—The irritation is confined to the moment of the bite. The aim to be sought is the extermination of the insect. This is often difficult when a thorough lodgment is secured, and it is often necessary that all wall-paper should be removed as well as loose woodwork. Bedsteads should be thoroughly scalded and then treated with the following: Two tablespoonfuls of metallic mercury should be thoroughly beaten up with the white of an egg until a froth is attained. Apply freely with a small paint-brush, filling in carefully all cracks and crevices. The pest is less apt to invade iron bedsteads, but even these must not be neglected, for they, too, in careless hands, may become infested. Solution of corrosive sublimate, 2 to 1000, may also be applied in the same manner.

(b) *Diptera*.

1. The *pulex irritans*, or common flea. Of these little creatures, the male is from 2 to 2.5 mm. (0.0787 to 0.1181 inch) long, the female as much as four mm. (0.1574 inch), red or dark-brown in color. It is also highly capricious in its tastes, disturbing some persons not at all, others seriously. It is not a parasite of man, and invades him usually because of its great abundance in certain places and countries. Though of world-wide distribution, it is more troublesome in hot countries where cleanliness of household, city, and person is a matter of indifference. The eggs are not laid on human beings, but in the cracks of boards, sweepings, and wooden spit-boxes.

Treatment.—The essential oils applied to the infested parts cause the retreat of fleas when applied.

2. The *pulex penetrans*, or sand-flea or jigger. The female buries herself in the skin of human beings as well as of dogs, swine, and other mammals, producing painful irritation, circumscribed swelling, and even suppuration. It especially attacks the feet. It prevails in tropical countries, especially in Central and South America. The eggs are land-hatched.

Treatment.—The flea may be picked out with a needle, after which the essential oils are rubbed in on the parts to keep it away.

3. *Myiasis*.—The diptera also contribute to parasites through their larvæ, which are deposited sometimes in open sores which have been neglected, and sometimes in the nasal passages and cavities—the ear, pharynx, vagina, etc. The condition is called myiasis, from the Greek *μύια*, a fly.

The most common of these is *myiasis vulnerum*, in which an ulcer becomes filled with maggots, which are the larvæ of the blue-bottle or common flesh fly, *sarcophaga carnaria*.

Myiasis narium, aurium, conjunctivæ, vaginæ, etc., are due to the *lucilia macellaria*, whose larva is deposited in these situations usually when they are diseased, and may produce serious mischief, perforating mucous membrane and even cartilage. The larvæ of the *lucilia nobilis* have also been found in the auditory passages, producing ringing of the ears as a symptom. The larvæ of *sarcophaga magnifica* have been found in ulcers and other situations, throughout Europe, and especially in Russia.

Cutaneous myiasis is commonly due to the larva of the *hypoderma bovis* or bot fly, the female of which lays her eggs on the skin of cattle and

sheep, in which the larva bores its way and forms the gad boil, about as large as a pigeon's egg. Rarely in tropical countries this happens in the skin of man. Cutaneous myiasis is sometimes caused by the larva of the *musca vomitoria*, one of the domestic flies. More frequently it causes internal myiasis, having been swallowed and again discharged by vomiting. More rarely dipterous larvæ are found in the feces, including those of the common house-fly and the *trichomyza fusca*, which has also been vomited.

SECTION XIV.

SUMMARY OF SYMPTOMS FOLLOWING OVERDOSES OF POISONS.

(Alphabetically Arranged).

TO WHICH IS ADDED A TABLE OF MINIMUM DOSE WHICH HAS CAUSED DEATH, AND MAXIMUM DOSE FOLLOWED BY RECOVERY.

ACONITE (*Monkshood; Wolfsbane; Blue Rocket*).—All parts poisonous. The tincture may be mistaken for sherry or whisky; it has an exceedingly acrid taste.

Symptoms.—These appear quickly, and consist of an acrid taste in the mouth, a feeling of warmth in the stomach, followed by a tingling sensation throughout the body; muscular weakness, slow, weak pulse; vomiting may be present; collapse follows. The mind is clear to the last.

Treatment.—Stomach-tube or emetics; recumbent posture, with feet somewhat elevated. Stimulants freely, such as ammonia, ether, digitalis, atropin, and strychnin. Heat to the extremities, and artificial respiration for two hours.

ALCOHOL.—Taken in the form of spirituous beverages. Acute alcoholic poisoning. A brief period of excitement, with flushing of the face, followed by unconsciousness, stertorous breathing, rapid and, finally, weak pulse, vomiting, a subnormal temperature, delirium, complete muscular relaxation, at times convulsions; the pupils are usually dilated. Recovery commonly takes place in a day or two, but remissions may occur. Odor of alcohol on the breath.

Treatment.—Evacuation of stomach by pump; emetics, like apomorphin, 1-10 grain (0.0064 gm.); washing out the stomach. Stimulation by ammonia, coffee, digitalis, strychnin, or even faradic current to muscles of respiration.

DELIRIUM TREMENS.—Delirium, with hallucinations; great restlessness and insomnia; slight fever, pulse rapid and soft.

Treatment.—Withdrawal of alcohol; bromids in large doses, or chloral, aided by a cold bath to produce sleep; nourishing food and stimulation if the condition demands it, even by alcohol.

AMMONIA.—Taken by mistake or with suicidal intent in the form of "household ammonia," water of ammonia, spirit of hartshorn, and in liniments.

Symptoms.—At once, burning pain in the mouth, throat, esophagus, and stomach; the lips and tongue are intensely swollen and inflamed; vomiting of blood-tinged mucus, suffocative cough, with rapidly increasing dyspnea. The face is pale, pulse is rapid and thready, and collapse soon develops. Death may follow at once or some days later, from the violent gastro-enteritis and stricture of the esophagus.

Diagnosis.—Odor of ammonia on the breath, vapors of the corresponding salt when a rod dipped in hydrochloric acid is held before the mouth, together with the sudden onset of the symptoms.

Treatment.—Neutralization with vinegar or some other dilute acid at once, the acid being mixed with some bland oil, if possible. If the patient lives, treat the results of the violent inflammation. Tracheotomy should be performed, if there is danger of death from edema of the larynx.

ANTIMONY.—Taken as a tartar emetic, the tartrate of antimony and potassium. A heavy, white, odorless, slowly soluble powder having a sweetish, metallic taste; charring on heating to redness.

Symptoms.—Metallic taste in the mouth, burning pain in esophagus, stomach, and abdomen, dysphagia, violent vomiting and purging of serous material, cramps in the stomach and muscles of the arms and legs. Finally, the symptoms of collapse—cold, clammy skin, great depression, respirations shallow, pulse weak and thready. There may be convulsions, delirium, and coma.

Treatment.—If no vomiting, apomorphin, 1-10 grain (0.0064 gm.), or another emetic; tannic acid as a chemical antidote, followed by washing out of stomach; external heat, stimulants to combat the collapse, and opium when the acute symptoms have disappeared.

ARSENIC.—Used in the form of arsenious acid in rat-poisons, in fly-paper, and to preserve stuffed birds and animals. Paris green, used as potato-bug poison, is an arsenite of copper, hence the symptoms are similar. Arsenious acid, or white arsenic, is an odorless, tasteless, white powder, quite heavy, and but slowly soluble in water.

Symptoms.—These appear usually in the course of an hour, and are those of violent gastro-enteritis, so severe as to suggest Asiatic cholera. Burning pain in throat and stomach, persistent vomiting of brown matter streaked with blood, though the vomited matter may be green from bile. Purging of serous and bloody material, and finally collapse. Fatal in a day or two, though a remission sometimes occurs on the third day. Nervous symptoms may appear, and at times a case of arsenic poisoning closely simulates acute yellow atrophy of the liver.

Treatment.—Early stage, stomach-tube, or emetics. Chemical antidote, the freshly prepared hydrated oxid of iron, made by precipitating the solution of tersulphate of iron by ammonia; the tincture of chlorid of iron may be used instead of the solution. Mix and strain, wash, and administer the magma. The best antidote is the ferri oxidum hydratum, U. S. P., or ferri oxidum hydratum cum magnesia, the latter acting also as a purgative. Otherwise treat the collapse.

ATROPIN (Belladonna).—The deadly nightshade. Used as a mydriatic and in liniments. The leaves impart a narcotic odor to the tincture, but recognition depends upon the physiological effect.

Symptoms.—The throat is dry, the pupils are dilated, the pulse is rapid and hard; respirations are quickened and deepened; there is great restlessness, occasionally talkative delirium. An erythematous rash is sometimes present. The urine contains the alkaloid, hence it will cause dilatation of the pupil if dropped into the eye of an animal.

Treatment.—Tannic acid, followed by the stomach-tube or emetics.

Physiological antidotes: Morphin, physostigmin, and pilocarpin. Artificial respiration for two hours. Catheterize, as patients frequently suffer from retention. Meet collapse by proper stimulation.

BELLADONNA.—See Atropin.

BROMIN.—A dark-red, very heavy liquid, emitting reddish vapors resembling chlorin.

The fumes, when inhaled, cause convulsive cough, bloody expectoration, dyspnea, and spasm of the glottis.

Treatment.—Fresh, moist air and cautious inhalations of ammonia.

BROMISM.—The symptoms of chronic gastro-intestinal disturbance such as fetor of the breath, anorexia, diarrhea; great depression of all the functions, especially the sexual function, with languor and mental apathy. A general eruption of acne is an early sign.

Treatment.—Stop the administration and aid elimination.

CARBOLIC ACID (AND CREASOTE) is a colorless or reddish liquid, or a crystalline solid, when pure; when impure, the color varies from this to black. It has a characteristic odor.

Symptoms.—These appear quickly. Burning pain in the mouth and stomach, though there may be no pain. Vomiting may be absent. Soon coma sets in, with feeble respiration, collapse, and convulsions. The urine is smoky, but the most characteristic sign is the white eschar on mouth and lips, with the odor of the acid on the breath.

Treatment.—Any soluble, non-poisonous sulphate, such as sulphate of magnesia or sulphate of sodium, as a chemical antidote. Stomach-tube or emetics, followed by washing out stomach with a solution of a sulphate. Oil to counteract the escharotic effect. Treat the collapse with heat, stimulation, etc.

CARBONIC ACID GAS.—The choke damp or after-damp of miners. May be accidentally inhaled in overcrowded rooms, in fermenting vats, over lime-kilns, or wherever the products of complete combustion cannot escape.

Symptoms.—Headache, dizziness, vomiting, and great drowsiness, with relaxation of the muscles; hurried respiration, with violent action of the heart. Soon coma ensues.

Treatment.—Fresh air, if need be; artificial respiration, kept up steadily and unceasingly; ammonia by inhalation; oxygen, if obtainable; cold douche to the head and chest, with stimulation as occasion requires.

CARBONIC OXID (*Carbon Monoxid*) is formed during the incomplete combustion of carbon, and is a direct poison, while carbonic acid gas, the product of complete combustion, kills merely by exclusion of oxygen.

Treatment as for carbonic acid gas.

CAUSTIC POTASH OR SODA.—Taken in the form of "lye."

Symptoms.—An acrid, burning taste, the burning extending down to the stomach, followed by vomiting, purging, and collapse. The mucous membrane of the mouth shows evidence of corrosion.

Treatment.—Olive oil, to saponify the alkali; demulcent drinks, dilute acids, like vinegar and lemon-juice, to neutralize. If the patient lives, the resulting stricture of the esophagus requires dilatation.

CHEESE POISONING.—Decayed cheese owes its poisonous properties probably to tyrotoxinon. Usually there is severe gastro-enteritis, with vomiting and purging.

Treatment.—The stomach-tube may be used if vomiting has not been very free; subsequent lavage; sedatives for the irritation.

CHLORAL.—A popular somnifacient and sedative. Occurs in deliquescent crystals with characteristic odor and acrid, burning taste.

Symptoms.—Profound unconsciousness, complete muscular relaxation; sensibility diminished or lost; the pulse becomes feeble and rapid, the respirations are diminished in frequency and may be stertorous; the temperature is depressed more than by any other toxic agent.

Treatment.—Evacuate the stomach; keep up the temperature by application of heat; rouse the patient; stimulate; use artificial respiration in conjunction with the battery.

CHLOROFORM.—Identified by its peculiar ethereal odor and sweet, pungent taste; a heavy, volatile, non-inflammable liquid, not miscible with water.

Symptoms.—First stage of narcosis, excitement, muscular rigidity, lessened sensibility to pain. Second stage, muscular relaxation, anesthesia of conjunctiva, insensibility to pain. Third stage, stertorous breathing, dilated pupils (not responding to light), abolition of all reflexes, muscles absolutely relaxed. Death usually by failure of circulation. The symptoms are the same if the chloroform is taken by the mouth.

Treatment.—In case the chloroform was used as an anesthetic, lower the head, slap a wet towel on the patient's chest; pull out the tongue to see that the mouth is clear; artificial respiration at the rate of twenty respirations a minute, aided by the cautious use of the battery (interrupted current).

When taken internally, stomach-tube or emetics; flicking with a wet towel; stimulation with coffee by rectum; whisky by mouth, if possible.

COCAIN.—Solution used as a local anesthetic, particularly in eye surgery.

Symptoms.—Vertigo, headache, paroxysmal dyspnea, rapid weak pulse, elevated temperature, mental excitement, blindness, delirium, coma, and convulsions. Some of these may be caused by the local application of solutions to mucous membranes. The pupil is dilated, but the power of accommodation remains in part.

Treatment.—Nitrate of amyl, stimulants, atropin, caffeine, and ammonia. Death is unusual.

CONIUM (*Poison Hemlock; Common or Spotted Hemlock*).—Not a native of this country, hence cases of poisoning must be restricted to the use of the preparations. The plant and some of the preparations have a peculiar odor, resembling the urine of mice.

Symptoms.—Prominent is the loss of muscular power, the patient stag-

gering as if intoxicated; the arms and chest are affected later on, and death may ensue from paralysis of the muscles of respiration. In other cases there are delirium, stupor, coma, and convulsions; the pupils are dilated, and ptosis is a peculiar symptom.

Treatment.—Stomach-pump or emetics; tannic acid, stimulants, heat, artificial respiration.

COPPER.—The sulphate, blue stone or blue vitriol, is used in the arts. Recognized by its crystalline shape, blue color, and acrid, metallic taste. Articles of food are frequently prepared in imperfectly cleansed copper kettles; a bright piece of steel, such as a knife, will show a deposit of metallic copper a few minutes after immersion in a liquid containing copper. Verdigris (subacetate) is another source.

Symptoms.—A metallic, astringent taste in the mouth; griping and colicky abdominal pains; vomiting, purging, accompanied by tenesmus, the stools being mucous or bloody. Respiration embarrassed, small, quick pulse, weakness, great thirst, coma, death.

Treatment.—Stomach pump or emetics if vomiting has not emptied the stomach; demulcents, like milk and eggs; chemical antidotes are soap, sodium carbonate, and the yellowish prussiate of potash. Opium should be used as a sedative.

DIGITALIS (*Foxglove*).—A native of Europe. The tincture has a distinct odor of tea, the drug itself lacking a narcotic odor.

Symptoms.—Vomiting and purging of green material; pulse slow, later rapid and irregular; headache, occasionally delirium and convulsions; the skin is cold and clammy, and the pupils are dilated. Coma and death come on quite suddenly, though the mind may be perfectly clear.

Treatment.—Stomach-pump or emetics if necessary; tannic acid, twenty grains (1.33 gm.), repeated frequently; strong tea; stimulation with whisky, ammonia, or hot coffee; maintain recumbent position for some time after all symptoms have subsided.

ERGOT.—Used to produce abortion.

Symptoms.—A large dose produces cramps in the legs, arms, and chest, dizziness, weakness, pulse small and pupils dilated, skin cold; there may be vomiting and diarrhea.

Chronic ergotism, produced by eating bread tainted with ergot of rye, causes muscular cramps, paresis, delirium, and convulsions; in other cases a dry gangrene. It occurs in Europe.

FISH-POISONING.—Tainted fish probably contains ptomaines, while several kinds of fish are constantly poisonous.

Symptoms.—Vomiting, irritation of the eyes, great depression, and severe nettle-rash.

Treatment depends upon the symptoms.

HYDROCHLORIC ACID.—See Mineral Acids.

HYDROCYANIC ACID (*Prussic Acid*).—The pure acid is an exceedingly poisonous gas. In medicine it is employed as a two per cent. aqueous solution. Contained in oil of bitter almonds distilled from the seed; not found

in the artificial or the purified natural product. Its salt, the cyanid of potassium, is employed as a quickly acting poison for the destruction of animals. Contained also in cherry-laurel water.

Symptoms.—Patient is nearly always insensible in two minutes if a fatal dose is taken. Loss of motor power, giddiness, slow respirations, pupils insensible to light, eyes protruding, pulse weak; frothing at the mouth, perhaps tetanic convulsions. The odor of bitter almonds is about the patient.

Treatment.—Stomach-tube or emetics, stimulants, hot and cold douche; artificial respiration, kept up steadily, as the patient is probably safe if tided over the first half-hour. Apply mild interrupted current to region of heart.

IODIN.—May be taken by mistake; the tincture has the odor of iodine, which somewhat resembles chlorin.

Symptoms.—The symptoms of a violent gastro-enteritis, such as burning pain in the throat, stomach, and abdomen, with vomiting and purging. The vomited matter may be yellow from iodine, or blue if starch is present in the stomach.

Treatment.—Starch (arrow-root) in any form as chemical antidote; stomach-tube or emetics; opium as sedative.

IODOFORM.—Rarely taken internally, but toxic symptoms may appear when used freely as an antiseptic dressing.

Symptoms.—Most marked among these are great somnolence, slight nocturnal delirium, headache, hurried breathing and rapid pulse. These, with a slight elevation in temperature, often resemble cerebral meningitis. A rash may accompany the intoxication.

Treatment.—If taken internally, emetics, etc. Substitute another antiseptic as a dressing and aid elimination.

LEAD.—Taken as sugar of lead (acetate), Goulard's solution (subacetate), lead water (subacetate), white lead (carbonate).

Symptoms.—In acute poisoning there are the symptoms of a violent gastro-enteritis, with colicky pains, especially about the umbilicus, and relieved by pressure; abdominal walls hard; cramps in the legs; convulsions.

Treatment.—Rid the stomach of the poison; use dilute sulphuric acid or a non-poisonous sulphate as a chemical antidote; demulcents with opium for the pain.

Chronic Poisoning.—Constipation, with colicky pains centering around the navel; abdominal walls retracted and hard; pulse apt to be hard and corded; headaches; paralysis of extensor muscles of forearm (bilateral wrist-drop); a blue line on the gums, due to a deposit of sulphid of lead.

Treatment.—A thorough course of potassium iodid; treat the constipation; avoid further trouble by cautioning lead-workers to clean their hands thoroughly, and by the use of sulphuric acid internally. The colic may require opium.

MEAT POISONING.—*Vide* Ptomain Poisoning.

MERCURY (*Corrosive Sublimate*; *Bichlorid of Mercury*; *Mercuric Chlorid*, or the *Perchlorid*).—Used in aqueous solution as bed-bug poison, as an insecticide, to preserve specimens, and as an antiseptic surgical dressing.

Symptoms.—In concentrated form it is corrosive, hence mouth and lips are swollen and white; a metallic taste; esophagus, stomach, and abdomen are the seat of intense pain; there are vomiting and purging of mucus and bloody material; scanty, albuminous urine; collapse.

Treatment.—Stomach-pump or emetics; white of egg as chemical antidote; demulcents; stimulants.

MINERAL ACIDS.

HYDROCHLORIC ACID (*Muriatic Acid; Spirit of Salt*).

Symptoms.—Similar to those mentioned under sulphuric acid, though the acid is not so powerful and leaves no distinctive stain. It may be recognized by its odor and by the white fumes formed when the gaseous acid comes into contact with ammonia. Medicinally and in the arts hydrochloric acid is used in aqueous solution, the commercial variety tinted yellow from a trace of iron.

Treatment.—Same as for sulphuric acid.

NITRIC ACID (*Aqua fortis*).—A colorless, moderately heavy liquid of peculiar and characteristic odor, staining organic tissues yellow.

Symptoms.—The same as those mentioned under sulphuric acid, though the characteristic yellow stain may be found on the lips.

Treatment.—As for sulphuric acid.

SULPHURIC ACID (*Vitriol; Oil of Vitriol*).—A very heavy, colorless, odorless liquid, having a very acid taste and mixing with water with the production of great heat. Used largely in the arts. Turns organic matter black.

Symptoms.—Burning pain from mouth to stomach; lips and mouth white, the vomited matter stained bloody and black; dysphagia; unconsciousness; collapse.

Treatment.—Immediate neutralization, or at least dilution, of the poison; soap and water, chalk, magnesia, lime-water, bicarbonate of sodium, or, in their absence, water in large quantity; demulcents and opium as a sedative. *N. B.*—Sulphuric acid may kill by edema of the glottis or by the secondary effects resulting from esophageal stricture and destruction of the gastric mucous membrane.

MORPHIN POISONING.—See Opium Poisoning.

MUSHROOM POISONING.—Harmless varieties may prove poisonous to some individuals. *Agaricus muscarius* is the most poisonous variety, containing the active principle muscarin. The fungus is bright red, with yellow spots. As a rule, highly colored fungi, with an astringent, styptic taste and a pungent odor should be avoided; they frequent especially dark and shady places.

Symptoms.—Excitement, violent colic, vomiting, and diarrhea; breathing stertorous; surface cold; pulse slow; death from cardiac failure.

Treatment.—Evacuate stomach and bowel; heat; stimulation; atropin as physiological antidote.

NICOTIN.—The liquid, volatile alkaloid of tobacco. An acrid, oily

liquid of amber color, smelling of tobacco. A very deadly and quickly acting poison.

Symptoms.—Nausea, vomiting, faintness, great weakness; pulse rapid and feeble; mental confusion; sight dimmed; skin cold and clammy.

Treatment.—Rid the stomach of the poison; administer tannic acid; strychnin; heat; stimulants; place patient in the recumbent posture.

NITROBENZOL (*Nitrobenzenc; Oil of Mirbane; Artificial Oil of Bitter Almonds*).—Used in the preparation of anilin dyes and in the arts on account of its flavor (soaps, etc.). Recognized by its highly characteristic odor.

Symptoms.—Usually not evident for an hour or two. Headache, weariness, nausea; the mind gradually becomes confused; there is great anxiety and cyanosis appears, the latter becoming extreme, until the whole body is blue. Stertorous breathing, coma, death by asphyxia or failure of heart.

Treatment.—As the poison is slowly soluble, wash out the stomach, even if a long time has elapsed since its administration; stimulants (whisky, not until after evacuation of stomach, because it renders the poison more soluble); artificial respiration; interrupted current.

OPIUM POISONING (ACUTE).—Taken accidentally or with suicidal intent in the shape of morphin or laudanum.

Symptoms.—Drowsiness, stupor, deep breathing; if due to laudanum, smell if it is on the breath; contracted pupil, slow, full pulse. For a time patient may be aroused by shouting into the ear.

Treatment.—Evacuate stomach by stomach-pump or tube, wash out thoroughly; administer strong coffee; flagellation and electricity to keep patient awake; if respiration fails, atropin and strychnin hypodermically; also electricity to phrenic nerve; artificial respiration.

OXALIC ACID.—Mistaken for Epsom salt; taken with suicidal intent. Occurs in prismatic, colorless, odorless crystals, with a very sour taste. Volatile without charring at a red heat.

Symptoms.—Those of a violent, rapidly fatal gastro-enteritis, associated with cramps in the legs; the mouth may be white. Collapse comes on quickly. Convulsions occur occasionally.

Treatment.—Carbonate of calcium in any form; chalk, whitening, or marble-dust; lime, lime-water. In an emergency whitewash from a wall. Follow by a purgative of castor oil.

PHOSPHORUS.—Employed in the form of a paste as a rat and roach poison; matches are sometimes sucked for suicidal purposes. The paste is recognized by its peculiar garlicky odor, and by the luminous fumes it emits in the dark.

Symptoms usually do not appear until after the lapse of a few hours. At first the ordinary signs of irritant poisoning appear, such as pain and vomiting, the ejected material being luminous in the dark. A garlicky taste in the mouth, and the odor of phosphorus may be perceptible on the breath. Later on there is severe abdominal pain, also pain in the region of the liver; this organ may be enlarged. The symptoms subside, but from the third to the fifth day more serious ones develop: jaundice, accompanied by pain and vomiting; discharges of blood from the bowel, with extravasations beneath

the skin. The urine may be suppressed or scanty, albuminous, and bile-stained; bowels constipated or loose, the stools clay-colored and sometimes phosphorescent. Death after grave nervous symptoms, such as headache, delirium, convulsions, stupor, and coma, and may occur very suddenly. Convalescence is much protracted if patient recovers.

Treatment.—Emetic of five grains (0.33 gm.) of sulphate of copper, which acts also as a chemical antidote. Permanganate of potassium in dilute solution. French oil of turpentine acts also as an oxidizing agent, but cannot be obtained in this country. Otherwise the treatment is symptomatic.

PTOMAIN POISONING.—Ptomains are alkaloidal bodies, the products of the decay of animal tissues. These are probably the cause of the severe abdominal pain, vomiting, purging of bloodstained material, partial paralysis, convulsions, and collapse.

Treatment.—Stomach-tube or emetics; demulcents; stimulants; heat.

PTOMAINE POISONING.—Ptomaines are alkaloidal bodies, the products of the decay of animal tissues. These are probably the cause of the poisonous action of tainted meat and fish, cream-puffs, ice-cream, *blanc mange*, and cheese.

Poisonous Fish.—Sickness and vomiting, great depression, irritation of the eyes, severe nettlerash. Shell-fish is especially apt to produce a rash in susceptible persons.

Poisonous meat contains ptomains, those produced when stale meat is just beginning to decay being more virulent than others which replace the first when decomposition is well under way.

Ices, Ice-cream.—The cheap varieties are colored with anilin dyes, which may not be free from arsenic. Again, the highly poisonous alkaloid, tyrotoxin, may have formed in the milk used, and to this principle most cases of poisoning of this kind are traced.

Symptoms vary—dryness of throat, vomiting, and purging are those most commonly observed.

Treatment must be symptomatic.

SILVER NITRATE (*Lunar Caustic*).—Used in the form of the fused nitrate as a caustic. Otherwise in colorless, rhombic crystals, freely soluble, with astringent metallic taste. Yields a white precipitate with chlorids and stains organic matter black.

Symptoms.—Partly gastro-intestinal and partly cerebro-spinal. Vomiting of white material which rapidly becomes black; vertigo, unconsciousness, epileptiform convulsions.

Treatment.—Common salt to be given immediately, followed by stomach-pump or emetic. Otherwise symptomatic.

STRYCHNIN.—An alkaloid occurring in *nux vomica* and *ignatia*. Appears in the form of white, prismatic, odorless crystals which have an intensely bitter taste. Used as a vermin killer.

Symptoms.—Ordinarily these appear quickly. A sense of suffocation, great difficulty in breathing, from paralysis of the muscles of respiration; great anxiety, though the mind is perfectly clear; twitching of the muscles, finally amounting to tetanic convulsions, with intervals in which the patient

is exhausted and bathed in perspiration; opisthotonos; death from asphyxia, or, between the attacks, from exhaustion.

In tetanus there is usually the history of a wound; symptoms develop much more gradually; the muscles of the jaw are early involved, and trismus is much more marked than spasm of the respiratory muscles, and the convulsions are tonic.

Treatment.—Emetics or stomach-tube at once—after the spasms have once set in, the introduction of a tube would excite them; tannic acid; nitrite of amyl; chloroform or ether, by inhalation; artificial respiration, if possible.

SULPHURETED HYDROGEN has the characteristic odor of rotten eggs. It forms the bulk of the gas emanating from sewers and cess-pools, some ammonium sulphid and nitrogen occurring with it. If dilute, the symptoms are nausea, diarrhea, depression, and headaches. In more concentrated form it produces unconsciousness, frequent respiration, rapid pulse, dysphagia, dilated pupils insensible to light, tonic convulsions, and a temperature as high as 104° F. (40° C.) during the convulsions. In a state approaching purity sewer gas kills almost instantly; in moderate amount it frequently causes death in twenty-four hours, all efforts to restore consciousness proving useless.

Treatment.—Fresh air; artificial respiration for many hours; ammonia by inhalation; stimulation.

ZINC.—The chlorid, in solution, is used as a disinfectant (Burnett's Disinfecting Fluid). A very heavy, corrosive, colorless liquid, of astringent taste. It partakes of the nature of a corrosive poison.

Symptoms.—Burning sensation in throat and stomach, perhaps signs of local corrosion. Nausea, vomiting, purging, dyspnea, convulsions, coma, death.

Treatment.—Carbonate of potassium or sodium in water; milk; eggs; tannic acid; opium as a sedative.

MINIMUM DOSE WHICH HAS CAUSED DEATH, AND MAXIMUM DOSE FOLLOWED BY RECOVERY.

NAME OF POISON.	MINIMUM DOSE WHICH HAS CAUSED DEATH.	MAXIMUM DOSE WITH RECOVERY.	USUAL FATAL DOSE.	FATAL PERIOD.
Aconite, . . .	From merely tasting Fleming's tincture to f ʒ j (3.7 c.c.) Fleming's tincture.	f ʒ iij (11.1 c.c.) Fleming's tincture.		Usually three or four hours.
Alcohol, . . .	½ pint gin (236.56 c.c.), 2 bottles of port (= 11 oz.) (29.57 c.c. alcohol). In a boy of seven years, f ʒ iv (120 c.c.) brandy.	1 quart gin (946.24 c.c.); 1 quart whisky (946.24 c.c.); 2 bottles port; 1 ½ pints (236.56 c.c.) mixed gin and brandy.		One-half hour to several days.
Ammonia, . . .	f ʒ ij (7.4 c.c.) aqua ammoniæ fortior.	f ʒ j (29.57 c.c.) aqua ammoniæ fortior.	f ʒ ss (15 c.c.) aqua ammoniæ fortior.	A few hours, months, or even years. An hour up to several days.
Antimony, . . . (Tartar Emetic)	2 grains (0.132 gm.). ¾ grain (0.0495 gm.) in a child.	ʒ ss (15.84 gm.).	ʒ j (4 gm.).	An hour up to several days.
Arsenic, . . .	Less than 1 ½ grains (0.099 gm.).	ʒ j—ʒ iij (3.96–7.92 gm.). Recovery probable after 1 gr.	1 ½ to 2 ½ grains (0.099 to 0.165 gm.).	Death usually within twenty-four hours.
Atropin, . . .	2 grains (0.132 gm.). ⅓ grain hypodermically; ⅛ grain by stomach.	1 grain, 1 ½ grains (0.066 to 0.099 gm.). Child two years old, 1 grain (0.066 gm.), child four years old, ½ grain (0.033 gm.).	½ to ¾ grain (0.033 to 0.0495 gm.).	Death usually within twenty-four hours.
Belladonna, . .	f ʒ j (3.7 c.c.) liniment.	f ʒ ss (15 c.c.) liniment; ʒ iij (11.88 gm.) extract.		Death usually within twenty-four hours.
Carbolic Acid,	f ʒ j (3.7 c.c.).	f ʒ j (3.7 c.c.).	f ʒ ss. (14.785 c.c.) of the pure, f ʒ j (3.7 c.c.) of the impure, acid	Death usually within an hour.
Chloral, . . .	10 grains (0.66 gm.); 20 grains (1.32 gm.); 30 grains (1.98 gm.).	180 grains (11.88 gm.); 460 grains (30.36 gm.).		
Chloroform,	15 drops (0.9 c.c.) inhaled; 30 drops (1.8 c.c.) inhaled; f ʒ ss (0.15 gm.) f ʒ j (0.3 c.c.) internally.	f ʒ iij (60 c.c.) taken internally; f ʒ iv (120 c.c.).		
Cocain, . . .	½ grain (0.033 gm.) in a child of eleven (in forty seconds); 12 grs. (0.792 gm.) (injected into urethra); 24 grs. (1.584 gm.) (injected into rectum).	24 grains (1.584 gm.) (by stomach).		One-half hour or less.
Colchicin and Colchicum, . .	⅓ grain (0.022 gm.) (alkaloid) f ʒ iiss (9.25 c.c.) wine of root; f ʒ iiiiss (12.25 c.c.) of root.	f ʒ j wine (29.55 c.c.); ¾ grain alkaloid (0.0495 gm.).		Twenty-four hours.
Copper Subacetate (Verdigris)	ʒ ss, ʒ j (16 to 32 gm.).			Four to twelve hours.
Copper Sulphate, . . .	Child sixteen months old, from merely sucking crystals; ʒ j (32 gm.) in an adult.	ʒ j (32 gm.) in an adult.		Four to twelve hours.
Digitalis,	Uncertain.	f ʒ iij (60 c.c.) tincture; ʒ j (4 gm.) powdered digitalis.		About twenty-four hours.
Gelsemium and Gelsemin,	f ʒ j fl. ext. (3.7 c.c.); m xij fl. ext. (in a child)			Three to four hours.

MINIMUM DOSE WHICH HAS CAUSED DEATH, AND MAXIMUM DOSE FOLLOWED BY RECOVERY—(Continued).

NAME OF POISON.	MINIMUM DOSE WHICH HAS CAUSED DEATH.	MAXIMUM DOSE WITH RECOVERY.	USUAL FATAL DOSE.	FATAL PERIOD.
Hydrochloric Acid, . . .	f ̄ ss (15 c.c.) in an adult, f 3 j (3.7 c.c.) in a child.		f ̄ ss (15 c.c.) for an adult; f 3 j (3.7 c.c.) for a child.	From a few hours to many weeks.
Hydrocyanic Acid, . . .	45 m (2.7 c.c.) diluted acid (2 per cent.). Insensibility from merely smelling the strong acid.	f 3 j (3.7 c.c.) Scheele's acid (4 per cent.).	45 m to f 3 j (2.7 to 3.7 c.c.).	Ten to fifteen minutes.
(Cherry-laurel Water), . . .	f ̄ ij (60 c.c.).			
(Oil Bitter-Almonds) (natural unpurified),	17 drops.			
(Potassium Cyanid), . . .	(contains about 10 to 15 per cent. HCN). 5 grains (0.33 gm.).	f 3 iv (15 c.c.).	10 to 30 drops (0.6 to 1.80 c.c.). 3 to 5 grains (0.198 to 0.33 gm.).	
Iodin, . . .	20 grains (1.32 gm.).	̄ 3 iv (16 gm.).		
Iodoform, . . .		̄ 3 j (32 gm.).		
Lead (Acetate), (Goulard's Solution), . . .		f ̄ xij (360 c.c.).		Few hours to several days.
(White Lead),		̄ 3 j (32 gm.).		
Mercury Bichlorid, . . .	3 grains (0.198 gm.).	̄ 3 j (32 gm.).	3 to 5 grains (0.198 to 0.33 gm.). 50 per cent. of cases fatal.	From ten hours to eleven days.
Morphin, . . .	¼ grain (0.0495 gm.); 1 grain (0.066 gm.).	75 grains (4.95 gm.); 20 grains (1.32 gm.).	2 to 6 grains (0.132 to 0.396 gm.).	Seven to twelve hours.
Nitrobenzol (Oil of Mirbane), . . .	From merely tasting it; 8 or 9 drops (0.4 to 0.54 c.c.).	f ̄ ss (1.85 c.c.).		Four to five hours.
Opium, . . .	f 3 ij (7.4 c.c.) laudanum; 2½ grains (0.165 gm.) extract; 3 j (3.96 gm.) laudanum; 2 or 3 drops (0.12 to 0.18 c.c.) laudanum in a very young child.	f ̄ ij (60 c.c.) laudanum; f ̄ iv to f ̄ v (120 to 150 c.c.) laudanum.	4 to 5 grains (0.264 to 0.33 gm.).	Seven to twelve hours.
Oxalic Acid, . . .	̄ 3 ij (0.132 gm.); 3 j (3.96 gm.) in a boy of sixteen.	̄ 3 ss (16 gm.).	̄ 3 ss (16 gm.).	Within one hour.
Phosphorus, . . .	Less than 1 grain (0.066 gm.). Child died from sucking 2 matches. Another from swallowing the tops of 8 matches.	After sucking 300 matches.	A little less than 1 grain.	One to five days.
Potassium Hydroxid (Cautic Potash), . . .	40 grains (2.64 gm.).		̄ 3 ss (16 gm.).	
Salt peter, . . .	̄ 3 j (32 gm.).	̄ 3 ij (64 gm.).	̄ 3 j to ̄ 3 iss (32 to 48 gm.).	A few hours.
Silver Nitrate, . . .	30 grains.	̄ 3 j.		
Strychnin, . . .	1/8 grain (0.0041 gm.) in a child of 2½ years; ½ grain (0.033 gm.) in an adult.	10, 12, 40 grains (0.66 to 0.792 to 2.64 gm.).	½ to 1 grain (0.033 to 0.066 gm.).	5 minutes to several hours. In adults during or after the 4th or 5th paroxysm; children 1-3d convulsion.

- Typhlitis, 394
- Typhoid fever, 17
 abortive form of, 32
 albuminuria in, 28
 antiseptic treatment of, 50
 atypical forms of, 31
 bacteriology of, 18
 bed-sores in, 47
 blood changes in, 30
 boils in, 33

- Typhoid:**
 bone lesions in, 34
 Brand bath treatment of, 41
 cardiac complications in, 34
 chills in, 31
 cholecystitis in, 35
 circulatory system in, 22
 complications in, 32
 constipation in, 46
 contagiousness of, 19
 cystitis in, 48
 delirium in, 28
 diagnosis, 36
 diazo-reaction of urine in, 29
 diet in, 41
 disinfection of stools in, 52
 Ehrlich's reaction in, 29
 eliminative and antiseptic treatment of, 50
 etiology, 17
 expectant symptomatic treatment of, 45
 hemorrhage in, 46
 hemorrhagic form of, 32
 herpes in, 24
 in children, 23, 40
 incubation of, 23
 indications for alcohol in, 45
 influence of age on, 20
 influence of seasons on, 20
 management of convalescence in, 48
 meteorism in, 26
 methods of reducing temperature in, 44
 milk leg in, 32
 mode of conveyance of, 20
 morbid anatomy of, 21
 nervous or meningeal form of, 32
 parotitis in, 33
 perforation in, 28-47
 peritonitis in, 47
 Peyer's patches in, 21
 predisposing causes of, 20
 prodromal symptoms, 23
 prophylaxis in, 52
 pulmonary form, 32
 relapses in, 35
 renal form, 28
 rose-colored spots in, 23
 sequelæ of, 32
 serum-therapy in, 51
 skin rashes in, 23
 splenic enlargement in, 21-24
 temperature in, 23
 thrombosis in, 32
 tonsillar form of, 32
 treatment of, 41
 by cultures of serum, 51
- Typhoid:**
 treatment by diet and rest, 41
 expectant symptomatic, 45
 of convalescence, 48
 of special symptoms, 46
 tubercular phthisis in, 34
 tympanitic distention in, 46
 typhoid spine in, 34
 unusual form of onset, 31
 urine in, 23
 walking form of, 23
 Widal reaction, 37
- Typhus abdominalis, 17**
 exanthematicus, 55
 fever, 55
 etiology,
 contagiousness, 55
 diagnosis of, 36
 eruption of, 56
 incubation of, 56
 morbid anatomy, 56
 prognosis of, 58
 symptoms of, 56
 treatment of, 58
 icterodes, 59, 83
 tropicus, 83
- U**
- Uffelmann's test for lactic acid, 337**
Ulcer, gastric and duodenal, 359
 course and termination of, 362
 diagnosis of, 362
 from cancer, 363
 etiology of, 359
 morbid anatomy of, 360
 prognosis of, 364
 symptoms of, 360
 hemorrhage, 361
 treatment of, 364
 operative, 366
- Ulceration of the bowel, 393**
Ulcerative colitis, 382
Ulcerative endocarditis, 570
Ulcus ventriculi pepticum, 359
 Ulnar nerve, lesions of, 1035
 Uncinariasis, 1193
 Undulant fever, 63
 Unilateral progressive facial atrophy, 1138
 Uremia, 688
 symptoms of, 688
 treatment of, 705
 Uric acid, thread test, 781
 Uricacidemia, 793
 Uricemia, 793
 Urinary organs, diseases of, 684
- V**
- Vaccina, 152**
Vaccine disease, 152
 bacteriology of, 153
- Vaccine:**
 disease, humanized lymph in, 153
 operation in, 153
 phenomena of, 153
 rashes, 154
Vaccinia, 152
 hemorrhagica, 154
 nature of, 152
Vaccinosyphilis, 155
 Vagus nerve, lesions of, 1019
Valvular (cardiac) defects, 574
 congenital, 575
 morbid anatomy of, 575
 relative frequency of, 591
 disease, chronic, prognosis of, 592
 treatment of, 593
 of dropsy, 598
 of dyspnea, 597
 of irregularities of heart action and palpitation, 599
 lesions, associated or combined, 592
Valvulitis, 567
Varicella, 156
Variola, 145
Variolæ sine variolis, 149
Vasomotor and trophic derangements, 1136
Vesical catarrh, 759
Vesicular emphysema, 532
Vesicular or herpetic stomatitis, 307
Visceroptosis, 376
 tiology of, 376
 symptoms of, 377
 treatment of, 378
Vision, modifications of, in nervous disease, 865
Vocal cords, paralysis of, 516
- W**
- Warty or verrucose endocarditis, 568**
Wasting palsy, 958
Water cancer, 311
Waxy kidney, 726
 liver, 457
Weil's disease, 300
Wernicke's scheme, 974
Whooping-cough, 157
 complications and sequelæ of, 159
 diagnosis of, 159
 morbid anatomy of, 158
 prognosis of, 160
 shape of chest in, 158
 symptoms of, 158
 treatment of, 160
Winckel's disease, 836
Woolsorter's disease, 196
Word-blindness, 976
Word-deafness, 976
Word-image, 972
Writer's cramp, 1115
 etiology of, 1115

Writer's cramp:
 diagnosis of, 1117
 treatment of, 1117

Wry-neck, 1027

X

Xerostomia, 313

Y

Yellow atrophy of the heart,
 610
 of the liver, acute, 469
 fever, 83
 albuminuria in, 86
 bacillus icterodes of, 84
 diagnosis of, 87

Yellow fever:

jaundice in, 86
 morbid anatomy of, 85
 prognosis of, 88
 prophylaxis of, 89
 slow pulse of, 87
 symptoms of, 86
 treatment of, 88
 by serum, 89
